Quantitative cell information quickly and accurately:

THE BARR & STROUD GN5 Integrating Microdensitometer

Improved image analysis techniques give fast scans of only 4 seconds duration with 0.25 micron resolution in the GN5 Integrating Microdensitometer. For accurate histochemical and cytochemical studies of your cell preparations this new instrument offers an accuracy better than ± 1% over an optical density range from less than 0.1 to greater than 2.5. Area measurement, electronic masking and narrowband illumination are some of the features which make this instrument particularly suited to your laboratory. The Barr & Stroud GN5 gives quantitative cell information fast and accurately. It is compact, reliable and ergonomically designed for easy operation.

Write or phone for our fully illustrated brochure, publication H-1734.

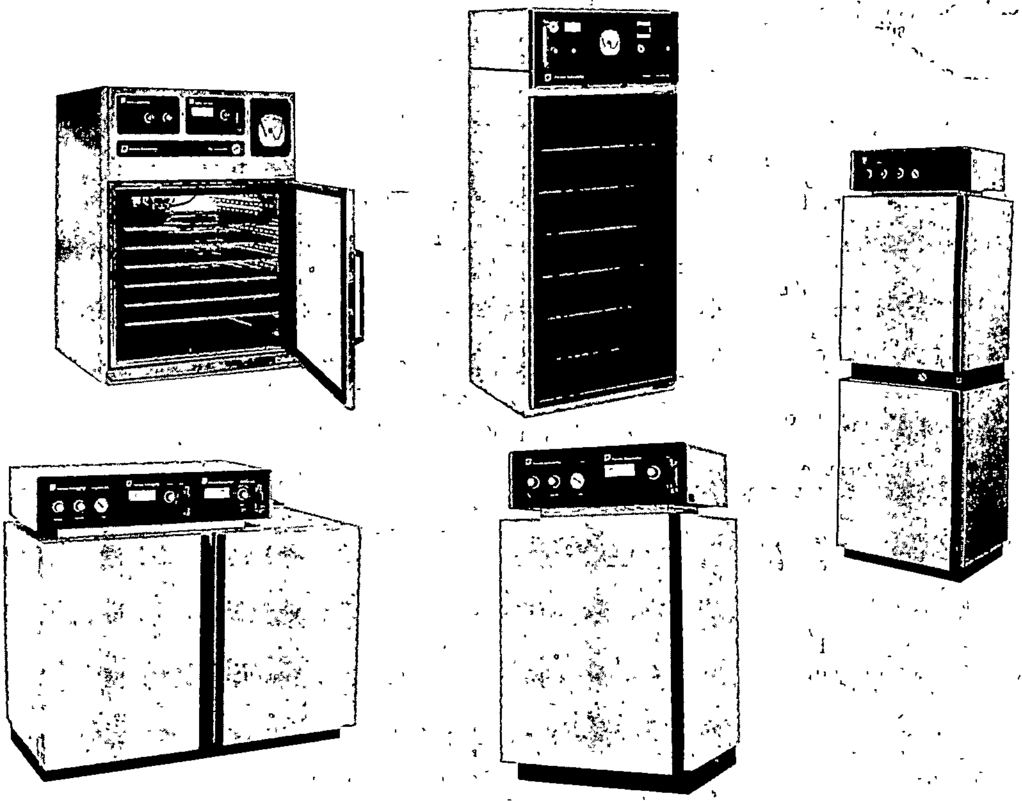
Inhibition of reverse transcriptases of primate type C viruses by 7S immunoglobulin from patients with leukaemia—*E. V. Prochownik and W. H. Kirsten* 64

CO_2 Incubators From Forma ... The Incubator People

Forced Draft and Water-Jacketed Models with solid-state, automatic CO_2 control.



Forma Water-Jacketed Incubators are available in single and dual chambered units, side-by-side, or *stacked, occupying only 4 sq. ft. floor space*. Each chamber will hold 22 stainless steel shelves in non-tip channel brackets. ☐ With standard or automatic CO_2 system. ☐ Humidified to 98% RH. ☐ Temperature control from 2° C above ambient to +60° C. ☐ Overtemp safety alarm standard.

Forma Forced Draft Incubators feature positive horizontal air flow—an aerodynamically engineered design that assures temperature control to within ± 0.1° C and overall uniformity to within ± 0.2° C. Available in 6, 12, and 29 cu. ft. capacities. ☐ With standard or automatic CO_2 system. ☐ Controlled humidification. ☐ Temperature ranges from 0° C to +60° C. ☐ Overtemp safety alarm standard.

The Forma Automatic CO_2 System is available on Forma Water-Jacketed and Forced Draft Incubators. The solid state, direct dial CO_2 control is effective to within ± .2% over a range of 0-20% with CO_2 savings of up to 90% over conventional methods. The automatic CO_2 system is also sold as a portable unit for easy installation on *any* stable incubator. No external air supply or purge buttons required. Large 4" scale meter for direct read-out.

Circle No. 03 on Reader Enquiry Form.

Guide to authors

- Articles are up to 3,000 words in length with at most six displayed items (figures and tables) and may either be reports of major research developments in a subject or broader reviews of progress.
- Letters are brief reports of research of unusual and wide interest, not in general longer than 1,000 words; at most they have three or four displayed items (figures and tables).
- 'Matters Arising' permits occasional short discussion of papers that have previously appeared in *Nature*. There is a limit of 300 words.

Manuscripts may be submitted either to London or Washington. Three typed copies should be submitted, each including lettered copies of figures. Typing (including references) should be double spaced. The title should be brief and informative. Pages should be numbered. References, tables and figure legends should start on separate pages. Experimental detail vital to the paper yet which would interrupt the narrative is best placed in the figure legends. Units should conform to the Système International. Greek characters should be identified in the margin on their first appearance. Equations should occupy single lines if possible, exp (a) is preferred to e^a if 'a' is more than one character. Articles should be accompanied by an abstract of not more than fifty words listing the main conclusions.

References are indicated by superscripts in the text. See any contemporary *Nature* for style, but note:

(i) To refer to several references by the same author at once, only one reference number need be given.

(ii) Cite first and last pages.

Abbreviations should follow the *World List of Scientific Periodicals*, fourth ed. (Butterworth, 1963-65). Symposia are often difficult to refer to and only published or soon-to-be-published volumes should be mentioned in references. Their publisher and place of publication should be clearly indicated 'Personal communication' and 'unpublished work' should be incorporated in the text.

Artwork should be sent with the manuscript. All artwork should be marked with the author's name. Line drawings should preferably be in Indian ink on heavy cartridge paper, although other materials are acceptable: thin, shiny, folded, torn or heavily handled material should be avoided. Matt rather than glossy photographs are preferred. Figures are usually reduced to one column width. The originals should be about as wide as a page of *Nature*. Figures, particularly maps, should contain nothing but essential material. It is preferred that the original be unlabelled, but with a copy containing lettering. Labelling on photographs should if possible be avoided entirely. We are always glad to see artwork for possible use on the cover, whether or not it is associated with a manuscript, but cannot guarantee the return of material.

In order to save on postal expenses we return only the top copy and artwork of manuscripts that we cannot publish.

A fuller guide appeared in *Nature* (**246**, 238; 1973).

Increasing haemoglobin β-chain synthesis in foetal development is associated with a declining γ- to α-mRNA ratio—*H. H. Kazazian, Jr, A. M. Silverstein, P. G. Snyder and R. J. VanBeneden* 67
Half life of yeast messenger RNA—*N. S. Petersen, C. S. McLaughlin and D. P. Nierlich* 70
Aminoacylation and nucleoside modification of *in vitro* synthesised transfer RNA—*M. Zeevi and V. Daniel* 72
Evolutionary origin of 5.8S ribosomal RNA—*R. J. Cedergren and D. Sankoff* 74
Bean halo-blight toxin—*R. E. Mitchell* 75

Matters arising

Niche breadth in Bryozoans—*P. H. Harvey, J. S. Ryland and P. J. Hayward* 77
Reply—*R. J. O'Connor, P. J. S. Boaden and R. Seed* 77
Niche breadth in Bryozoans—*R. H. Crozier and R. W. Day* 77
Reply—*R. J. O'Connor, P. J. S. Boaden and R. Seed* 78
Enteropancreatic circulation of digestive enzyme—*R. J. Beynon and J. Kay* 78
Reply—*H. Götze, S. S. Rothman and C. Liebow* 79
Doubts about the role of the locus coeruleus in learning and the phosphorylation mechanism engaged in the cerebellum—*A Routtenberg* 79
Reply—*P. F. C. Gilbert* 80

BOOK REVIEWS

The Nature of Scientific Discovery (Owen Gingerich, editor)—*John Watling* 81
Handbook of Perception Vol. 5 (E. C. Carterette and M. P Friedman, editors)—*J D. Mollon* 82

Announcements 84

Reader enquiry form xxviii

In response to many requests from readers, we are now producing a bi-monthly author index. The first of these (for Volume 259) is on pages v-viii. The authors of feature articles at the front of the journal, in addition to the authors of scientific papers, are included in this index. We shall continue to publish an Annual Index.

The Zoological Record

YOU NEED A KEEN EYE

for literature searching today

The **ZOOLOGICAL RECORD** can provide you with quick and easy access to the masses of papers being published in zoology enabling you to

- *trace all recent publications on a particular subject*
- *compile a complete record of an author's work*
- *assemble a comprehensive bibliography for any given topic*
- *spend less time on literature searching and more time on other activities*

The **ZOOLOGICAL RECORD** is the world's largest and most comprehensive bibliography in zoology

For further details contact ⇨ Mr. B. Anderson,
The Zoological Record,
The Zoological Society of London,
Regents Park, London NW1 4RY.

Annihilation of matter and antimatter and the cosmic X-ray background—*P. Carlqvist and B. Laurent* 225
X-ray observations of GX17+2 and GX9+9 by Arybhata—*K. Kasturirangan, U. R. Rao, D. P. Sharma and M. S. Radha* 226
Reliability of sunspots as tracers of solar surface rotation—*J. M. Beckers* 227
Physical argument and hypothesis for Sun–weather relationships—*K. D. Cole* 229
Early lunar magnetism—*S. K. Banerjee and J. P. Mellema* 230
Radiocarbon evidence for deglaciation in north-western Himalaya, India—*G. Singh and D. P. Agrawal* 232
Eastern Greenland basalts and their supposed plume origin—*P E. Brown and J. E. Whitley* 232
Late-glacial and postglacial sedimentation in the Peris–Padarn Rock Basin, North Wales—*H. M. Tinsley and E. Derbyshire* 234
Relationships of Middle and Upper Pleistocene Hominids from sub-Saharan Africa—*G. P. Rightmire* 238
A spatial approach to insect population dynamics—*B. E. Freeman* 240
Phytoalexin induction as a new dynamic approach to the study of systematic relationships among higher plants—*J. L. Ingham and J. B. Harborne* 241
Evidence of hormonal control of ovulation in tsetse flies—*M. F. B. Chaudhury and T. S. Dhadialla* 243
Growth regulation in chimaeras between large and small mice—*R. C. Roberts, D. S. Falconer, P. Bowman and I. K. Gauld* 244
Evidence for a new diffusible element of mating pheromones in yeast—*J. B. Hicks and I. Herskowitz* 246
Regulation of the fibroblast cell cycle by serum—*R. F. Brooks* 248
T-lymphocyte response to Friend virus-induced tumour cell lines in mice of strains congenic at *H–2*—*K. J. Blank, H. A. Freedman and F. Lilly* 250
Demonstration of sensory neurones in the ectopic cuticle of spineless-aristapedia, a homoeotic mutant of *Drosophila*—*I. I. Deak* 252
EEG α symmetry and visuospatial performance—*C. J. Furst* 254
Bicuculline reversal of deprivation amblyopia in the cat—*F. H. Duffy, S. R. Snodgrass, J. L. Burchfiel and J. L. Conway* 256
Dopamine release in substantia nigra?—*J. Korf, M. Zieleman and B. H. C. Westerink* 257
Release of dopamine from dendrites in rat substantia nigra—*L. B. Geffen, T. M. Jessell, A. C. Cuello and L. L. Iversen* 258
Foetal thymidine kinase in tumours and colonic flat mucosa of man—*J. S. Salser and M. E. Balis* 261
Immunofluorescent localisation of human pregnancy-specific β-globulin in placenta and chorioepithelioma—*Y. S. Tatarinov, D. M. Falaleeva, V. V. Kalashnikov and B. O. Toloknov* 263
Immunological and biochemical characterisation of type C viruses isolated from cultured human AML cells—*H. Okabe, R V. Gilden, M. Hatanaka, J. R. Stephenson, R. E. Gallagher, R. C. Gallo, S. R. Tronick and S. A. Aaronson* 264

Guide to authors

- Articles are up to 3,000 words in length with at most six displayed items (figures and tables) and may either be reports of major research developments in a subject or broader reviews of progress.
- Letters are brief reports of research of unusual and wide interest, not in general longer than 1,000 words; at most they have three or four displayed items (figures and tables).
- 'Matters Arising' permits occasional short discussion of papers that have previously appeared in *Nature*. There is a limit of 300 words.

Manuscripts may be submitted either to London or Washington. Three typed copies should be submitted, each including lettered copies of figures. Typing (including references) should be double spaced. The title should be brief and informative. Pages should be numbered. References, tables and figure legends should start on separate pages. Experimental detail vital to the paper yet which would interrupt the narrative is best placed in the figure legends. Units should conform to the Système International. Greek characters should be identified in the margin on their first appearance. Equations should occupy single lines if possible, exp (a) is preferred to e^a if 'a' is more than one character. Articles should be accompanied by an abstract of not more than fifty words listing the main conclusions.

References are indicated by superscripts in the text. See any contemporary *Nature* for style, but note:

(i) To refer to several references by the same author at once, only one reference number need be given.

(ii) Cite first and last pages.

Abbreviations should follow the *World List of Scientific Periodicals*, fourth ed. (Butterworth, 1963-65). Symposia are often difficult to refer to and only published or soon-to-be-published volumes should be mentioned in references. Their publisher and place of publication should be clearly indicated. 'Personal communication' and 'unpublished work' should be incorporated in the text

Artwork should be sent with the manuscript. All artwork should be marked with the author's name. Line drawings should preferably be in Indian ink on heavy cartridge paper, although other materials are acceptable: thin, shiny, folded, torn or heavily handled material should be avoided. Matt rather than glossy photographs are preferred. Figures are usually reduced to one column width. The originals should be about as wide as a page of *Nature*. Figures, particularly maps, should contain nothing but essential material. It is preferred that the original be unlabelled, but with a copy containing lettering Labelling on photographs should if possible be avoided entirely. We are always glad to see artwork for possible use on the cover, whether or not it is associated with a manuscript, but cannot guarantee the return of material.

In order to save on postal expenses we return only the top copy and artwork of manuscripts that we cannot publish.

A fuller guide appeared in *Nature* (**246,** 238; 1973).

Characterisation of a virus (HL23V) isolated from cultured acute myelogenous leukaemic cells—*E. Chan, W P. Peters, R. W Sweet, T Ohno, D. W. Kufe, S. Spiegelman, R. C. Gallo and R E Gallagher* 266

Construction of a P plasmid carrying nitrogen fixation genes from *Klebsiella pneumonae—R. Dixon, F Cannon and A. Kondorosi* 268

Expression of Klebsiella nitrogen fixation genes (*nif*) in *Azotobacter—F. C. Cannon and J. R. Postgate* 271

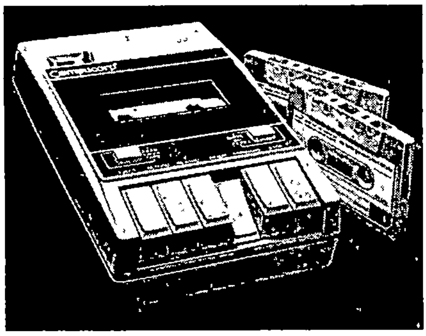
Sumlock Compucorp 325 and 326. A unique range of programmable calculators from just £665.

The 325 and 326 microcomputers are probably the most versatile units on the market. They offer a comprehensive combination of scientific and statistical features–including cassette drive–at a highly competitive price. The portable 326 with a 160 instruction capacity costs just £665. The desk top 325 with a 416 instruction capacity costs just £895.



Just look at the features. Each offers you: algebraic logic; 4 level parentheses; trigonometry; logarithm and statistical functions; scientific notation; a built-in metric converter and 12 data stores. Add its ease of programming, its excellent editing capability, its formatting and the fact that it offers you conditional and unconditional jumping and branching to sub-routines and you'll agree that the 325 and 326 offers you unique value-for-money especially as both models give you…

Tape cassette storage included in price.

A magnetic tape drive linked to either model and included in the price stores over 100,000 program instructions on a single standard cassette. The programs can of course be written by the user and may be loaded onto the cassette as may the contents of data stores. Programs may be 'overlaid' which, subject to the length of the cassette, expands the capacity of equipment automatically. The power of the system is also demonstrated by the…

Software for your applications.

Available for the full range of technical and scientific applications the software is fully documented and readily available on magnetic tape. Software Paks include a Math Pak 1, Numerical Calculus Pak, Vector and Matrix Math Pak, Univariate Statistics Pak, Regression Analysis Pak, Anova and t-test Pak, Electronics Pak 1, Structural Design Pak, Beam Pak 1, Antenna Design Pak and more.

Each Pak covers a major application area and consists of a number of problem-solving programs. For example:- The 326 Univariate Statistics Pak is designed to provide the parameters commonly sought from univariate data. Provisions have been made wherever possible to provide for grouped entry of data, as well as removal of unwanted data.

The programs of this Pak are as follows: Mean Standard Deviation, Variance, Standard Error of the Mean (N-1 Formula) · Mean Standard Deviation, Variance, Standard Error of the Mean (N Formula) · Arithmetic, Geometric, Harmonic and Generalized Means · Coefficients of Skewness and Kurtosis, 3rd and 4th Moments about the Mean · Minimum, Maximum and Range · First Eight Moments about the Origin · Rth Central Moment about the Origin · Call Frequency Distribution · Rth Factorial Moment about the Origin · Moving Average · Random Number Generator · Computations and Permutations.

Programs in the Regression Analysis and Anova Paks are similarly comprehensive and range from Multiple Linear Regression to Bartletts test for homogeneity, Treatments-by-Subjects and t-tests.

Fill in the coupon now for further details.

Please send me more details about the Rockwell 325/326 series and its software ☐

I am particularly interested in the following applications ____________

Please also send me further details about the larger 425/445 series of programmable calculators ☐

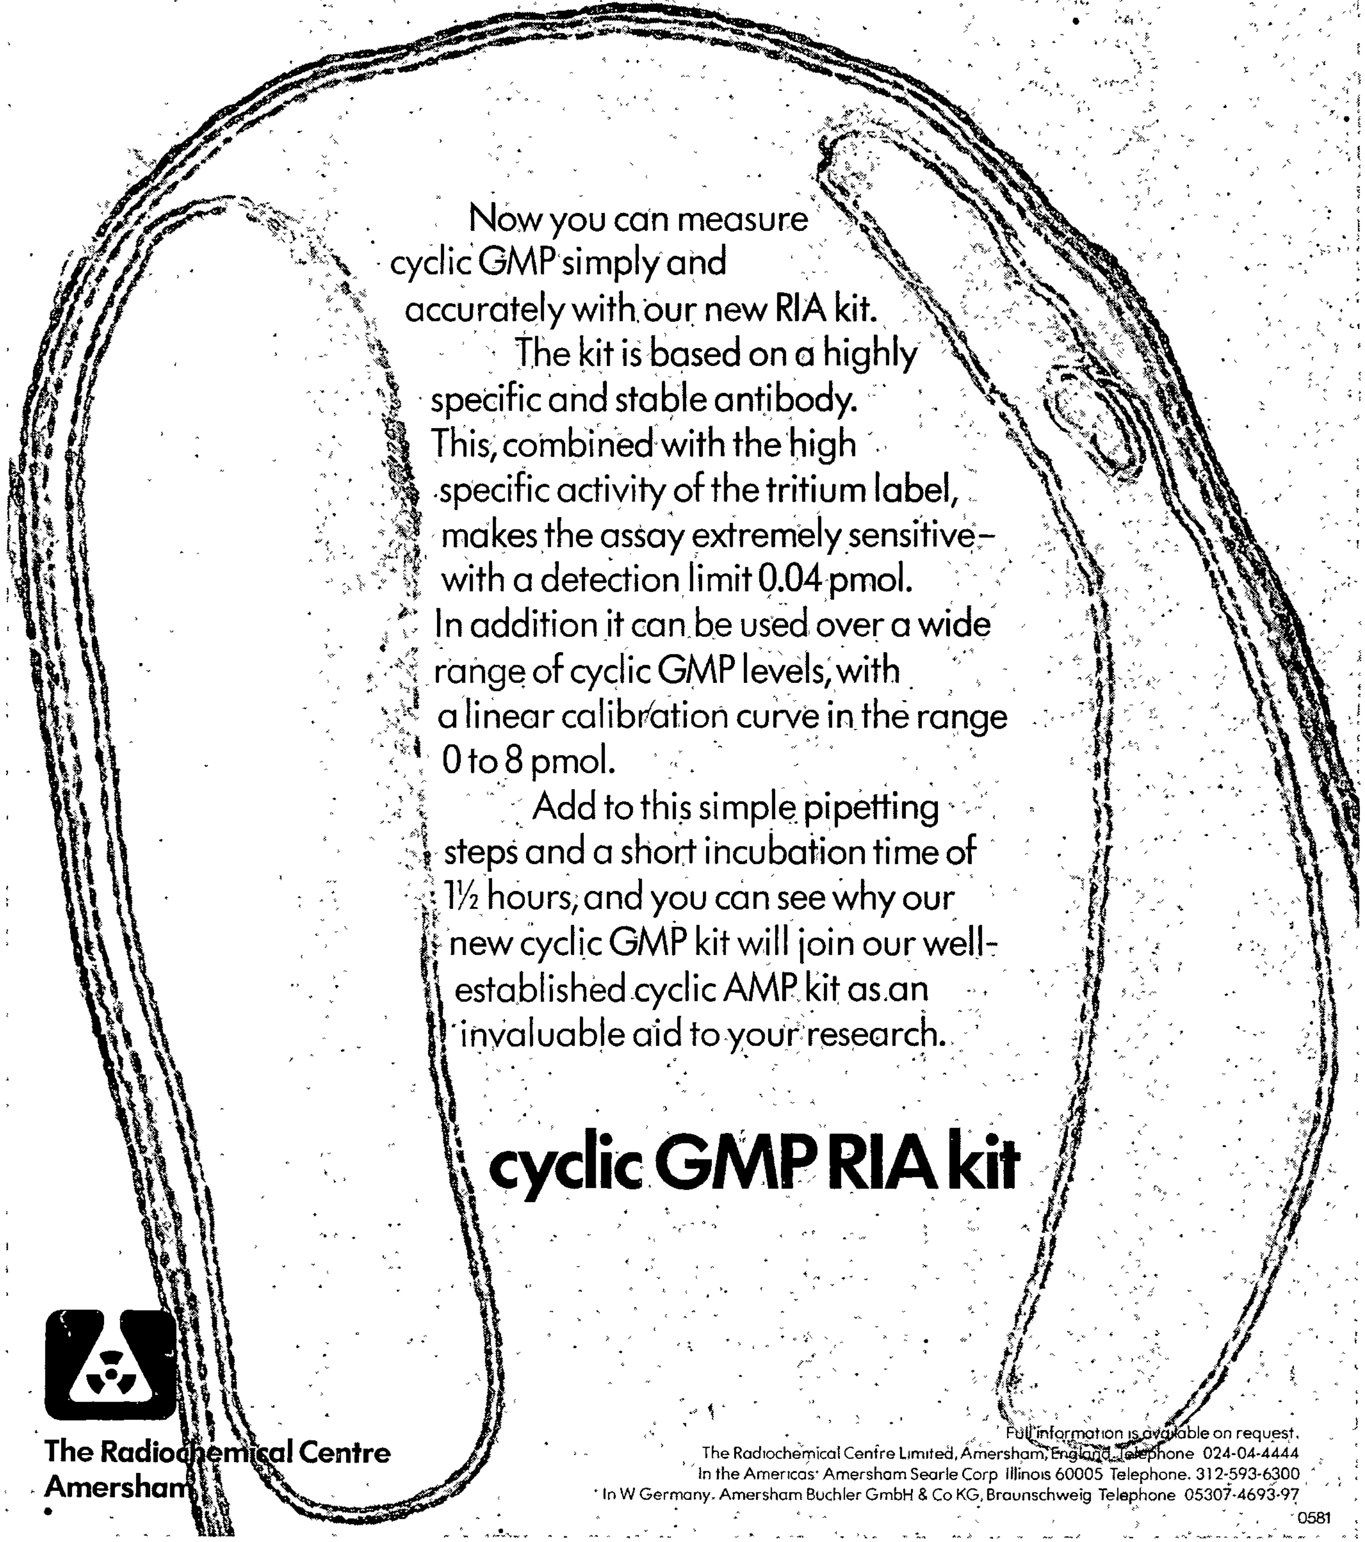
Pharmacological effects of phosphatidylserine liposomes—*A. Bruni, G. Toffano, A. Leon and E. Boarato* 331

NOW IT'S SO EASY TO MEASURE CYCLIC GMP



Now you can measure cyclic GMP simply and accurately with our new RIA kit.

The kit is based on a highly specific and stable antibody. This, combined with the high specific activity of the tritium label, makes the assay extremely sensitive–with a detection limit 0.04 pmol. In addition it can be used over a wide range of cyclic GMP levels, with a linear calibration curve in the range 0 to 8 pmol.

Add to this simple pipetting steps and a short incubation time of 1½ hours, and you can see why our new cyclic GMP kit will join our well-established cyclic AMP kit as an invaluable aid to your research.

cyclic GMP RIA kit

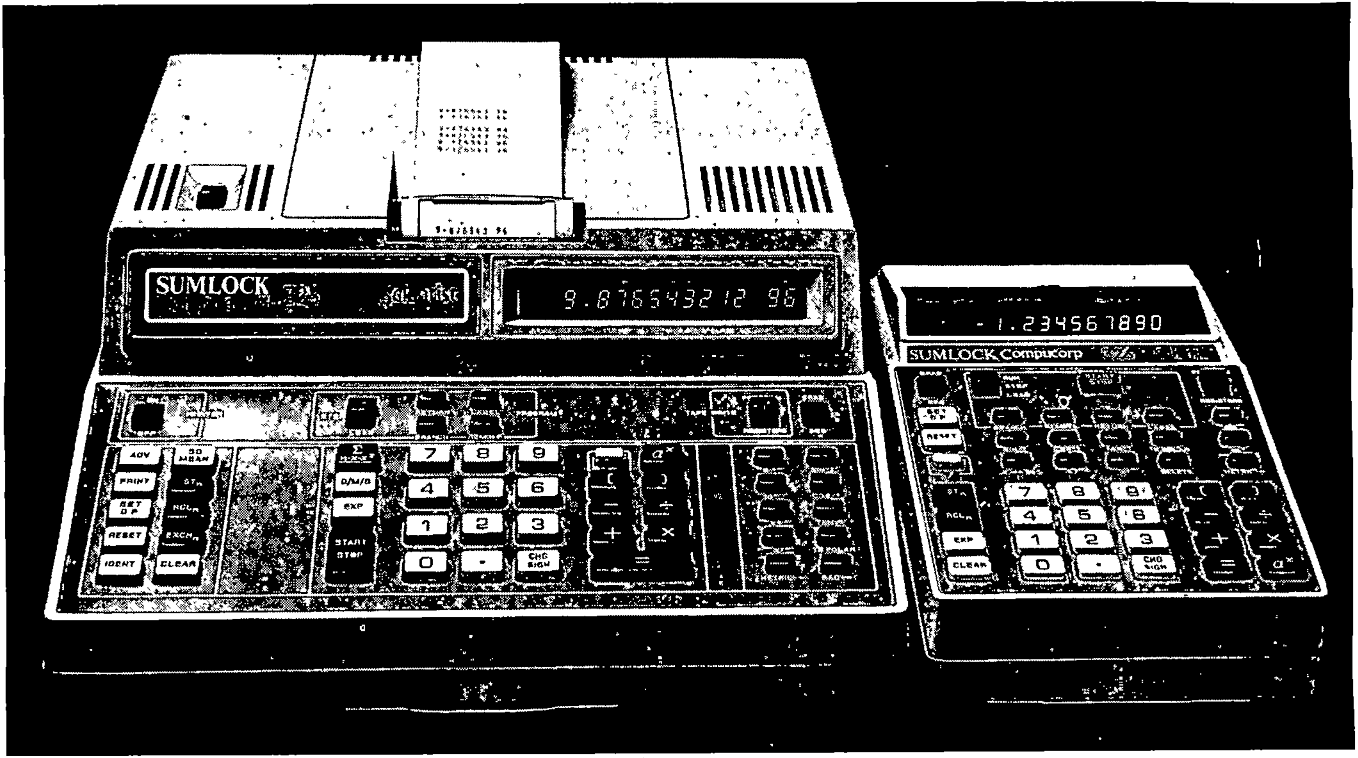
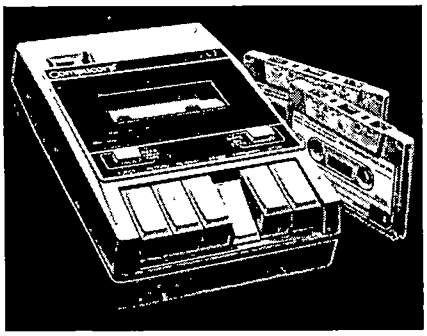
Reader enquiry service xxi



Sumlock Compucorp 325 and 326. A unique range of programmable calculators from just £665.

The 325 and 326 microcomputers are probably the most versatile units on the market. They offer a comprehensive combination of scientific and statistical features–including cassette drive–at a highly competitive price. The portable 326 with a 160 instruction capacity costs just £665. The desk top 325 with a 416 instruction capacity costs just £895.



Just look at the features. Each offers you: algebraic logic; 4 level parentheses; trigonometry; logarithm and statistical functions; scientific notation; a built-in metric converter and 12 data stores. Add its ease of programming, its excellent editing capability, its formatting and the fact that it offers you conditional and unconditional jumping and branching to sub-routines and you'll agree that the 325 and 326 offers you unique value-for-money especially as both models give you…

Tape cassette storage included in price.

A magnetic tape drive linked to either model and included in the price stores over 100,000 program instructions on a single standard cassette. The programs can of course be written by the user and may be loaded onto the cassette as may the contents of data stores. Programs may be 'overlaid' which, subject to the length of the cassette, expands the capacity of equipment automatically. The power of the system is also demonstrated by the…

Software for your applications.

Available for the full range of technical and scientific applications the software is fully documented and readily available on magnetic tape. Software Paks include a Math Pak 1, Numerical Calculus Pak, Vector and Matrix Math Pak, Univariate Statistics Pak, Regression Analysis Pak, Anova and t-test Pak, Electronics Pak 1, Structural Design Pak, Beam Pak 1, Antenna Design Pak and more.

Each Pak covers a major application area and consists of a number of problem-solving programs. For example:-
The 326 Univariate Statistics Pak is designed to provide the parameters commonly sought from univariate data. Provisions have been made wherever possible to provide for grouped entry of data, as well as removal of unwanted data.

The programs of this Pak are as follows: Mean Standard Deviation, Variance, Standard Error of the Mean (N-1 Formula) · Mean Standard Deviation, Variance, Standard Error of the Mean (N Formula) · Arithmetic, Geometric, Harmonic and Generalized Means · Coefficients of Skewness and Kurtosis, 3rd and 4th Moments about the Mean · Minimum, Maximum and Range · First Eight Moments about the Origin · Rth Central Moment about the Origin · Call Frequency Distribution · Rth Factorial Moment about the Origin · Moving Average Random Number Generator · Computations and Permutations.

Programs in the Regression Analysis and Anova Paks are similarly comprehensive and range from Multiple Linear Regression to Bartletts test for homogeneity, Treatments-by-Subjects and t-tests.

Fill in the coupon now for further details.

Please send me more details about the Rockwell 325/326 series and its software ☐

I am particularly interested in the following applications ____________

Please also send me further details about the larger 425/445 series of programmable calculators ☐

Guide to authors

- Articles are up to 3,000 words in length with at most six displayed items (figures and tables) and may either be reports of major research developments in a subject or broader reviews of progress.
- Letters are brief reports of research of unusual and wide interest, not in general longer than 1,000 words; at most they have three or four displayed items (figures and tables).
- 'Matters Arising' permits occasional short discussion of papers that have previously appeared in *Nature*. There is a limit of 300 words.

Manuscripts may be submitted either to London or Washington. Three typed copies should be submitted, each including lettered copies of figures. Typing (including references) should be double spaced. The title should be brief and informative. Pages should be numbered. References, tables and figure legends should start on separate pages. Experimental detail vital to the paper yet which would interrupt the narrative is best placed in the figure legends. Units should conform to the Système International. Greek characters should be identified in the margin on their first appearance. Equations should occupy single lines if possible, exp (a) is preferred to e^a if 'a' is more than one character. Articles should be accompanied by an abstract of not more than fifty words listing the main conclusions.

References are indicated by superscripts in the text. See any contemporary *Nature* for style, but note:

(i) To refer to several references by the same author at once, only one reference number need be given.

(ii) Cite first and last pages.

Abbreviations should follow the *World List of Scientific Periodicals*, fourth ed. (Butterworth, 1963-65). Symposia are often difficult to refer to and only published or soon-to-be-published volumes should be mentioned in references. Their publisher and place of publication should be clearly indicated. 'Personal communication' and 'unpublished work' should be incorporated in the text.

Artwork should be sent with the manuscript and clearly marked with author's name and the figure number. Line drawings to be in Indian ink on heavy cartridge paper, tracing paper or similar materials: thin, shiny, torn or folded material should be avoided Scales for graphs should be chosen such that simple figures will not occupy an inordinate amount of space. Most figures are reduced to one column width so originals should be about as wide as a page of *Nature*. To enable figures, particularly maps, to be edited in the same style as the text they should contain only essential material. Ideally, an unlabelled original and a labelled copy should be provided. labelling on photographs should, if possible, be avoided entirely. Records, charts etc. which will not reproduce well should be redrawn or simply described in the text. We are always glad to see artwork for possible use on the cover, but cannot guarantee its return.

In order to save on postal expenses we return only the top copy and artwork of manuscripts that we cannot publish.

A fuller guide appeared in *Nature* (**246**, 238; 1973).

Sister chromatid exchanges in ageing and repair-deficient human fibroblasts—*H. Kato and H. F. Stich* 447
Differential chromatid staining by *in vivo* treatment as a mutagenicity test system—*W. Vogel and T. Bauknecht* 448
Analysis of sister chromatid exchange formation *in vivo* in mouse spermatogonia as a new test system for environmental mutagens—*J. W. Allen and S. A. Latt* 449
Fate of thiazolidine ring during fragmentation of penicillin by exocellular DD-carboxypeptidase-transpeptidase of *Streptomyces* R61—*J.-M. Frere, J.-M. Ghuysen, H. Vanderhaeghe, P. Adrianes, J. Degelaen and J. De Graeve* 451
Phage-coded protein prevents restriction of unmodified progeny T4 DNA—*K. Dharmalingam and E. B. Goldberg* 454

Correspondence 572

NEWS AND VIEWS
Ball lightning/rRNA genes/Red Queen hypothesis/Nuclear physics/Histone H1/Mercury/Conservation 573

ARTICLES
Radiocarbon chronology for early Maya occupation at Cuello, Belize—*N. Hammond, D. Pring, R. Berger, V. R. Switsur and A. P. Ward* 579
Genetic hypertension in rats is accompanied by a defect in renal prostaglandin catabolism—*J. M. Armstrong, G. J. Blackwell, R. J. Flower, J. C. McGiff, K. M. Mullane and J. R. Vane* 582
Early Mesozoic rifting and fragmentation of the Cordilleran orogen in the western USA—*R. A. Schweickert* 586

LETTERS TO NATURE
Observational tests in cosmology—*E. R. Harrison* 591
Evidence for a 17-d periodicity from Cyg X-3—*S. S. Holt, E. A. Boldt, P. J. Serlemitsos, L. J. Kaluzienski, S. H. Pravdo, A. Peacock, M. Elvis, M. G. Watson and K. A. Pounds* 592
Satellite observations of planetary waves in the mesosphere—*M. D. Austen, J. J. Barnett, P. D. Curtis, C. G. Morgan, J. T. Houghton, G. D. Peskett, C. D. Rodgers and E. J. Williamson* 594
Ball lightning—*M. Stenhoff* 596
Possible relationship between soil fulvic acid and polymaleic acid—*H. A. Anderson and J. D. Russell* 597
Hyperbolic umbilic catastrophe in crystal fracture—*J. M. T. Thompson and P. A. Shorrock* 598
Arrest of deep scattering layer migration by a positive thermal gradient—*I. E. Davies* 599
A- and *B*-type hydrogen bond modifications of potassium hydrogen tartronate—*J. A. Kanters and J. Kroon* 600
Speed of podzolisation—*T. R. Paton, P. B. Mitchell, D. Adamson, R. A. Buchanan, M. D. Fox and G. Bowman* 601
Transfer of mildew resistance from the wild oat *Avena barbata* into the cultivated oat—*T. Aung and H. Thomas* 603
Cyanogenic polymorphism in bracken in relation to herbivore predation—*G. A. Cooper-Driver and T. Swain* 604
Inhibitory binocular interaction in human vision and a possible mechanism subserving stereoscopic fusion—*K. H. Ruddock and E. Wigley* 604
Suckling stimulation induces aggression in virgin female mice—*B. Svare and R. Gandleman* 606
Transmission of Trypanosoma rotatorium from frogs to white mice—*J. Hysek and Z. Zizka* 608
Study of haemopoietic microenvironment *in vitro*—*G. E. van Zant, E. Goldwasser and J. M. Baron* 609
Several proliferative phases precede maturation of IgG-secreting cells in mitogen-stimulated cultures—*M. Zauderer and B. A. Askonas* 611
Control of C3 levels in mice during ontogeny by a gene in the central region of the *H-2* complex—*A. Ferreira and V. Nussenzweig* 613
Microtubule assembly mutant—*E. C. Raff, A. J. Brothers and R. A. Raff* 615
Mechanical properties of vascular smooth muscle cells *in situ*—*M. J. Mulvany and W. Halpern* 617
Calcium activation produces a characteristic response to stretch in both skeletal and cardiac muscle—*R. L. Moss, M. R. Sollins and F. J. Julian* 619

Guide to authors

- Articles are up to 3,000 words in length with at most six displayed items (figures and tables) and may either be reports of major research developments in a subject or broader reviews of progress.
- Letters are brief reports of research of unusual and wide interest, not in general longer than 1,000 words; at most they have three or four displayed items (figures and tables).
- 'Matters Arising' permits occasional short discussion of papers that have previously appeared in *Nature*. There is a limit of 300 words.

Manuscripts may be submitted either to London or Washington. Three typed copies should be submitted, each including lettered copies of figures. Typing (including references) should be double spaced. The title should be brief and informative. Pages should be numbered. References, tables and figure legends should start on separate pages. Experimental detail vital to the paper yet which would interrupt the narrative is best placed in the figure legends. Units should conform to the Système International. Greek characters should be identified in the margin on their first appearance. Equations should occupy single lines if possible, exp (a) is preferred to e^a if 'a' is more than one character. Articles should be accompanied by an abstract of not more than fifty words listing the main conclusions.

References are indicated by superscripts in the text. See any contemporary *Nature* for style, but note:

(i) To refer to several references by the same author at once, only one reference number need be given.

(ii) Cite first and last pages.

Abbreviations should follow the *World List of Scientific Periodicals*, fourth ed. (Butterworth, 1963-65). Symposia are often difficult to refer to and only published or soon-to-be-published volumes should be mentioned in references. Their publisher and place of publication should be clearly indicated. 'Personal communication' and 'unpublished work' should be incorporated in the text.

Artwork should be sent with the manuscript and clearly marked with author's name and the figure number. Line drawings to be in Indian ink on heavy cartridge paper, tracing paper or similar materials: thin, shiny, torn or folded material should be avoided. Scales for graphs should be chosen such that simple figures will not occupy an inordinate amount of space. Most figures are reduced to one column width so originals should be about as wide as a page of *Nature*. To enable figures, particularly maps, to be edited in the same style as the text they should contain only essential material. Ideally, an unlabelled original and a labelled copy should be provided: labelling on photographs should, if possible, be avoided entirely. Records, charts etc. which will not reproduce well should be redrawn or simply described in the text. We are always glad to see artwork for possible use on the cover, but cannot guarantee its return.

In order to save on postal expenses we return only the top copy and artwork of manuscripts that we cannot publish.

A fuller guide appeared in *Nature* (**246**, 238; 1973).

Ultrastructural identification of granules containing oxytocin and vasopressin—*F. Tasso, D. Picard and J. J. Dreifuss* 621

Primary structure of human β-lipotropin—*C. H. Li and D. Chung* 622

Cross tolerance between morphine and methionine-enkephalin—*A. A. Waterfield, J. Hughes and H. W. Kosterlitz* 624

Analgesia induced *in vivo* by central administration of enkephalin in rat—*J. D. Belluzzi, N. Grant, V. Garsky, D. Sarantakis, C. D. Wise and L. Stein* 625

Inability of bats to synthesise L-ascorbic acid—*E. C. Birney, R. Jenness and K. M. Ayaz* 626

Interaction of Walker 256 mammary carcinoma and foetal rat liver in organ culture inhibits enzyme maturation—*F. Farron and J. R. Lightholder* 628

Mechanism for suppression of cellular biosynthesis of prostaglandins—*H. W. Cook and W. E. M. Lands* 630

Evidence for the proximity of sweet and bitter receptor sites—*G. G. Birch and A. R. Mylvaganam* 632

Uptake and catabolism of low density lipoprotein by human lymphocytes—*D. Reichl, A. Postiglione and N. B. Myant* 634

Nuclear retention of receptor–oestrogen complex and nuclear acceptor sites—*J. H Clark and E. J. Peck, Jr* 635

Interferon action may not be effected by induction of a cellular ribonuclease—*H. Maenner and G. Brandner* 637

Changes in histone f2a2 associated with proliferation of Friend leukaemic cells—*L. A. Blankstein and S. B. Levy* 638

DNA ligases during rat liver regeneration—*S. Söderhäll* 640

Single-stranded regions in regenerating rat liver DNA—*L. M. Hoffman and J. M. Collins* 642

Nalidixic acid and bacterial chromosome replication—*G. C. Crumplin and J. T. Smith* 643

π Turn is a conformational pattern in RNA loops and bends—*S.-H. Kim and J. L. Sussman* 645

Systematic nomenclature for the RNA polymerase genes of prokaryotes—*S. S. Hayward and J. G. Scaife* 646

Enthalpy–entropy compensation of oxamate binding by homologous lactate dehydrogenases—*P W. Hochachka, C. Norberg, J Baldwin and J. H. A. Fields* 648

Possible Gibbs–Donnan mechanism for cation uptake—*C. W. Ogston* 650

Matters arising

Evidence for two sodium sites in the external aspect of Na-K pump in human erythrocytes—*A. S. Hobbs and P. B. Dunham* 651

Reply—*J. D. Cavieres and J. Ellory* 652

Haze in the stratosphere from the Fuego eruption—*F. E. Volz and E. P. Shettle* 652

Reply—*R. S. Scorer* 652

BOOK REVIEWS

The Correspondence of Isaac Newton Vol. 5, (Rupert A. Hall and Laura Tilling, editors)—*J. W. Herivel* 653

Guide to authors

- Articles are up to 3,000 words in length with at most six displayed items (figures and tables) and may either be reports of major research developments in a subject or broader reviews of progress.
- Letters are brief reports of research of unusual and wide interest, not in general longer than 1,000 words; at most they have three or four displayed items (figures and tables).
- 'Matters Arising' permits occasional short discussion of papers that have previously appeared in *Nature*. There is a limit of 300 words.

Manuscripts may be submitted either to London or Washington. Three typed copies should be submitted, each including lettered copies of figures. Typing (including references) should be double spaced. The title should be brief and informative. Pages should be numbered. References, tables and figure legends should start on separate pages. Experimental detail vital to the paper yet which would interrupt the narrative is best placed in the figure legends. Units should conform to the Système International. Greek characters should be identified in the margin on their first appearance. Equations should occupy single lines if possible, exp (a) is preferred to e^a if 'a' is more than one character. Articles should be accompanied by an abstract of not more than fifty words listing the main conclusions.

References are indicated by superscripts in the text. See any contemporary *Nature* for style, but note:

(i) To refer to several references by the same author at once, only one reference number need be given.

(ii) Cite first and last pages.

Abbreviations should follow the *World List of Scientific Periodicals*, fourth ed. (Butterworth, 1963-65). Symposia are often difficult to refer to and only published or soon-to-be-published volumes should be mentioned in references. Their publisher and place of publication should be clearly indicated. 'Personal communication' and 'unpublished work' should be incorporated in the text.

Artwork should be sent with the manuscript and clearly marked with author's name and the figure number. Line drawings to be in Indian ink on heavy cartridge paper, tracing paper or similar materials: thin, shiny, torn or folded material should be avoided. Scales for graphs should be chosen such that simple figures will not occupy an inordinate amount of space. Most figures are reduced to one column width so originals should be about as wide as a page of *Nature*. To enable figures, particularly maps, to be edited in the same style as the text they should contain only essential material. Ideally, an unlabelled original and a labelled copy should be provided: labelling on photographs should, if possible, be avoided entirely. Records, charts etc. which will not reproduce well should be redrawn or simply described in the text. We are always glad to see artwork for possible use on the cover, but cannot guarantee its return.

In order to save on postal expenses we return only the top copy and artwork of manuscripts that we cannot publish.

A fuller guide appeared in ***Nature*** **(246, 238; 1973).**

Increased membrane fluidity implicated in acceleration of decay of post-tetanic potentiation by alcohols—*P. B. J. Woodson, M. E. Traynor, W. T. Schlapfer and S. H. Barondes* 797
Single-channel currents recorded from membrane of denervated frog muscle fibres—*E. Neher and B. Sakmann* 799
Selective inhibition of potassium conductance in node of Ranvier with a photoaffinity label derived from tetraethylammonium—*F. Hucho, C. Bergman, J. M. Dubois, E. Rojas and H. Kiefer* 802
α Foetoprotein and serum albumin show sequence homology—*E. Ruoslahti and W. D. Terry* 804

Getting down to business?

From the laboratory to the production line; a particularly difficult route, it seems, for British industry. First we look at the question of academics becoming industrialists.

OVER the past eight years the Wolfson Foundation has been supporting university-based research and development projects aimed at helping the national economy. Four million pounds has been made available for the period 1968–78, and sixty projects have been supported. A new round of grant applications is being solicited at present and a further £2 million will be made available to university groups with proposals which "have a real bearing on industrial production". Some of the more successful of those who have earlier held grants from the Wolfson Foundation were in London recently to talk about their experiences.

Success can be difficult to measure. Some units have actually managed to generate sufficient income from royalties, consultancies and contract-work to guarantee them a life of their own when the Wolfson support runs out. Others have found that the work they were doing was (and this phrase came up more than once) too far ahead of its time in the industrial context; though this may not be unsuccessful in a broader context. But one field in which the admirable efforts of the Wolfson Foundation have as yet to bear much fruit is in persuading members of the academic community to stand full-square behind their own inventiveness and launch a company to take advantage of the business opportunities with which they are presented.

The foundation would no doubt argue that it has never been its role to encourage university staff to forsake the campus, nor was the money it supplied to be seen as venture capital. "We are not a merchant bank", said Lord Zuckerman, one of the foundation's trustees. And yet it needed only a little goading before he would add that academics had too little courage and were far too sessile when it came to considering industrial prospects. What he had hoped for was an increase in the number of small companies working from a technological basis of high quality.

Spin-off industry is, of course, a thoroughly American concept, and it would be foolish to ape the practice simply because it comes from a country with a long record of academic–industrial rapport; after all, Route 128 has had its hard times. There are, however, some very positive reasons why universities should spawn more independent business.

Perhaps the most mundane reason is that if university and private business compete for the same work, it is possible for universities to fudge the overheads issue. This is not necessarily done malevolently—many at the Wolfson meeting were seriously questioning how they could make a realistic estimate of overheads—but the mingling of functions in a university environment is not, one suspects, a very healthy way of maintaining good university–industry relations. Nor, for that matter, is the use of students to provide the labour, in the long term.

A more important reason to encourage more spinning-off is the pressing need to demonstrate to students the role of private industry and the profit motive in a mixed economy. If he sees his teachers and advisers going through the motions of recommending to him the virtues of the private sector whilst themselves clinging to the security of the common-room, even though sitting on a fine business prospect, the advice can hardly bear much conviction.

There is much scope for misunderstanding in industrial–university collaboration. Each can so easily believe the other to be unreliable in delivering the goods. In particular the academic often see "The Board" as a remote and fickle body, prone to abandon high technology at the slightest sign of recession or in the event of a take-over. Surely, then, the answer is often in the academic's own hands: form his company, control his own board, then at least it will not be possible to blame anyone else if things go wrong—nor will anyone else reap the profits if things go right.

To the vice-chancellor the thought of losing good staff is obviously a worrying one, but there is no real reason why the long-term benefits should not be substantial. Much is talked and little is yet done about bringing scientific and engineering departments into closer liaison with industry for teaching purposes, both at the undergraduate and postgraduate level. Whom better to start such schemes with than managers of companies put together within, and spun off from, universities?

The development gap

. . . but what is NRDC doing? Professor S. D. Smith, who is both Professor of Physics at Heriot-Watt University and Chairman of Edinburgh Instruments Ltd, writes on the problem of support for development.

The Science Research Council (SRC) dispenses about £100 millions for research purposes each year. The community using it almost certainly contains the greatest concentration of academic brain power, but only a minor proportion of innovative, entrepreneurial and even practical ability, in the UK. But is there a mechanism to turn the practical results of this national investment efficiently into industrial products that could contribute to the economy?

Most people would, I submit, say no. One body representing academics, the Standing Committee of Professors of Physics, recently submitted a document to a Parliamentary Committee on Science and Technology stating that "most university investigators would prefer to invent nothing than something which might fall into the hands of the National Research Development Corporation" The organisation which automatically acquires rights for the exploitation of any activity currently funded by the SRC.

The appropriate development funding to take a device from a research laboratory to production line can be several times the cost of the original research Certainly obtaining original research results is easier than making the equipment viable on a routine basis; for example, the laboratory research yielding the vertical temperature sounder known as the Selective Chopper Radiometer for the satellite Nimbus 4 cost about £40,000 while the development programme to engineer it for space cost nearer to £200,000.

One major problem is that NRDC funds for development extend only to about £5 millions per annum—insufficient, on the above arguments, to develop even a small proportion of "device-successful" research originating from the SRC. Even more important, NRDC officials themselves differ on whether or not the NRDC is there to encourage innovation and help British industry. But if its specific objective is not to help British industry, what is its purpose at all? Not only does modest development not seem to meet with favour in the NRDC; under the harsh financial terms the NRDC attempts to extract from companies and investors, it seeks far ranging rights and then attempts to get its money back on *each* specific project by way of royalties at the rate of up to 12% per year on the unit selling price.

There are two immediate difficulties with this. Firstly, only about one out of ten projects may be *financially* successful, although a larger proportion may be technically successful. Secondly, the burden of a 12% royalty, being very large in proportion to the possible profit margin (probably about the same) in any competition with (in particular) American companies, can drive the selling price above a realistic level. I also suspect that the principle of trying to recover money *rapidly* on each specific project is wrong.

A related problem is that the NRDC only gives 50% of development funds. For both small and large industry today, this poses an almost insuperable problem of where to find the other half. A further condition invariably includes giving *all* rights and patents to NRDC: this is quite inconsistent with partial funding! The harshness of such terms make NRDC a worse prospect than a merchant bank—the more so because of the wearisome negotiations that drag on for months into years with innumerable wrangles with officials, accountants and so on. Thus in many ways it does *not* fulfil the role of financing truly developmental projects. There is only one saving grace; the NRDC shoulders the burden of loss in event of a failure. As I see it, the only way for a company to make a commercial success of an affair with the NRDC is to extract as much money from them as possible and then declare the project a failure.

So, how does a successful development occur at all? I believe that the British scientific instrument industry is almost in a position of not being able to progress without that element of luck or good fortune characterising all science and industrial development. The state of the laser industry and of the optical components industry and subtechnologies shows this clearly. The fact that things do happen is, I believe, quite often due to spin-off from some large project which carries with it a necessity for engineering and technical development. The development of some component or system then takes place, initially through what I would call "tame orders". Such an order a company can cope with; it can carry out the work for a given amount of money. This must be responsible for much more development than the NRDC route.

Such procedure brings into question the role of agencies beyond the SRC/NRDC area and in particular the Ministry of Defence and so on, where the method is commonly applied. There are two disadvantages: this source of support is not generally accessible, as of right, as a route for development to companies working outside the "defence" area or by the university research community; and, second, it is dictated very much by the whim of current "defence" thinking. I believe that there is case for optimising the rules of the games for research and development expenditure in the direction of helping the development of devices when they lead towards industrial products. Opponents would argue that many of these things will not be economical anyway; but we are spending the money in any event with equally little economic reason.

Why don't we, as a matter of urgency and seriousness, optimise development routes? Some moves would require political initiation, but the terms of reference are not so difficult to envisage. With large projects (like the SRC's Laser Laboratory), some integration into British industrial effort should be attempted as a matter of policy. It must be wrong for the good of the nation to proceed into new technical areas independently of encouraging improved technology in the country. Then, instead of the NRDC, perhaps we require a new branch of the SRC, that can commission development work or pre-production orders and coordinate this activity with the pure science expenditure. Awards could be made and judged against a serious review of technical performance with the sanction of no more funds against inefficiency. Where industry is involved a shared support of the order 80% from SRC to 20% from industry might be right, combined with a liberal and flexible attitude to rights and patents.

To cries of "featherbedding", the answer is not to have no bedding at all. An energy gap may be a source of devices in semiconductors; a development gap is no source at all. This nettle must be grasped at the level of politics.

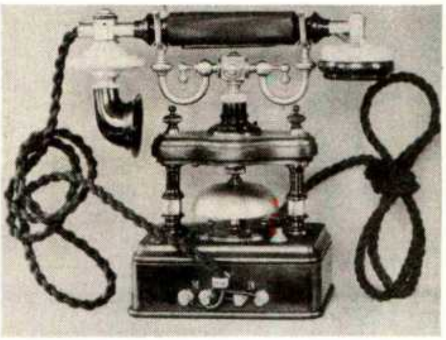
Speaking up for the telephone

Next week sees the centenary of the telephone. Below, a look at telecommunications in Britain



IT MAY be going too far to suggest that, in telecommunications, the pace of research and development may have all but outstripped our capacity to appraise and utilise it. But now more than ever (and in telecommunications more than anything) it takes specialists, in electronics and electrical engineering, to comprehend the intricacies, if not the implications, of the astonishingly broad and complex range of telecommunications "breakthroughs" in the 100 years since Alexander Graham Bell spoke seven words to his assistant on the first telephone.

Telecommunications is widely recognised in Britain as lying firmly within the public domain, being the nuts and bolts of a public service provided by the Post Office, a nationalised undertaking. The Post Office itself acknowledges this; so too does the government. And most people in Britain expect it. Yet the reality looks rather different, for the boundaries of the telecommunications industry are far from coincident with those of the British economy's public sector.

The Post Office, formerly the GPO but made a corporation in 1969, has long had a monopoly of the country's telecommunications *services*. The assets of the system it runs, which is the third largest in the world, are valued at over £4000 million; the Post Office is the country's biggest employer, with almost 250,000 of its 430,000 employees in telecommunications; investment in the year 1974-75 totalled £788 millions, of which 76% (about £600 millions) went on growth and the rest to maintaining and improving the existing system. The figures are enormous; but they form only part of the UK telecommunications picture.

Quite as important is the Post Office's position regarding procurement. In supplies it has nothing like a monopoly. Indeed, just last year, the Post Office produced a document containing recommendations on whether it should manufacture "in-house" more of the substantial amounts of equipment, worth hundreds of millions of pounds, which its existing suppliers produced for it. The question highlighted the network of links between the Post Office, a public corporation, and its main suppliers, all private enterprises with famous names—Plessey, GEC, Pye TMC and Standard Telephones and Cables (STC). A few months later, the nature of those links was further highlighted by announcements from all of these companies of impending mass redundancies as a consequence of a cut-back by the Post Office in its projected orders for telephone exchanges, transmission equipment and telephone sets.

The reasons behind this upset were also revealing. They related, at least in part, to a 30% reduction in the Post Office's estimate on orders for 1975-76 and 1976-77 compared to its estimate a year earlier; this reduction was in turn a reflection of declining demand in the face of rising costs which the Post Office found itself obliged to pass on under the UK government's rediscovered "profitability" regime for the public sector. But the need for redundancies would have arisen anyway, since it was also the result of the design and labour-saving manufacture of electronic exchanges being introduced to replace more conventional electromechanical exchanges and so provide the basis for a massive modernisation programme for the UK telecommunications system.

Reactions to these redundancies also showed the sort of economic factors at work, but revealed political ones too, for the additional unemployment at a time of deepening recession naturally evoked deep emotions. Calls for the introduction of the electronic exchanges to be postponed and for old order levels to be restored, if successful, would have given the Post Office too many of the wrong exchanges which it could not really afford anyway (unless it passed the costs on).

Research and development

That new technologies as well as the plight of the economy are responsible for these cut-backs is just one indication of the central role which research and development plays in British telecommunications. There are others, of course, but a glance at the Post Office's books is sufficient to confirm its importance. In 1974-75, expenditure by the Post Office on research and development climbed fully 30% in value to £28.9 millions. Even more striking, about 93% of this (£27.1 million) was devoted to telecommunications, divided as follows: 59% (£16.1 millions) on "new systems", 25% (£6.8 millions) on "existing systems and related advisory services", and the rest (£4.2 millions) on exploratory research.

A Science Research Council publication released in 1974, surveying current research activities in the UK, says Post Office research and development then involved "some 3,500 staff, of whom about 1,000 are qualified scientists or engineers". The Research Department, now located at Martlesham, the new research centre opened last year, conducts exploratory research into new systems and services as well as the technology, materials and devices to back them up; the Development Department elaborates this work, which focuses chiefly on "switching" (exchanges) and transmission.

Important as it is, however, the Post Office's teams are not the only ones in operation even amongst the public corporations. Work is also done by both broadcasting networks (the BBC and the IBA) and by British Rail. Furthermore, there is the mostly-secret Ministry of Defence activity, through the Signals Research and Development Establishment, the Admiralty Surface Weapon Establishment and the Royal Aircraft Establishment; and the SRC has its own Appleton Laboratory. Each of the Post Office's main suppliers—major companies all—also has sizeable research facilities, on a scale similar to that of the Signals Research and Development Establishment. The work done in these is, the SRC says, undoubtedly influenced by the Post Office, because it is their major customer; between them, in fact, they share several hundred million pounds worth of Post Office business annually. Finally, there are the universities and polytechnics, whose work involved (in 1972-73) 526 people and an expenditure of almost £350,000, the greatest amount coming from the public sector.

The research net is thus spread fairly wide. But what is caught in it? Practically everything conceivable and more besides, if such breakdowns by establishment as are available are anything to go by. While the jaundiced eye might cynically view those research efforts which are made glamorous by publicity-conscious promoters as mere attempts at self-justification, it would probably still focus on the extensively-publicised telecommunications work of the Post Office; after all, the telephone service remains the most direct contact with the world of telecommunications for the large majority of people.

Take the humble telephone set itself. In concept the instrument has changed little: but in a new microphone, sound generates an electric signal from a plastic diaphram with a built-in charge which is boosted by a transistor amplifier. Do the problems of general application, which are large, make such time, money and effort worthwhile? Professor Merriman, Senior Director (Development) with Post Office Telecommunications, has explained that the benefit of such devices lies "in their implied potential for modifying the balance of investment" between telephone sets and their lines to the local exchange. Similar economic arguments are deployed regarding development of the lines themselves. But the chances of reducing costs, without a "fundamental" change in technology, are, he has argued, "reaching an asymptotic limit".

Transmission and exchanges

It is precisely such a change which offers the possibility of transforming the main transmission systems, for here research and development has progressed enormously, particularly in the last ten years. Two entirely new forms of transmission system are being developed which virtually outdate the now-customary coaxial cable and microwave systems.

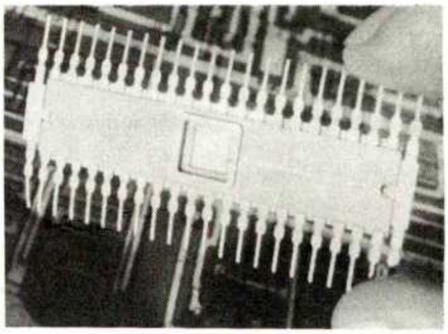
One uses "optical fibres" and transmits signals in the form of light pulses down extremely thin strands of glass fibre. They can carry more messages further and more cheaply with fewer amplifiers than conventional cables. The other uses "waveguides", and is described by the Post Office as "a kind of piped microwave radio"; in it, signals are borne on waveforms down a copper pipe. In both cases digital transmission is involved, where signals are sent as a code of *pulses*, obtained and retranslated through what is known as pulse code modulation, rather than in the customary analogue form, where electrical *waves* corresponding to sound need greater boosting.

But perhaps most attention, certainly in the case of the Post Office supliers, is being devoted to "switching", or exchanges. The key electronic development which is outdating electromechanical arrangements is the integrated circuit, or "chip", hundreds of which are no larger than a pin's head: made of semiconductor, these will replace the large electromagnetic relays; linked to form "processors", they could control central as well as local exchanges. The TXE2 is smaller and uses more basic technology than the TXE4, the electronic exchange developed for large local exchanges of up to 40,000 lines. For the suppliers they offer tremendous export potential, particularly with respect to countries establishing whole new telephone systems.

Switching now represents something like a third of the Post Office's overall investment and is probably the most substantial element of the telecommunications industry's annual production. With the refinement of the electronic exchange, the development path for Britain's telephone system seems fairly clear for the rest of the decade. But it is the result of decisions taken over a period of some 15 years. Moreover, further developments in switching technology are anticipated, and soon. *Their* application demands foresight too; but it also demands consideration of the precise manner in which they will fit in to technological changes in signals and transmission. That means one thing if costs are to go on being reduced in the 1980s: as Merriman has put it, future switching technology "inescapably must be conceived in the context of total systems development and as part of the progressive move towards all-digital, microelectronic, software-controlled systems".

Which introduces what the Post Office calls its "System X", the catchword it proudly uses for overall modernisation of Britain's telephone system. The catchword is necessary: any explanation of it descends quickly into the jargon of systems analysis. The basic idea seems to be that a comprehensive strategy laid now by the Post Office and the industry for the future will, over the years as it is introduced on a larger and larger scale, plan and coordinate the direction of research at all levels, anticipate developments in advance which might in turn be incorporated into the strategy, and generally ensure balanced development and progress.

If the money is there. Thus far, as the figures themselves show, telecommunications has not had it all that bad: few other high technology sectors can point to coherent plans for the 1980s so confidently. And they do not relate only to the telephone system: the list of services now or soon to be provided includes radiopaging (the doctors' "bleepers"), Viewdata (up-to-the-minute information on the telly at the push of a button), Confravision and Viewphone (long-distance conferences between individuals who can see each other and exchange papers) and Fax, or facsimile transmission (a telex-photocopy combination). Even within the realm of telephony itself, improved international dialling and telex facilities, additional use of radio and satellites, automatic dialling devices, push button phones—all are held out, and the list goes on. Fourteen years after Telstar, in fact, space technology still represents a new frontier, and the Post Office has a share in a total of seven satellites.



Integrated circuit for electronic exchange

In Britain, telephones have until recently proved an enormous growth area, and even last year's downturn was then regarded by the Post Office as purely temporary. There are now around 21 million telephones in the whole country. The Post Office argues that real costs to the consumer have fallen over the years, and have done so because of foresight over technological developments in transmission and exchanges. The experts, in telecommunications as in other comparable fields, wish to see the progress made thus far continue at the same if not an increased pace—partly, the cynics would say, to keep themselves in business, though also to supply a continuing demand at a reasonable cost. But projections for the hopefully rosier future can be wrong in an inflationary era. Moreover, the pace of well-financed development being what it is, if demand for various services does grow, even System X could be outdated by the time it is fully installed.

It is precisely this sort of consideration which highlights what many people regard as the real dilemma of telecommunications in Britain 100 years after the telephone: the inevitable duality of a rapid growth in telecommunications knowledge, on the one hand, and, on the other, the lengthy periods needed for appraisal and implementation. Decisions on the direction of research, on appreciation of results and on their application—the argument runs—consume inordinate amounts of time which the additional element of public accountability tends to lengthen still further. It is an argument used to press for greater competition in telecommunications services and to encourage less duplication of research. Others would like to see less research altogether and more grist to the consuming public's mill.

The end result is a mixture of efficiency and inefficiency, profit and loss, bitterness and sweetness: less something Britain can afford than something she cannot afford to be without—and a far cry from those days over a hundred years ago when those who could conceive the idea of transmitting a voice over wires nevertheless thought it would be of little practical value. ☐

Making the annual pilgrimage

Seven years since it last graced Boston with its presence, the American Association for the Advancement of Science (AAAS) returned there a fortnight ago for its 142nd annual meeting. Roger Woodham reports on a heady week during which some Americans admired their national science effort—and others took it to task

MINORITIES in science, the Viking lander mission to Mars, the inevitable questions surrounding energy policy in general and nuclear power in particular, the views of organisations like Science for the People on everything from genetic manipulation to the busing of schoolchildren . . . this is a selection of topics which is at once typical and atypical of the Boston AAAS meeting. Atypical, because few if any of the 5,000-odd attending the meeting will have found it possible to draw all its diverse threads together; but typical, because it represents in a broad-brush fashion the tenor of the whole meeting. Some impressions:

- Allied to the whole question of opportunities for minority groups in science —consideration of which included papers like "Spanish-surname Americans in the sciences"—was the matter of women in science, or rather the lack of them. This was the subject of an unusual morning session on Great Women in Science, attended as might or might not be expected by 150 women and 10 men. The message was clear—either, like Margaret Burbidge of the University of California (who has recently been voted Woman of the Year in California), they had been actively encouraged from an early age, or, like Mildred Dresselhaus of MIT (one of three women members of the National Academy of Engineering), they had simply "stumbled into science and engineering".

When it comes to recognition of female scientists, it transpires that the National Academy of Sciences only does slightly better than its engineering counterpart. It has 21 women members at present, out of a total of 1,144, and has only ever had 26. But it can claim to have done better than the Royal Society of London in electing its first woman member in 1925 rather than 1948 Equal recognition, the meeting concluded, is as much (if not more) of a problem for women as equality of opportunity.

- One recurrent theme was concerned with the tying together of federal government decisions on tax and economic matters, research and development, and regulatory policy. Dr William D. Carey (Executive Officer of the AAAS) contended that the burgeoning of regulations involving industry had led directly to general caution on the part of innovative industrial concerns and the handing down of cautionary decisions. Ninety per cent of industrial research and development is defensive, not imaginative, he declared.

Taking a broadly similar line, Dr Derek C. Bok, President of Harvard University, made remarks that will be echoed by his counterparts on the other side of the Atlantic. He complained that "the government has felt constrained to make painful choices about research priorities; choices that demonstrate the power of the purse to control the growth and shape of the universities". In times of money shortage, he went on, "the needs of institutions of special quality are readily dismissed as elitist and unnecessary". Crash programmes for this or that are all very well, but by focusing attention so heavily on immediate national problems, public officials run the risk of restricting "advances in fundamental knowledge that will leave us ill-prepared for the crises yet to come". Echoing Dr Carey, Dr Bok said that declining funds threatened the most novel risk-taking forms of science.

- No fewer than fifteen individuals directly involved in the Viking Mars programme—and one Congressman, Don Fuqua, known to be well disposed towards space science—contributed to a day-long seminar that not only mapped out what the mission hopes to achieve, but reflected, quite soberly, on what may happen next.

Viking, or rather the Vikings, for there were two identical spacecraft launched within a few weeks of each other in October last year, go into orbit around Mars on June 19 and August 7. And as Dr James S. Martin, the Viking project manager, put it, there's no flexibility in that date, whereas the patriotic notion of landing Viking 1 on Mars on July 4, at a place in the Martian Northern Hemisphere appropriately called Chryse ("hope"), could be scrapped if the information sent back from Mars orbit suggested that some other time or place for the landing would be appropriate. Viking 2 is scheduled to land on September 4 (in a different place) but again the Viking 1 lander and the part of it left in orbit would be helping to update Viking 2's final plans.

Everyone seemed to be agreed that the future for the space sciences would in large measure be shaped by the results that come out of the Viking project—not only the photography of the landscape, by cameras capable of a resolution of 2 to 4 millimetres, but also the outcome of scooping up Martian soil and feeding it on a "rich organic soup", among other things, to see if there are any signs of life.

If there were, that might also be the signal for renewed activity in the search for extraterrestrial intelligence—another seminar topic which saw AAAS participants packed in the aisles. The idea of spending $10,000 million on Project Cyclops, a giant 'listening' programme, is one that is pretty well buried, but more modest schemes to carry on and expand the listening work of the Arecibo radio telescope would undoubtedly blossom if Viking struck lucky.

Assuming some middle-of-the-road outcome for the Viking project—which certainly means no photographs of footprints—and bearing in mind the constraints of the NASA report *Outlook for Space,* which lays down those classes of project that should be attempted—what alternative ways ahead are there? More Vikings of the same kind, Vikings that can be mobile on the Martian surface, Vikings that drop penetrometers from orbit (instrument packages capable of burying themselves hundreds of metres down in the right conditions and sending back data such as temperatures), Vikings that can return a shovelful of Martian soil to Earth—all these are possibilities, as is further collaboration with the Soviet Union. But what everyone seems to be ruling out is landing a man on Mars, at least before the year 2000. That would undoubtedly violate NASA's guidelines for space research in the last twenty years of the twentieth century.

- Science for the People—a radical group that can see very little right in American science, it seems—has almost made it into the Establishment of the AAAS. During the past five years or so it has had a tolerate–hate relationship with the association at annual meetings, sometimes involving the police; this year it had its seminars formally included in the AAAS programme. Science for the People will snipe at anything—including Boston's school busing problem and the cost of electricity—but at the Boston meeting it was mainly addressing itself to topics like cancer research The group asked, in one of its sessions, for example: "Why has so little effort been devoted to the problem of preventing cancer caused by occupational and environmental agents, when it is widely recognised that 80 to 90% [*sic*] of all cancer is caused this way?" □

THE GAMBIA

More the people than the place

Dr R. S. Bray, Director of the Medical Research Council laboratories in The Gambia, looks at life and work there.

THE 1975 balance sheet for medical research in The Gambia shows a reasonably healthy credit. Not everyone wants to do their medical research in a tiny republic stuck out in the savannah of West Africa, but there are compensations. The research is directly about people: organisms and medical phenomena are in people not guinea pigs, and epidemiology figures large. For this you need not merely people, you need nice friendly people. and an understanding population helps to make this the Kingdom of Heaven to an epidemiologist.

The Gambia's people have a willing belief in the delights and benefits of medical research and a considerable dignity to abash the over-assertive. When it came to importing a South African worker to do some haematological investigations, it was with some misgivings that the Ministry of Health was approached about his entry. But—"Bring him in," they said, "we'll show him how nice we are". And they did: he came back the following year and is now thinking of teaching them Rugby!

There are some drawbacks, of course. The rainy season can be tiresome, though there's lots of lovely organisms rife. Distinct seasons do make epidemiology interesting, but it's hard to work full-time on parasites which insist on disappearing by February and not reappearing until July. And of course we are remote. The cut and thrust of one's peers is sorely missed—each researcher tends to be working on a sufficiently different subject to be able to make confident statements based on shaky premises with never a demur heard.

Efforts continue to be made to get onto good terms with The Gambia's neighbours. Visits to Dakar are regular for such essentials as liquid nitrogen and frog's legs. But efforts to revive some institutional form of anglophone West African co-operation in medical research move slowly. The giant to the south—Nigeria—looms over all calculations. They have their own organisations, and the knowledge that they will foot the larger part of the bill for regional co-operative efforts doesn't impel them precipitously into such endeavours. But some concrete results have emerged. A collaborative investigation on malaria and the oral contraceptive pill was initiated between the Komfo Anokye Hospital, Kumasi, Ghana and the MRC, Gambia with IPPF acting as midwife. Equipment has been another productive source of co-operation. It isn't worth £15,000 (for a cobalt 60 source) to irradiate some malaria infected mosquitoes occasionally, so they are taken to Accra where the Ghana Atomic Energy Commission's machine is used with their enthusiastic co-operation.

Malaria figures large as always in medical research. It is still uncontrolled in Africa though the easy availability of antimalarial drugs and domestic sprays is having an effect in and around cities. The sexual forms of the malaria parasite are being studied to see how and when it arises. The major gaps in the knowledge of African malaria are the reasons for the slow and gradual acquisition of immunity, but techniques for exploration of this phenomenon are hard to come by. Work is going on to investigate malaria in the first six months of life and in pregnant women, where variations in immune status may offer some clues. Vaccination is on the horizon, and work continues on the techniques necessary for the collection of suitable antigen Work is also done on filariasis and the onset of elephantiasis, schistosomiasis and the longevity of the worm in the face of acquired immunity, the effect of various diseases on cellular immune processes, malnutrition and the contribution of disease to the onset of marasmus, the manner in which female mosquitoes find their hosts, the contribution of mycotoxins to primary hepatoma and on the susceptibility of N'Dama cattle to trypanosomiasis.

And of course there is the grandest tropical health study of them all—Ian McGregor's 26-year-old survey of 4 rural communities in West Kiang district. This unique work brings together 26 years of morbidity and mortality data, growth statistics, endemic and epidemic disease information, serological results and medical genetics. When eventually collected and collated it will form a standard of reference for medical demography and for medical genetics unsurpassed in Africa. Already the information spun off has been of enormous importance.

Always looming, however, is the fact that 4 to 5 of every 10 children born in Black Africa die before adolescence. When projects are designed, this fact can encourage, even justify—for if an experiment works which brings the disappearance of this disease forward one month, 100,000 lives might be saved. A sobering thought. □

IN BRIEF

JET lag

EEC efforts to take the Joint European Torus (JET) fusion reactor from the design to the construction and experimental stage were still stuck firmly in the political mud last week when community ministers failed to agree on a site for the project after a 16-hour tussle in Brussels. There was agreement on building and financing the project, but national opposition to an earlier Commission finding in favour of the site at the Community's joint research centre at Ispra, northern Italy, forced an impasse which the ministers finally sought to resolve by establishing a new committee; this will investigate the relative technical advantages of the contending sites and decide whether experience in fusion research and plasma physics is relevant in choosing between them. Ministers are due to meet again in mid-June, over six months after the next five-year stage of the £96-million EEC fusion research programme should have begun

Nuclear trade measures

In Washington, a Senate sub-committee on arms control heard last week that the "Group of Seven" nuclear exporting nations—Britain, Canada, France, Japan, the Soviet Union, the United States, and West Germany—have agreed still-secret measures to extend safeguards against the misuse of exported nuclear technology. Some clue to the nature of the pact comes from new US Government principles which require foreign recipients of nuclear facilities, equipment and materials to comply with the internationally accepted safeguards already laid down by the International Atomic Energy Agency (IAEA), and to demand identical assurances from any country subsequently handed similar technology. Recipients will also be restricted from using imported facilities for explosive purposes, whether peaceful or not, as a result of the new US policy.

Serendipity in science?

"There is nothing more practical than a good theory", said Mr Brezhnev, addressing the Twenty-Fifth Congress of the Communist Party of the Soviet Union last week. These words, reiterated by Academician Anatolii P. Aleksandrov, President of the Soviet Academy of Sciences, were apparently intended to justify expenditure on basic research in a Five Year Plan which urges that science should be made cost-effective and more closely linked to production. Citing examples ranging from nuclear physics and MHD-generators to cytology and genetics, Aleksandrov stated that basic research "radically changes technology, leads to the appearance of new materials, and opens up possibilities of using new, often unexpected phenomena, which have no connection with the original field of research".

Dragon reprieve?

The death-throes of the 15-year old Dragon high temperature reactor project at Winfrith in the UK may last longer than expected if a proposal from the European Commission in Brussels is approved. The Commission wants to see the team kept together until the end of the year, mainly to allow the results of the whole project to be evaluated, but also, in turn, to leave the way open for any possible but unlikely resuscitation. The proposed maintenance would cost about £1½ million.

BNFL complication

As British Nuclear Fuels Ltd awaits cabinet approval for its controversial Japanese nuclear processing deal, there are reports of French moves to break into the contract Britain, being a member of the reprocessing group set up with France and Germany known as United Reprocessors Ltd, is obliged to discuss the French bid for a possible 50% share in the contract, or risk competing with France for the entire deal, worth up to £600 millions over the decade following 1980.

Dumping decision

Whatever the outcome of the BNFL negotiations, Britain is to continue dumping low activity material in the deep ocean. In a House of Commons written reply last week, the UK Energy Secretary Anthony Wedgwood Benn stated that desirable disposal rates of the "low activity plutonium contaminated solid radioactive waste", stored mostly at Windscale and Drigg in Cumbria, are well within International Atomic Energy Agency safety limits. They do, however, exceed the dumping levels arranged by the Nuclear Energy Agency of the Organisation for Economic Cooperation and Development, and Britain is to push for higher limits.

Angling right

KENNETH MELLANBY

SOME members of the Council of the Royal Society for the Prevention of Cruelty to Animals (RSPCA), following their success in persuading the society to oppose fox hunting, are trying to engineer the acceptance of a similar policy towards angling. They say it is cruel and should be banned. If they are successful, the conservation of our environment, and in particular of our rivers, could suffer great damage.

Angling is by far the most popular outdoor sport in Britain, having as many as three million adherents. On an average weekend during the fishing season, there are likely to be as many as five individuals sitting patiently by our rivers and canals waiting for a fish to bite for every one spectator attending a professional football match. Although some members of angling clubs from the midlands may lighten the tedium of their coach journey home from the dykes of East Anglia by song lubricated with bottled beer, this seldom if ever leads to the sort of vandalism apparently inseparable from watching some of our more notorious soccer teams The unobtrusive behaviour of fishermen generally is the reason why others are so surprised to learn of their numbers.

However, anglers can be aroused to effective action when their waters are polluted. Although salmon and trout can flourish only in the cleanest streams, even so-called "coarse" fish (which supply the bulk of the sport in England) are delicate indicators of pollution. There have been thousands of occasions when the first warning that some unauthorised and toxic effluent has been discharged into a river has been given by a fisherman who has spotted dead or dying fish which might never have been noticed by the river authorities. The Anglers' Cooperative has been effective in taking legal action to stop such practices Of course anglers can only operate in rivers pure enough to contain fish, and so our filthiest waters do not receive their attention. This is perhaps one reason for the slowness with which they are cleaned up. But once a river is clean enough to be invaded by fish, it is the angler who plays the greatest part in safeguarding it and who may be responsible for further improvements.

Anglers not only outnumber other sportsmen; they also greatly outnumber all our organised environmental and wild-life conservationists. Angling is, furthermore, a sport with adherents from all social classes, including those unlikely to be involved in the more elitist forms of conservation. Yet, as I have indicated, anglers are really *effective* conservationists. It would thus be to their mutual benefit if the two groups could get together to cooperate whenever possible. If bodies like County Conservation and Naturalists' Trusts could recruit a proportion of the anglers operating in their area, they could often quadruple their numbers and end the criticism that they are only a bunch of middle class protectionists working for their own selfish ends. The conservation bodies could help the anglers, for instance, by making waters in suitable reserves available for fishing, and by preventing bodies like the RSPCA (many of whose members are the self-same middle class conservationists) from endorsing policies likely to damage the countryside.

Presumably the move to ban angling is an attempt to benefit the fish. It might prevent a number of fish from being hooked, an experience which can hardly be pleasant, though there is disagreement about the extent to which fish and other cold-blooded animals experience what we describe as "pain". However, without the vigilance of the anglers, fish kills would almost certainly become commoner, and fish might be completely exterminated from many of our waters. It is not unreasonable to suggest that the experience of a fish, choking to death in unnecessarily deoxygenated streams, or writhing in apparent agony after exposure to poisoned effluents, could involve greater cruelty than that arising from normal fishing practices.

Today there is such pressure on our countryside and on its wildlife that all forces need to be mobilised to protect the environment. Freshwater is the habitat most endangered by pollution. It is to be hoped that those members of the RSPCA who are so strongly opposed to fishing will come to realise what would be the eventual consequence of their present policy. Fortunately they are more likely to destroy their own society than to stop a sport which has such widespread support from all sections of the community, and which contributes so much to preserving our environment.

Alternative refrigerants

SIR,—We have carried out a survey of possible substitute refrigerants that could be used in the event that it becomes necessary to ban the use of refrigerant-12, CF_2Cl_2. Very few compounds meet the requirements of being nontoxic and nonflammable, having long-term stability in a refrigeration system and a short residence time in the lower atmosphere. A good alternative to R-12 must have a normal boiling point near −30 °C. We have considered all compounds known to boil between −45 and −15 °C. The list includes approximately 80 compounds of which all but seven can be immediately ruled out as good alternatives. The remaining candidates include CF_3I (b.p.= −23 °C), C_3F_8 (b.p.= −36.7 °C), *c*–C_3F_6 (b.p.= −33 °C), CF_3CH_2F (b.p.= −26.5 °C), *c*–C_3OF_6 (b.p.= −29 to −30 °C), $CF_3OC_2F_5$ (b.p = −23.3 °C), and CHF_2Cl (b.p.= −40.8 °C).

Of these compounds CF_3I may have inadequate long-term thermal stability, decomposing to the products C_2F_6 and I_2. We are uncertain as to the flammability of CF_3CH_2F, and it would be very difficult to prepare this partially fluorinated hydrocarbon in good yield. Perfluoroproprane, C_3F_8, appears to be an ideal refrigerant. We are concerned, however, that this compound would have a much longer atmospheric residence time than R-12 and thus build up to be photolyzed at much longer wave-atmosphere. This would be undesirable since it is not possible to predict beforehand all possible environmental effects of a contaminant. Because of the strain energy in perfluorocyclopropane, *c*–C_3F_6, we expect that this compound to be photolysed at much longer wavelengths than C_3F_6 and thus have a shorter atmospheric residence time. Also, the boiling point of this compound is nearer to that of R-12 and for this reason would be a better substitute. The cyclic ether, perfluoropropylene oxide, and perfluoromethylethyl ether appear to be good substitutes. Presumably, these compounds would rapidly decompose once released into the atmosphere. We are concerned that these compounds may have anaesthetic properties and that they may lack long-term stability in the presence of trace amounts of water. Refrigerant-22, CHF_2Cl, is already used in a wide range of applications. However, its boiling point is much lower than that of R-12 so that its vapor pressure is higher, and thus requires much sturdier and therefore much more expensive refrigeration hardware.

Our civilisation can function without aerosol cans, but not without refrigeration Except for R-22, any of the alternatives we have suggested would require five to ten years to be produced at the required level. Any decision to ban the use of R-12 should take into account these facts

Carbon dioxide reduction

SIR,—As is well-known, the oil crisis raises three distinct technical problems: overall shortage of fuel, shortage of suitable portable fuel (now normally hydrocarbons), and shortage of raw material for organic chemical industry.

Several possible solutions have been advanced for the overall fuel shortage and, if they prove adequate, this should cease to be a problem. If not, we are in a more difficult situation than most of us yet realise.

It has been proposed that the use of hydrogen, readily available with sufficient power, may be an answer to the second problem. For the third no long term answer has been advanced; the use of coal will provide a temporary answer after oil is exhausted, and coal can also be used to produce portable hydrocarbon fuel.

I have already suggested (*Nature*, **251**, 469) that it is worth looking again at the production of furfural from agricultural waste as a partial, but renewable, answer to the second and third problems.

I do not myself believe that the technology of the liquid hydrogen economy will prove practical on the wide scale, and it seems to me that only organic compounds, though not necessarily hydrocarbons, can provide an answer to the need for a portable fuel.

Thus an answer to both the second and third problems may need a large scale, renewable source of organic compounds. The only inexhaustible source of carbon is carbon dioxide. Given an adequate supply of hydrogen, it is possible to reduce carbon dioxide as is normally done with carbon monoxide in the Fischer Tropsch reaction. It is the purpose of this letter to draw attention to this possibility, and to suggest that the time for basic investigation of this reaction is now, before the need arises.

Science and industry

SIR,—The urgent need for 'Harnessing Science and Industry' in Israel (February 12, page 442) must also apply in the UK. Indeed, discussion is urgently required as to how better use might be made of British scientific innovation and talent, and your leading article (January 29) has done something in this direction by touching upon the possibilities of encouraging more scientists into industry.

But the problem is both deep-seated and urgent. There was a move recently to focus attention on this problem by establishing an exhibit (and perhaps a study centre) in buildings surviving from one of the earliest science-based industries in this country—that is, on the site of the historic Perkin and Sons dyeworks at Greenford Green, Middlesex, a mid-nineteenth century enterprise with an enviable record for turning the results of the latest scientific research into technological and commercial success. Ironically, this move failed in January of this year with the deliberate demolition of the buildings of interest due to a lack of appreciation of scientific and technological matters by businessmen and civil-service administrators.

IQ tests and majority groups

SIR,— In common usage, and by statute for elections in the USA, "majority" is a number of excess of half the total. In a total with three or more subgroups, the largest is a "plurality". A plurality may also be, but need not be, a majority I suggest that in Dr Harrington's very valuable study (December 25, page 708), since none of the populations contained a majority, the largest group in each population was a plurality. His results seem to indicate that the more numerous, or principal, groups are favoured by current testing procedures; a most important finding indeed

Social insects and the evolution of altruism

from John Krebs and Robert M. May

It is an astonishing fact that many professional biologists still do not understand the essence of Darwinian natural selection. Many people still think, and write, that adaptations evolve by natural selection because they are 'good for the species as a whole'. This sort of statement can be found in such influential writings as Konrad Lorenz *'On Aggression'* and the Nuffield Sixth Form Teachers' Guide. Natural selection is a matter of differential survival and reproduction of individuals (or to be precise of genes), not of species. Adaptations evolve because they enable genes in individuals to out-do genes in their conspecifics, and natural selection relentlessly pursues this course without regard to the survival of the species or population as a whole. For many purposes it does not matter whether one appreciates this distinction, but in analysing the evolution of social behaviour it is crucial, so it is not surprising that some of the most important developments in understanding natural selection have come from this field.

The central theoretical issue in the evolution of social behaviour is the problem of altruism. In biological terms, an altruistic act is one which decreases the fitness (survival and reproduction) of the actor, while increasing the fitness of another individual (the recipient). If such genetically altruistic behaviour occurred in nature, it would undermine the very core of Darwinian natural selection, which is why the problem is so interesting.

Charles Darwin himself remarked in the *Origin of Species* that the apparent altruism demonstrated by the social insects posed 'the one special difficulty which at first appeared to me insuperable, and actually fatal to my whole theory'. He then went on to give reasons why natural selection may sometimes operate at the level of family groups rather than individuals, in effect anticipating the idea of 'kin selection' which plays such an important part in modern ideas of the evolution of social behaviour in animals.

Some types of apparent altruism such as parental behaviour are easily understood. A parent bestows care on its young, often at considerable cost to itself, but of course the young represent the parents' gene contribution to the next generation and natural selection by definition favours individuals who maximise their gene contribution to future generations. But children are not the only bearers of a parent's genes: brothers, sisters, cousins and so on all share a considerable proportion of their genes by common descent. So the same reasoning that applies to parents and their children applies to all kin. W. D. Hamilton, in two seminal papers (*J. theor. Biol.*, **7**, 1, 17; 1964), developed the concept of inclusive fitness—the idea that in order to estimate the fitness of an individual it is necessary to take into account the survival and reproduction of kin. In practical terms, you might make a genetic profit by helping your brother to have an extra child, even at some cost to yourself, because your brother's child shares a quarter of your genes by direct descent. The general conditions favouring this type of 'kin altruism' can be stated precisely.

Your kin share a certain proportion of your genes, for example full siblings have a probability of 0.5 of sharing any particular gene by descent; nephews and uncles 0.25, and first cousins 0.125. This probability of sharing genes is referred to as the coefficient of relationship r; more formally it is defined as the conditional probability that individual B has a particular gene given that individual A has it. An altruistic act will benefit (in genetic terms) the actor as long as the benefit to the recipient is greater than the cost to the actor by a factor equal to $1/r$.

In the case of full siblings if you sacrifice your life for your siblings, more than two must survive as a result of your death for the 'altruistic' sacrifice to increase your fitness. Any apparently altruistic behaviour which can be accounted for within this framework is genetically selfish and therefore consistent with Darwinian theory, for since gene types are the basic stuff of evolution, it is inclusive fitness, not individual fitness that is maximised by natural selection.

This important concept of inclusive fitness was used by Hamilton to explain the evolution of the most extreme altruistic behaviour in the animal kingdom, that of worker castes in the social Hymenoptera (bees, wasps and ants). In these social insects the reproductively competent queen produces sterile worker females, whose task is to spend their life rearing the other fertile male and female offspring of the queen. Worker behaviour superficially appears the ultimate in disadvantageous behaviour from the point of view of the individual perpetuating its genes. But, because in the Hymenoptera the males are haploid and the females diploid, the worker female is in fact more closely related to her sisters than to her own hypothetical offspring. Daughters contain a full set of their father's genes, and so sisters related through both parents have a higher degree of relationship to each other ($r=0.75$) than to their own children ($r=0.5$). Conversely, a male is more closely related to his daughter ($r=1$) than to his siblings ($r=0.5$). Females are related to their brothers with $r=0.25$.

So the daughters of a queen who are faced with the choice of rearing their own daughters or staying at home to rear younger sisters should prefer the latter course (which is possible in the social Hymenoptera because the generations overlap) because by rearing sisters, a female produces more of her genes in the next generation than by rearing the same number of daughters.

The haploid/diploid separation of the sexes in the Hymenoptera explains why sterile worker castes have evolved at least eleven times in this one group but only once (in the termites) in the whole of the rest of the class Insecta, in which both sexes are diploid, although the Hymenoptera comprise only 6% of all insects. A particularly telling point is that this altruism is sex-limited: only females are workers and all males are reproductive.

In an exciting new paper, Trivers and Hare (*Science*, **191**, 249; 1976) have developed Hamilton's theory further and produced dramatic evidence to support its predictions. They begin by remarking that although this asymmetry in the way Hymenopteran individuals are related to one another predisposes daughters towards the evolution of eusocial behaviour (defined as that combination of co-operative brood care, division of the group into reproductive and sterile castes, and overlap of at least two generations, which characterises the 'truly' social insects), it does not compel it. Trivers and Hare have now clarified the precise circumstances in which asymmetric degrees of relatedness can lead to the evolution of eusociality and have generated several predictions which can be tested quantitatively.

Whereas a female worker is more closely related to her sisters than to her hypothetical daughters, this is not so for her brothers, with whom she has a r of only 0.25 (as Hamilton well realised) If a worker invested an equal amount of effort into rearing brothers and sisters her average r to the siblings she rears would be 0.5, no better than she would do by having her own children. Hence, if the workers are to make a genetic profit from their apparently selfless devotion to rearing siblings, they must put more effort into rearing reproductive sisters than into brothers. The appropriate extra effort follows from the r values above and is a 3:1 preference for sisters over brothers in the sexual brood (the ratio measured, for example, in dry weight). With this ratio, the gene which the worker shares with the male is three times as likely to be present at the foundation of the new colony than the gene which the worker shares with the female, thus cancelling out the initial difference in r between the worker and the male.

On the other hand the queen of the colony, who actually lays the eggs prefers an equal investment in the sexes among her progeny (as proved by R. A. Fisher many years ago as a general rule for all sexually reproducing organisms). So within the colony there is a conflict of interests: the apparently altruistic worker can only pursue the genetically selfish course dictated by natural selection if she devotes three times as much effort to reproductive sisters as to brothers, whereas the queen can only maximise her fitness by equal investment.

Therefore, when a mother queen lays all the eggs and the worker caste is completely in control of rearing the larvae, the ratio of investment should approximate 3 : 1. On the other hand, if the queen has control over the ratio of investment, it should remain at 1 : 1. When one or more workers lay eggs the situation is complicated and intermediate. In no circumstances is there any advantage to altruistic behaviour by the haploid males.

Trivers and Hare present good evidence, culled from various sources, for the sex ratios of reproductives ("alates") produced by some 21 ant species in which one queen lays all the eggs (monogynous). Sex ratios and relative weights are obtained by digging up complete nests during the time when alates are present, and from these data an estimate of the relative cost to a colony of a female alate compared to a male can be made. There is a good fit to the predicted 3:1 ratio; the departure from a 1:1 ratio is highly significant ($P<<0.01$).

Various other tests are carried out, although in most cases the data are softer or scarcer, and the points on the regression plots more scattered, than for the monogynous ants. Thus in slave-making ants, the queen's brood is reared not by her own daughters but by slaves (stolen from other species) who have no genetic relationship to the brood. Consequently the queen should achieve her preferred ratio of investment of 1 : 1. Two slave-making species indeed have ratios close to 1 : 1, while three closely related non-slave makers (of the genus *Leptothorax*) adhere to the 3 : 1 ratio. In polygynous ant species, a queen may permit one or more of her fertilised daughters to settle within her nest: large polygynous nests may contain granddaughter or even later generation queens. This makes for a complicated situation, with a tendency for ratios of investment to be biased towards males. Such seems to be the case for seven polygynous species for which data are available. The Hymenoptera also include solitary, non-social bees and wasps. Estimates of the ratios of investment in twelve species of solitary bees and five species of solitary wasps are scattered near 1:1, and none are greater than 2:1. Corresponding ratios for eusocial bees and wasps are hard to come by, because there are time-consuming technical difficulties in distinguishing reproductives from workers. The ratios of investment for five species of social bumblebees (*Bombus*) are scattered in the range 1.2 : 1 to 3 : 1.

Trivers and Hare's paper is of profound importance. It puts the capstone to an edifice that draws together genetic principles and Darwin's theory of natural selection towards explaining the evolution of the social insects. Many other questions now open up. For example, among the most complicated caste structures are those belonging to some of the "leaf-cutter" ant species of the tribe Attini. These ants bring plant material into their nests, where it is used to culture fungi which they eat: very crudely, they may be thought to have accomplished the transition from the "hunter-gatherer" existence of most social insects, to an "agricultural" society. It is surely not coincidental that they possess one of the richest caste systems, and it will be interesting to understand how it came about.

Besides providing direct evidence for Hamilton's kingship theory, Trivers' data are the first to test the outcome of parent-offspring conflict. This type of conflict must be widespread in animals with parental care, because a child is related to itself by a r of 1.0 and to its mother by 0.5, so that the two individuals have different genetic interests dictating their behaviour. Although R. D. Alexander (*Ann. Rev. Ecol. Syst*, **5**) has developed the hypothesis that parents always have the upper hand over their offspring, Trivers' data show the opposite.

As so often happens in the evolution of ideas, it now seems that the social insects, which initially seemed to threaten Darwin's theory, are providing it with one of its most dramatic and quantitative triumphs. □

Organometallic chemistry

from Ronald Mason

'WHAT is the use of a book' thought Alice 'without pictures or conversations' The hundredth issue of the *Journal of Organometallic Chemistry*—a growth stock if ever there were one—is a unique issue in that the editors invited some of the leading research workers to contribute a personal account of their involvement in the field and discuss its development. The result is fascinating—the single picture is of lamentable quality but the conversations go a long way to eroding the old adage about scientists not understanding history (and *vice versa*!)

Organotransition metal chemistry owes much of its present shape and status to the discovery of the π-cyclopentadienyl and *bis*-benzene 'sandwich' compounds in 1951 and the two Nobel Laureates associated with the discovery —Fischer and Wilkinson—provide articles which are interesting in their contrast. Wilkinson's recollections are intensely personal and warming to any advocate of the proposition that science is, above all else, a human activity. Fischer chose to discuss his most recent results on carbyne-complexes so we are deprived of the comparative viewpoint. Retrospectively, one of the more interesting points about the immense literature which has been generated by the original work is that the compounds have provided little direct spin off, most of the present concern in organometallic and low valent complex chemistry concentrating elsewhere, with metal carbonyls, π-alkyl complexes, tertiary-phosphine and -phosphite complexes and σ-bonded compounds providing more scope in synthesis and catalysis; if one accepts this argument, the articles provide for introspection and the prospects for the subject are not easily discernible.

The future for organometallic chemistry, and indeed for chemistry, is stiffly linked to the development of new approaches in synthesis. The synthetic strategies of organometallic chemistry are much less determined and sophisticated than those of organic chemistry but the serendipities of the past twenty years have been signposted and a rational basis for synthesis is emerging. Thus, so far as σ-bonded transition metal organometallics are concerned, the realisation of the difference between their kinetics and thermodynamic stabilities has led several research groups to design stable molecules through precluding, *inter alia,* the β-elimination reaction. The use of metal atom vapours in synthesis is providing species which had wrongly been thought of as thermodynamically unstable and these complexes may see much use as precursor reagents The philosophy of the stabilisation of reactive species such as cyclobutadiene and benzyne is encapsulated in an article by Pettit and extrapolated to metal-carbenes and -carbynes which have much potential as intermediates in synthesis. In the context of the use of metals in organic synthesis, an obvious omission is one which takes no explicit account of the work of Wilke and his colleagues, particularly the recent studies in chiral and heterocyclic ring synthesis.

It will be interesting to see whether, as I believe, there will be a substantial shift soon in emphasis from organo-transition metal chemistry to main group organometallics. Brown, Gilman and, to a lesser extent, Hawthorne help us to anticipate the move but the main reasons for such a change are that, following a lengthy period of establishing the basic methods of synthesis and general properties of Group IVB-organometallics, many novel advances are coming along quickly including the fairly convincing demonstration of the existence of long-sought species such as $Me_2Si{=}CH_2$ and $Me_2Si{=}O$, the easy generation of silylene species, and the discovery of a wide range of novel rearrangement reactions. The upsurge of the use of organosilicon compounds in organic synthesis has reached into industrial processes with trimethylsilyl compounds involved in the manufacture of antibiotics. Eaborn touches lightly on this area in the hundredth issue, particularly with respect to the potential synthetic use of aryl-MR_3 bond cleavage. And one can remember the long standing use of organo-lead and organo-tin compounds A long term future for main group organometallics is assured again by the recent discovery of the biological activity of certain cyclic siloxanes, which have similar properties to the oestrogenic steroids, and of the silatranes whose versatile therapeutic properties include claims for the treatment of baldness! One might go further. parenthetically, and generalise beyond organometallic chemistry: main group chemistry is now ready for the intensive approaches and techniques which have given a maturity to 'd' block chemistry.

It seems a pity that structural aspects of organometallic chemistry are hardly considered explicitly, given the symbiotic relationship of synthesis and, in particular, X-ray crystallography. Our understanding of the metal–carbon bond has changed profoundly, not least because of the insight which the Dewar-Chatt model provided for metal π-complexes It is obviously a matter of personal taste and prejudice but, given his immensely varied and seminal contributions, I would have preferred to see Chatt discussing metal-carbon bonds and the reactivity of low-valent complexes, rather than highlighting the recent advances in metal-dinitrogen chemistry; but that part of his article which deals with the formation of nitrogen-carbon bonds can be assured of concentrated study over the next five years Cotton's article on the dynamic or fluxional behaviour of organometallics in solution substantially remedies the balance but here one wonders if the last milestones have not been passed and that it will be other approaches which will provide a quantitative description of intramolecular potential energy surfaces

A final thought is appropriate on the mechanisms of reactions of organometallic molecules, a topic which is in a primitive state compared with that obtaining in physical organic chemistry. Surely this is an area of mainstream development for it involves study of the reactions of coordinated ligands and the metal-activation of covalent bonds, two matters which lie at the heart of any discussion of homogeneous and heterogeneous catalysis. Stone's contribution reminds us of the tremendous effort that has gone into studies of organometallic and coordination complexes of d^8 and d^{10} metal ions and which have provided a variety of homogeneous catalysts and, for example, a much better understanding of the role of steric effects in reactivity (*vide* the activation of carbon-hydrogen bonds). The chemistry of polynuclear complexes has only just begun in anything like a systematic way and persuasive evidence is already available that some may not only be effective catalysts in their own right but their reactions can provide insight into the spectrum of physical and chemical processes that occur at surfaces of heterogeneous catalysts.

There have been sceptical, well-publicised comments on the maturity of organometallic chemistry which have carried the implication that the field will provide few novelties in the future. This proposition can be debated over all researches in the natural sciences but the prospects of metal ions providing more versatility and control over the reactions of organic molecules seem clearer and more rationally based than those of a decade ago. The two hundredth issue of the *Journal of Organometallic Chemistry* could provide an acid test of this forecast. ☐

Revolutionary SiC fibre

from Robert W. Cahn

G. K. CHESTERTON once wrote a rollicking poem about the Rolling English Road, and commented affectionately on the entertaining journey from somewhere-or-other to Birmingham, by way of Beachy Head. Anyone who knows England knows that it is not sensible to go to Beachy Head if you want to finish up in Birmingham, no matter where you start from. But it was an Englishman who had the crazy notion of making pure carbon (Birmingham) by first making an elaborate polymer (Beachy Head) and then destroying it by heat. Watt's technique of stretching oxidising and pyrolysing polyacrylonitrile to create strong carbon fibre was highly unconventional, but it worked triumphantly.

Now an equally eccentric and equally brilliant Japanese chemist, Seishi Yajima, has found an equally unconventional way to make strong, continuous fibres of silicon carbide. A preliminary summary of his method has been published in *Chemistry Letters* (Japan), (No. 9, 931; 1975).

More detailed publication is on the way, and Yajima (who is head of the Oarai branch of the Research Institute for Iron, Steel and Other Metals of Tohoku University) has also privately circulated an account of his underlying philosophy. He explains that conventional organic chemists have long striven to convert inorganic materials to organic (this goes right back to Wohler's synthesis of urea), but they have an inbuilt resistance to turning back an organic material, attained in complex form by considerable efforts, into an inorganic material of simple structure by heat or chemical treatment 'The organic chemist intrinsically detests a high temperature. He cannot stand the destruction of a complicated structure which has been obtained by painstaking efforts.' Yajima is an unconventional organic chemist who has overcome the phobia of fire.

Fibre-reinforcement for service at high temperatures is fraught with difficulties Carbon fibre is too reactive, alumina is too weak, SiC whiskers are too short and too expensive. Intrinsically, however, SiC has all the required properties, and Yajima set out to make strong, continuous fibre He starts with dimethylchlorosilane, $(CH_3)_2SiCl_2$, reacts it with lithium and a catalyst to form dodecamethylcyclohexane, $[(CH_3)_2Si]_6$, which is polymerised in an autoclave The molecular weight fractions are separated by repeated solvent extraction and a solution of molecular weight ~1,500 is solvent-spun into a fragile, brittle fibre This is then pyrolised in a vacuum at temperatures in the range 800–1,300 °C to turn it into β SiC. Infrared spectroscopy and X-ray diffraction were used (the details are in process of publication) to follow the stages of pyrolysis The best fibres (1,300 °C heat-treatment) have strengths of 300–350 kg mm^{-2}, and elastic moduli of 30 mm^{-2}. Diameters are typically 10–20 μm

The extraordinary feature of the fibres is that although their strength matches that of SiC whiskers, their structure is totally different. Electron microscopy and analysis of X-ray diffraction line profiles both reveal a structure of minute crystallites, 7 nm across, without preferred orientation. This fine structure is crucial if pyrolysis is done at 1,500 °C, giving considerably larger crystallites, the strength falls sharply. Prolonged attempts were made to match this structure by sintering ultrafine SiC powders, but these were never fine enough to achieve high strength. Yajima can only speculate as to the reasons for the remarkable strength associated with the ultrafine morphology

The SiC fibres are extremely resistant to heat and oxidation, and will withstand, undamaged, prolonged exposure under load to a flame at 1,200 °C. By contrast, SiC whiskers lose strength above 600 °C No information is given about the economics of the process, but it appears that the process can be made to work on an industrial scale.

Yajima claims that his work is the first instance of a metal atom being introduced into the skeleton of an organic polymer. This innovation has resulted in an inorganic product which appears at last to open the way to an effective fibre-reinforced composite, SiC-in-metal, which can give effective service at high temperature. ☐

Signals for protein synthesis

from a Correspondent

WHAT features of mRNA primary or secondary structure are responsible for protein synthesis? Possession of a 5′-terminal AUG allows synthetic polynucleotides to function in many initiation assays but initiation codons are by no means unique to initiation sites. In eukaryotic messages, 'cap structures' have recently been shown to aid ribosome binding (Both *et al.*, *Cell*, **6**, 185–195; 1975) but no comparable feature has been found within prokaryotic mRNAs. Here the picture appears to be more complex, and considerable perception on the part of Shine and Dalgarno (*Proc. natn. Acad Sci. U S.A.*, **71**, 1352–1346; 1974) was required to identify what, recent evidence suggests, is indeed a signal for bacterial ribosomes.

Shine and Dalgarno point to a group of residues, mostly purines, found preceding the initiation codon by about 10 bases in the various initiation sites which have been sequenced—this partially conserved sequence could potentially base-pair with the 3′-terminus of 16S rRNA They cite evidence implicating this part of the rRNA molecule in initiation and postulate that the selection of an initiation site is influenced by the potential of any given site to base-pair with 16S rRNA (Shine and Dalgarno, *Nature* **254**, 34–38; 1975). What is lacking in this imaginative hypothesis is any direct evidence that this base-pairing actually takes place, and it is this point to which Steitz and Jakes (*Proc. natn. Acad Sci U.S.A* , **72**, 4734–4738; 1975) have addressed themselves

They make use of the ability of colicin E3 to cleave 16S rRNA 50 bases from its 3′-terminus When *E. coli* ribosomes were allowed to initiate on the ^{32}P-labelled A protein initiation site of R17 phage and were then treated with colicin E3, the detergent SDS released most of the counts as a complex between the labelled initiation site and the 3′-terminal fragment of 16S rRNA. The complex was detected on polyacrylamide gels migrating more slowly than either the free initiation site or the colicin fragment—without colicin, the counts were recovered at 16S on sucrose gradients. The complex is an RNA · RNA duplex since it can be formed by the isolated RNAs, though presumably the extent of its formation is then much lower. The crucial observation is that if the binding of mRNA to ribosomes is inhibited by aurin tricarboxylate, only small amounts of this complex can be detected. Since this inhibitor does not affect the annealing of RNA, the most reasonable conclusion to draw is that binding of ribosomes to the initiation site facilitates the 'Shine–Dalgarno' base-pairing. This approach cannot tell us whether this interaction is occurring during initiation or during the subsequent disruption of the ribosomes Few people would deny, however, that these experiments give substantial support to the hypothesis of Shine and Dalgarno.

If we may accept that base-pairing between the R17 A protein initiation site and the 3′ end of 16S rRNA takes place during initiation, we must examine whether this phenomenon is of more general significance. Steitz and Jakes describe an experiment in which ribosomes were allowed to bind to intact R17 before exposure to RNase: the three initiation regions were then isolated as ribosome-protected fragments Although the A protein initiation site shows the greatest complementarity with 16S rRNA, it is the site least favoured by this ribosome binding /protection reaction. Other, stronger signals direct ribosomes preferentially to the replicase and coat protein initiation sites. There is evidence from ribosome reconstitution experiments suggesting that, in addition to 16S rRNA, the ribosomal protein S12 plays a role in recognising the other initiation sites (Held *et al*, *Biochemistry*, **13**, 2115–2122; 1974) Whatever signals are recognised in the replicase and coat protein initiation regions, they appear to lie outside the region conventionally isolated as a ribosome-protected fragment because, of the isolated fragments, only the A protein initiation fragment can bind efficiently to ribosomes (Steitz, *Proc. natn Acad. Sci. U.S.A.* **70**, 2605–2609; 1973).

This is not to say that other recognition signals do not lie within the ribosome-protected regions, only that in the case of the R17 synthetase and coat protein genes, these are not sufficient by themselves to permit efficient ribosome binding. Other features shared by many ribosome-protected fragments have been noted by Pieczenik *et al.* (*J molec. Biol.* **90,** 191–214; 1974) in their studies on ribosome-binding sites from phage f1. First, the sequence coding for the first few amino acids often contains termination triplets in the two unused reading frames. These might serve to abort peptide bond formation after an out of phase initiation. Any feature characteristic of an initiation site, however, might be utilised in the recognition process and indeed, a role for the 3′ end of 16S rRNA in recognising termination triplets was postulated by Shine and Dalgarno (*Proc. natn. Acad. Sci. U.S A.,* **71,** 1342–1346; 1974). The other feature of coding sequences within initiation sites is palindromic sequences, that is, sequences such as C-A-G-G-A-C which 'read' the same in both directions. It is difficult to view palindromes as recognition elements since it would seem that they can only be identified by those who can read. In the absence of any evidence, both the out of phase termination triplet and the palindromic sequences should be considered characteristics of initiation regions. The only features presently identifiable as recognition signals are the 'caps' in eukaryotic mRNAs and the sequences complementary to 16S rRNA in prokaryotic mRNAs

If the Shine–Dalgarno base-pairing signal is an important feature of initiation sites, strong selective pressures would act against any change in the relevant rRNA sequence This sequence, however, has diverged somewhat within bacterial species and, in eukaryotes, the 3′ end of 18S rRNA bears no resemblance to that of 16S rRNA, although this sequence is apparently invariant within the eukaryotes Whether or not a similar scheme exists in eukaryotes is debatable. Dasgupta *et al.* (*Nature,* **256,** 624–628; 1975) have determined the nucleotide sequence of the initiation region of brome mosaic virus RNA-4—the mRNA for BMV coat protein. The sequence exhibits a weak, four-base complementarity with the 3′ end of 18S rRNA. More interesting is the manner in which this region was isolated. The BMV RNA was subjected to limited RNase digestion and the fragments so produced were bound to wheat germ ribosomes. The region used for sequence analysis was then isolated from the 80S ribosomes as the only bound fragment which was annealed to the rRNA—the coding properties of this fragment demonstrate that it is indeed the authentic initiation region of this mRNA. A similar observation suggesting a functional role for mRNA: rRNA base-pairing comes from Kabat (*J. biol. Chem ,* **250,** 6085–6092; 1975). Kabat isolates rabbit globin mRNA complexed to rRNA and finds that this complex is more active in translation by RNase-treated ribosomes than is the free mRNA. It is tempting to speculate that the RNase treatment has removed an exposed region of the rRNA which functions in initiation site recognition and that the exogenous rRNA can substitute for this missing sequence. It should be noted, however, that both 18S and 28S rRNA show this potentiation activity. Further studies with eukaryotic mRNA species will be required before conclusions can be drawn with any confidence.

What then is an initiation site? In bacterial systems it can be a fairly extensive region possibly extending into coding sequences. Within this region there may exist a number of features of primary or secondary structure which serve to direct ribosome binding. These signals must be available to ribosomes and not masked either by mRNA secondary structure or by proteins bound to the message. This latter may be an important control point regulating the synthesis of individual proteins in situations where transcriptional control is not appropriate (as in the RNA phages or in early embryogenesis). It is likely that as more extensive sequence information becomes available we will come to recognise more of the features responsible for directing the binding of regulatory proteins and ribosomes. ☐

Transform faults to spreading offsets

from Peter J. Smith

The term 'transform fault' has become an integral part of the language of the Earth sciences. It was introduced by Wilson (*Nature,* **207,** 343; 1965) to describe a fault that terminates abruptly at points where its motion is 'transformed' into a movement of a quite different feature, and was first used specifically in connection with offset spreading oceanic ridges, where strike–slip motion is limited to the zone between the two ridge segments. But this is a purely phenomenological definition carrying no information about how such faults originate. And therein lies a problem which according to Vroman (*Tectonophysics,* **30,** T11; 1976) has led to a "mire of misunderstandings".

The difficulty is that the, albeit necessary, adoption of a descriptive definition has apparently encouraged many workers to assume that all faults conforming with it have the same cause. Not that the cause has been established, even for the familiar transform faults in the ocean floor. Shear fault patterns on land are the result of brittle fracturing in an elastic solid, and it has therefore seemed reasonable to many to assume that the dense grid of 'shears' representing transform faults in the solid ocean floor is produced likewise In Vroman's view, however, this is not necessarily the case. On the contrary, the lack of a conjugate set in the pattern of oceanic transforms suggests that these offsets were created in material having Newtonian properties and responding to the laws of laminar flow. The apparent paradox that transform faults are now found in solid crust is then to be resolved by assuming that the faults are inherited from a time before the Newtonian liquid's solidification.

To develop these ideas, Vroman refers back to the original laboratory experiments of Oldenburg and Brune (*Science,* **178,** 301; 1972) who showed that spreading axes, transform faults and their associated fracture zones could be generated in freezing paraffin wax. One of the important results obtained by Oldenburg and Brune was that whereas the liquid material upwelling along a regular spreading axis solidifies and enlarges each plate equally, accretion takes place differentially along an initially jagged axis in such a way as to smooth out the irregularities According to Vroman's interpretation of the Oldenburg–Brune model, however, spreading axes also exhibit more prominent irregularities which are essentially everlasting.

These 'kinks' are thought to play an important part in the development of the spreading pattern. As liquid is carried away to the two accreting walls of the spreading axis, a flow pattern is induced. But the kinks in the walls exert a frictional force on the liquid and thus produce finite differences in flow velocity which perturb the accretion process. The lines connecting corresponding kinks become zones of weakness which may fracture with the slightest encouragement, such as might be given by small thermoelastic stresses during the final stages in the cooling of the liquid. In short, Vroman suggests that there is a 'rate of shear' between neighbouring stream tubes which produces transform faults parallel to the stream lines at the liquid surface. On the other hand, some transform faults are evidently not related to kinks. In such cases, shear may result not from irregularities in the spreading axis walls but more directly from irregularities (inhomogeneous viscosity, for example) in the intervening liquid itself.

Vroman as good as admits that his interpretation of the Oldenburg–Brune model may be contentious, but as further evidence, points to the Gulf of Aden where transform faults can be seen to connect corresponding kinks in the opposing shelf margins. Moreover, this real example adds a further dimsension to the argument in that the kinks here are old and evidently precede the onset of spreading; they presumably occur where the new spreading axis intersects an old fault system. To this extent, therefore, transform fault locations may be governed by the prespreading history of the area concerned.

But be that as it may, Vroman's analysis clearly applies to the transform faults of the ocean floor. At the same time, however, there are several transcurrent faults in solid continental rocks which, because they happen to terminate at structural features which 'absorb' their motion, must also be termed 'transform faults' according to Wilson's strict definition. In other words, Wilson's definition includes faults of two quite different origins; and it is this ambiguity which has led to the misunderstandings and even "evil consequences".

It would appear to Vroman therefore that the term 'transform fault' is no longer restrictive enough to be useful. The unique character of oceanic 'transform faults' lies not in their transforming properties but in their origin. For this reason, Vroman proposes that the term be abandoned in the oceanic context and replaced instead by the name 'spreading offset'. □

Progress with X rays

from Andrew Fabian and James Pringle

On January 27–29 about 200 astronomers and physicists assembled at the Massachusetts Institute of Technology for a meeting of the High Energy Astrophysics Division of the American Astronomical Society. The subect was X-Ray Astronomy.

THE morning sessions were taken up with invited contributions, several of which were genuine and useful reviews of the invited topics. Too many speakers, however, provided an unbalanced view of the field with particular emphasis on their own achievements. The content of the contributed papers reflected the attitude of the conference organisers to theoretical matters. Of more than 70 short contributions accepted by the organisers, only three were on theoretical topics. This meant that not only was theory underrepresented (and possibly misrepresented), but also that a number of the supposedly observational contributions contained more than their advertised share of theoretical explanation, some of it of dubious quality. Most of the contributed papers were of high quality and several interesting new results were presented.

The body of data on the pulsing X-ray sources is increasing. Most of the periods are in the range of minutes, but R. Lucke (Naval Research Laboratory, Washington DC) reported that the X rays from the source in the small Magellanic cloud, SMC X-1, are pulsed with a period of 0.716 s. The pulsed fraction is about 25% between 1.6 and 7 keV, and possibly variable at lower energies, when data from a rocket flight and the Apollo spacecraft 1.5 yr later are compared. S. Rappaport (MIT) showed preliminary results on the changing period of the pulsed transient source A0535+26, although the observations are not complete or sufficiently extensive to be very useful. G. Fabbiano (Center for Astrophysics, Harvard University) reported the discovery of a glitch, giant by pulsar standards, in the pulse period of Cen X-3. The period changed by about two parts in 10^5 in less than a day. W. Forman (Center for Astrophysics) has analysed some of the later Uhuru data and 23 new weak galactic sources have been found. The 'extended low' in the 35-d cycle of Hercules X-1 contains a phase where pulsed emission is detected at about 30% of the level of the normal 'on-state'. C. Jones (Center for Astrophysics) stated that this feature has been detected every time that this phase has been observed.

Evidence is also growing that sporadic burst behaviour may be a common feature in the X-ray sky. R. D. Belian (Los Alamos Scientific Laboratory) reported that a number of bright X-ray flares of a few minutes duration had been seen by the two Vela 5 satellites, possibly all coming from a region in the constellation of Norma. Several speakers reported transient X-ray behaviour at high galactic latitudes, and G. Jernigan (MIT) presented data on the 10-s flares first seen by the ANS satellite (Grindlay *et al.*, *Int. astron. Union Circular* No. 2879, 1976), from the direction of the globular cluster NGC 6624. A sequence of nine flares has been seen, recurring with an average of 15,718 s, although there appears to be a jitter of up to 1,000 s. Several other flares have been observed near this region of the sky, but directional information excludes the globular cluster.

One striking feature of the meeting was the quality of the spectra obtained from the Ariel 5 satellite. L. Culhane (Mullard Space Science Laboratory, University College London) showed that the spectral data now acquired from clusters of galaxies require more sophisticated models than the simple one-temperature thermal bremsstrahlung fits previously used. Indications of an emission line, possibly due to iron, in the spectrum of the Perseus cluster provided a foretaste of possible abundance analyses in such distant objects. P. J. N. Davison (Mullard Space Science Laboratory) and S. H. Pravdo (Goddard Space Flight Center, Greenbelt) showed clear evidence for iron line emission from the Cassiopeia A supernova remnant, as viewed by the Ariel 5 and OSO-8 satellites, respectively. Another glimpse of the future was provided by P. Gorenstein (Center for Astrophysics). He presented an X-ray picture of the Perseus cluster obtained with an imaging X-ray telescope from a rocket flight lasting a few minutes. The launch of a similar instrument on the satellite HEAO-B must revolutionise the present hazy knowledge of the X-ray sky. □

The brain of the "reeler" mouse

from Shin-Ho Chung

Recent anatomical studies on neurological mutant mice have provided fascinating insights into the sequence of events leading to the formation of the brain. Before making synaptic contacts with one another, young neurones migrate from an inner mitotic layer to their eventual destinations where they form laminar aggregates. Because a defective gene in the mutant mouse disrupts a certain stage of this complex and precisely ordered sequence of events, analysis of the affected brain gives insight into both the action of the mutant gene and the normal mechanisms controlling neurogenesis. In some mutants, the genetic disturbance is confined to a specific region of the brain (News and Views, *Nature*, **257**, 86; 1975), whereas in others, such as the "reeler", the consequences of the defective gene can be noted in a variety of different cortical structures.

The autosomal recessive "reeler" gene arose by spontaneous mutation, and the homozygous mutants have an unsteady gait suggestive of inebriation (Falconer, *J. Genet.*, **50**, 192; 1951). Histological examination has revealed that cellular organisation in the brain is grossly disrupted, especially in the cerebellum, the hippocampus and the neocortex (Meier and Hoag, *J. Neuropathol. exp. Neurol.*, **21**, 649; 1962; Hamburgh, *Dev. Biol.*, **8**, 165; 1963;

Cragg, *Expl. Neurol.*, **49**, 858; 1975). Instead of forming tightly packed layers oriented uniformly towards the cortical surface, cells in the corresponding layers of the "reeler" are very loosely packed and randomly oriented. Caviness and Sidman (*J. comp. Neurol.*, **145**, 85; 1972; *ibid*, **147**, 235; 1973) have noted in the "reeler" a second systematic error in that the loosely packed layers are inverted relative to their positions in the normal brain. In the olfactory cortex, for example, the larger pyramidal cells are below an outer zone of small polymorphic cells, which is the reverse of the order in the normal brain.

The failure to achieve the normal laminar aggregates in the mutant brain is not caused by an abnormality in the time of cell generation or the ability of cells to migrate in their normal sequence (Caviness, *J. comp. Neurol.*, **151**, 113; 1973; Devor *et al.*, *ibid*, **164**, 471; 1975) Autoradiography has shown that each class of cells in the "reeler" undergoes final mitosis at the normal time during embryonic development, and the onset of migration into the cortical plate also proceeds normally. During the terminal phase of migration, however, the mutant gene misdirects morphogenetic events governing cell position. Normally, newly mitosed cells migrate outwards towards their final position, with successive layers being formed by younger cells migrating through previously laid-down strata of older cells. Thus, in the normal animal, the younger the cell the further it has to migrate to its final destination. In the "reeler", this process is reversed. Instead of stopping at the correct location, the first wave of migrating cells advances to the superficial layers, and subsequently generated cells take up deeper positions.

In spite of this eversion of cell layers resulting from aberrant cell migration, subsequent developmental processes appear to proceed normally. Trajectories of the principal axons to their appropriate regions are sometimes altered to seek out remote abnormally positioned cells (Frost and Caviness, *Proc. A. Meeting Soc. Neurosci.*, **4**, 217; 1974). In other regions where the path of growing axons remains unaltered, displaced cells compensate for the misalignment by extending their dendrites further than they normally do, meandering tortuously until the correct input is found (Devor *et al.*, *op. cit.*; Bliss *et al.*, *Brain Res.*, in the press). When examined electrophysiologically, the patterns of cell to cell connectivity are remarkably like the normal, at least in the hippocampus (Bliss and Chung, *Nature*, **252**, 153; 1974). Thus the brain appears sometimes to make use of compensatory mechanisms to establish functional integrity.

That a single gene mutation causes the same sort of cellular disarray in very different parts of the brain suggests that there is a developmental mechanism with a unique molecular basis that is common to them all. It has been widely conjectured that the interaction between migrating young neurones and their input axons from other parts of the brain is crucial for the normal ordering of neuronal networks. In many areas, these input axons reach their appropriate sites coincidentally with or in anticipation of the arrival of their target cells. Such a precisely synchronised afferent–efferent interaction may be at fault in the "reeler". For example, the axons may be delayed in arriving or the young cells themselves may fail to interact properly with their partners. Alternatively, migrating cells may lack a surface property which facilitates aggregation once they have reached their destination. This line of speculation leads to a biochemical search for a missing or altered protein on the cell surface. In this context, it is relevant that cortical cells cultured *in vitro* from "reeler" mice do not aggregate to form the laminar arrays characteristic of cells from normal littermates (DeLong and Sidman, *Dev. Biol.*, **22**, 584; 1970). The sequence of molecular events linking the "reeler" gene to the abnormal pattern of cell migration will undoubtedly be unravelled; and the elucidation of such a process will be a landmark in the understanding of how the brain is formed. □

Deformation within continental plates

from J. Sutton

Now that it is possible to measure the very small movements that occur within continental plates a variety of researches become feasible. As a group of papers read at the fifth international symposium on Recent Crustal Movements (*Tectonophysics*, **29**; 1975) shows, the relations between movement in the Rhineland and the regional stress field produced in Central Europe as a result of the movements in southern Europe and the opening of the Atlantic are now well established. Compressive stress acting on north-west and south-east lines produces slip at rates of 0.05–0.3 mm yr^{-1} in the Rhineland valley. These movements, slow by comparison with those in California or New Zealand, which may be 500–1,000 times as great, are accompanied by shallow earthquakes which occasionally cause damage and deaths as at Basel in 1356 when 300 persons were killed. Ahorner (*Tectonophysics*, **29**, 233; 1975) emphasised how small are the movements which explain the seismicity of the region. At greater depths, flow of rock is important and Illies (*Tectonophysics*, **29**, 251; 1975) described how the mantle has risen for 6 km into the crust below the Rhinegraben rift system. Illies suggested that subcrustal masses displaced by plate collision, induced volcanism and intraplate rifting north of the Alps.

In last week's issue of *Nature* (page 648) Coward discussed another aspect of intraplate tectonics, the possible influence of pre-existing structures on present day movements. He described structures from near Adelaide, an area like southern Germany in that it lies between a plate boundary, the Pacific margin, and an ancient stable area in West Australia. In Australia as in Europe, recent volcanics are virtually absent where very old rocks outcrop (western Australia, Sweden and Finland), but are sporadically distributed through parts of both continents which have been deformed since the Precambrian.

Coward described deformation within a well known belt of folded rocks east and north of Adelaide. He has determined the extent of deformation across a belt some 150 km wide where shearing about 500 Myr ago produced displacements which he estimates to amount to 150 km. Making comparisons with other belts of intensely deformed rock formed by shearing parallel to their length, Coward suggested that the South Australian belt might have extended at least 10 times the length of such displacement. Such a long structure might be expected to affect both upper mantle and crust.

Coward went on to make the point that the Adelaide region is a zone of recent seismic activity and referred to the work of Cleary and Simpson (*Nature*, **230**, 239; 1971), in which they considered the distribution of earthquakes within the Australian continent, and where they discussed three seismic zones within Australia that could be lined up with sections of the Antarctic Ridge where earthquakes occur along offsets. One of these zones which passes near Adelaide and which follows the Ordovician structures mentioned by Coward, continues, Cleary and Simpson suggested, into the most westerly of the offsets in the oceanic ridge recognised by Sykes (*J. Geophys. Res.*, **75**, 5041; 1970) off South-East Australia. The implication is that the present day seismicity follows lines of weakness established within rock deformed much earlier in the geological history of Australia.

Such a relationship may illustrate a

conclusion drawn by Watterson (*Nature*, **235**, 521; 1975), that large scale ductile simple shear belts in which deformation is usually accompanied by a reduction in grain size, may produce a permanent weakness in the crust. Watterson suggested, following work in West Greenland, that diffusion at grain boundaries plays an important role in ductile deformation, and the reduction in grain size with the consequent increase in such boundaries permanently reduces the strength of rock so deformed. The South Australia belt discussed by Coward might have been weakened in this way (also see Dunnet, *Phil. Trans. R. Soc., Lond.*, **A280**, 641; 1976). Coward suggested that the transform fault which offsets the Antarctic ridge south of Adelaide formed where the zone of ductile deformation was crossed in early Tertiary times by the spreading axis from which Australia and Antarctica were to separate. Cleary and Simpson suggested that the pattern of seismicity within Australia—essentially a belt in the south-west, another passing through Adelaide to the centre of the continent and on to the western coast and a third and more diffuse zone running parallel to the Pacific coast from Victoria to southern Queensland—could be accounted for by contrasts between the ancient shield to the west and a relatively "soft" layer beneath south-eastern Australia. They noted evidence suggesting a strongly developed low velocity layer and probably, therefore, a substantial zone of low strength in the upper mantle below south-eastern Australia. The observations of Coward and Watterson indicate that belts of ductile shear which probably extended down to the base of the crust could introduce a further weakness into the lithosphere which would be reflected in the distribution of earthquakes, and which might have influenced the many Tertiary volcanic centres of eastern Australia. □

Spectrin-like proteins

from Dennis Bray

A RESEARCH worker at the Pacific Research Center, Honolulu, tries to prepare tubulin from sea urchin eggs by a standard method and obtains an unexpected result. The extract obtained with glycerol and a chelating agent forms a gel on warming as usual, but this is made of filamentous actin instead of microtubules. The actin is combined with two other proteins, one of which has a molecular weight of 220,000 (Kane, *J. Cell Biol.*, **66**, 305; 1975). A second investigator, by a different ocean, isolates the acrosome of an echinoderm sperm. This is composed of unpolymerised actin and a high molecular weight protein with a similar behaviour on SDS–acrylamide to spectrin—the major structural component of mammalian erythrocyte membranes. The author suggests that the two might be related and, in collaboration, shows that human spectrin and rabbit muscle actin can interact (Tilney, *J. Cell Biol.*, **63**, 349a; 1974; Tilney and Detmers, *J. Cell Biol.*, **66**, 508; 1975).

Within a year two other laboratories find that they too can obtain clear watery extracts which set when warmed. One is from *Acanthamoeba*, the other from rabbit lung macrophages. In both of these the gelled material comprises actin together with one or two other proteins. The purified high molecular weight protein from macrophages binds directly to F-actin and is compared with spectrin (Pollard, *Biophys. J.*, **15**, 124a; 1975; Hartwig and Stossel, *J. biol. Chem.*, **250**, 5659; 1975). A new high molecular weight protein is isolated from smooth muscle. It is a major component and present in kidney, lung, liver and brain, but not skeletal muscle. On immunological evidence it is associated with the fibrillar arrays within cultured cells. It is not myosin and the authors compare it to spectrin and the recently described actin-binding protein of rabbit macrophages (Wang *et al.*, *Proc. natn. Acad. Sci. U.S.A.*, **72**, 4483; 1975).

The casual reader of these papers, trying to keep up with the breathless pace of developments in cell motility, will find them intriguing in content and captivating in style. He will also, unless he is careful, come away with the wrong conclusion. For, although each is distinct and in essential details quite different, there is a strong underlying similarity in approach and interpretation (which has been emphasised in the gloss above). Although it is not explicitly said, there are broad hints from the *dramatis personnae* that there is a moral. The audience is led to make its own conclusions, one version of which is that a high molecular weight protein, similar to spectrin, is present in many kinds of cell and influences the polymerisation of actin. But is this justified? Let us examine the evidence.

To begin with the new proteins are not necessarily the same. They are grouped together under the generic description of 'high molecular weight' but in a way this is misleading. It implies that there is some structure or function that always goes with a polypeptide of more than 200,000 daltons, and we do not know this to be true. There is no reason why the molecular weights of these proteins should not be as precisely compared as any other—but so far this has not been done. At present they could vary by as much as 30,000 daltons: which as evidence of identity is not compelling. Other properties, such as solubility and actin-binding are not quantitative in the present context and, moreover, show differences as well as similarities. Second, these proteins are not spectrin. Of those that have been compared directly on SDS–acrylamide gels, two are clearly heavier and one overlaps in only one of its components. The other obvious test—that of immunological cross-reaction—has so far not been reported, although at least one of the laboratories involved must have all the necessary ingredients. In fact, less than a year ago they used an antibody to spectrin to demonstrate that this protein is absent from most tissues (Painter *et al.*, *Proc. natn. Acad. Sci. U.S.A.*, **72**, 1359; 1975). As to whether the proteins are 'spectrin-like'—the question is as insubstantial as it sounds. Criteria which have been advanced in support of this aetherial quality are high molecular weight (see above), solubility in low ionic strength solutions and 80% ethanol, absence of ATPase activity and failure to form filaments in isotonic buffers. Finally, they are not necessarily involved in actin polymerisation, although it would be of great interest if they were. The possibility arises because all but one of the proteins is extracted together with actin which later polymerises, but the direct evidence, which can only come from tests with purified components, is so far lacking. Therefore, although these new and noteworthy phenomena are clearly related, it is too early to say in what way. In particular, a simple explanation of the kind given above is at present untenable. □

A hundred years ago

THE *Morgenblad* of Christiania states that a singular phenomenon was observed there after a recent violent storm A number of worms were found crawling on the snow, and it was impossible to find the places from which they had issued, everything being frozen in the vicinity. Similar circumstances were reported from several places of Norway.

MANY of our readers, we are sure, will rejoice to hear that a movement is on foot in Germany to abolish the crabbed printed German alphabet and adopt Roman type. We sincerely wish the movement may lead to the desired result, and that it will extend to the still more vexatious written alphabet. from *Nature*, **13** (March 2), 357; 1876.

Suppression of malignancy in human cells

Eric J. Stanbridge

Department of Medical Microbiology, University of California, Irvine, College of Medicine, Irvine, California 92664

Fusion between malignant and normal human cells results in the suppression of malignancy as measured by tumour formation. Malignant–malignant hybrids retain their malignant character. The human cell system has advantages for the study of the control of malignancy.

BOVERI proposed that malignant expression may originate from chromosome imbalance[1] and there is little doubt that the transition from a normal to a malignant cell involves alteration of cellular regulation events, which presumably stem from changes in the genome. Such alterations could conceivably be induced by carcinogens or oncogenic viruses, or arise spontaneously as a result of somatic mutation. It is possible, therefore, that a normal cell becomes malignant on addition of genetic material, as with oncogenic viruses, or because a genetic regulating function becomes inactivated, or because of a combination of these events[2].

Genetic analysis of malignancy (defined here as the ability of cells to proliferate and produce tumours in appropriate hosts) has been facilitated by the ability to hybridise somatic cells from the same or different animal species. The work of Barski, Ephrussi and associates[3–5], using hybrids between highly malignant and normal or low malignant mouse cells, suggested that malignancy was a dominant trait; that is, all hybrid cell populations produced tumour in suitable hosts. Later, however, Harris, Klein and associates[6–12] demonstrated convincingly that malignacy is suppressed in hybrids between malignant and non-malignant or low malignant cells and that malignancy behaves as a recessive trait in these conditions. This disparity in results was later recognised as being due to the loss of chromosomes from the respective hybrid populations[6–13]. Based on extensive chromosome analysis, Harris *et al.*[7–12] proposed that a specific chromosome(s) is involved in the suppression of malignancy, and that when this chromosome(s) is lost the malignant trait is re-expressed. The frequency of production of tumours by hybrids between malignant and normal cells was apparently related to the stability of the chromosomes of the hybrid population.

Most reported genetic analyses of malignancy have involved intraspecific cell fusion, using cells of rodents and other species. I now wish to report the suppression of malignancy in human–human cell hybrids and discuss some of the advantages of this system.

Parent and hybrid cells

The malignant cell populations used were two HeLa variants D98/AH-2 and HBU which lack detectable hypoxanthine guanine phosphoribosyl transferase and thymidine kinase activity, respectively[14,15]. Actively proliferating or senscent diploid human fibroblasts were used as the normal parent populations. An inoculum of 1×10^5 cells of either HeLa parent produces tumours in 100% of inoculated animals, whereas 5×10^7 normal fibroblasts produce no tumours (unpublished).

Fusion of cells was accomplished with inactivated Sendai virus according to Harris and Watkins[16]. The procedures used to select hybrids are outlined in Table 1. Briefly, malignant–malignant hybrids between the two HeLa parents were selected in HAT medium[17]. As the normal diploid population had no genetic markers we used three semiselective techniques. (1) HeLa variants were fused with senescent fibroblasts which had lost their proliferative capacity and hybrids were selected in HAT medium. HeLa parent cells died in HAT and the senescent fibroblasts would not grow in any growth medium; thus only HeLa–fibroblast hybrids survived and replicated. (2) Since it could be argued that normal cells at the end of their proliferative lifespan have accumulated errors that interfere with their normal regulatory functions[18], actively dividing fibroblasts were treated with iodoacetate. Cells treated with iodoacetate die unless rescued by fusion with untreated whole cells (in this case HeLa variants)[19]. Hybrids were again selected in HAT medium. (3) HeLa–normal fibroblast mixtures at a ratio of 10,000 : 1 were fused and hybrids were selected in HAT medium. This semi-selective procedure took advantage of the fact that human fibroblasts divide very slowly at low population densities. Rapidly dividing hybrid clones were detected readily and removed from the few contaminating fibroblasts.

The morphological characteristics of the mass populations of parent and hybrid cells are illustrated in Fig. 1. The malignant–malignant hybrid ESH6 (Fig. 1*d*) retained the epithelial-like morphology of the two parental HeLa variants (Fig. 1*b* and *c*). The only distinguishing features were increased cell size and larger nucleoli. All the malignant–normal hybrids had a morphology intermediate between that of the epithelial-like malignant parent and the fibroblastic normal parent (ESH5 only illustrated in Fig. 1*e*). This intermediate morphology has been retained in mass culture for several months and at least 60 population doublings. Clones were selected, however, which more closely resembled either the fibroblastic or epithelial-like parent (Fig. 1*f*).

In their organisational behaviour the malignant–normal

Table 1 Selection of human cell hybrids

Hybrid designation	Parent cells	Selective medium
ESH2	D98/AH-2 + senescent fibroblast	HAT*
ESH3	D98/AH-2 – iodoacetate-treated fibroblast	HAT
ESH5	D98/AH-2 + proliferating fibroblast 10,000:1 ratio	HAT
ESH6	D98/AH-2 + HBU	HAT

* HAT medium is Eagle's basal medium supplemented with 10% foetal calf serum, 1×10^{-4} M hypoxanthine, 4×10^{-7} M aminopterin, and 1.6×10^{-5} M thymidine.

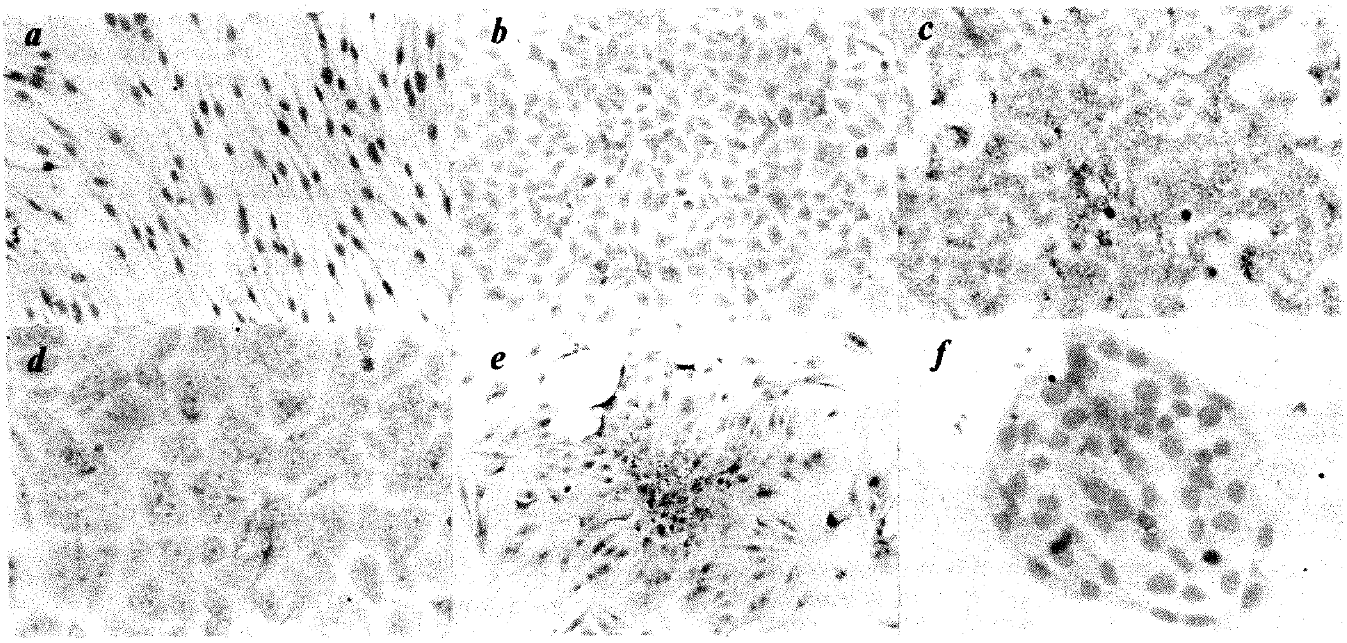

Fig. 1 Morphology of parent and hybrid cell populations. *a*, Normal fibroblast; *b*, malignant parent D98/AH-2; *c*, malignant parent HBU; *d*, malignant–malignant parent ESH6. The hybrid retains the epithelial-like morphology of parent cells shown in *b* and *c*. *e*, Malignant–normal hybrid ESH5. Morphology is intermediate between that of the parent cells shown in *a* and *b*. *f*, Clone of malignant–normal hybrid ESH3. Cells more closely resemble the malignant parent D98/AH-2.

hybrids more closely approximated that of the malignant parent cells. There seemed to be no density-dependent inhibition of division and the cells grew to high population densities (Fig. 2). In mass culture or in clones, however, the cells generally tended to be loosely packed and aligned themselves on their long parallel axes. Studies to be reported elsewhere have shown that the sensitivity of these hybrids to serum growth factors is intermediate between that of the malignant and normal parent cells. The malignant–malignant hybrids behaved in all respects like their malignant parent cells.

Chromosome constitution and assay for malignancy

Chromosome analyses of parental and hybrid cells are presented in Table 2. All the normal fibroblast cell strains used had a stable diploid karyotype. D98/AH-2 and HBU both had a relatively narrow modal distribution with means of 61 and 57, respectively (Fig. 3). The earliest time when various hybrids could be analysed was 4 weeks after fusion. In all cases, the mean chromosome constitution was slightly less than the expected mean calculated for the retention of the total complement of chromosomes from both parents. Thus, as in other animal cell systems[20], there seemed to be early loss of chromosomes from hybrids. Whether the loss was random or non-random with respect to specific chromosomes has not been determined. After the early segregation events the chromosome content of the hybrids stabilised. We have observed very little loss of chromosomes in 5 months, during which the hybrid populations underwent at least 70 doublings (see, for example, ESH6 data in Table 2 and Fig. 4).

A problem when human cells are used for analysing malignancy is to find a suitable host in which to test the malignant potential of such cells. We have reported that human and animal malignant cell lines and biopsied human tumour material established and produced tumours in immunosuppressed mice, whereas normal cells failed to proliferate[21,22]. We also found that when mixtures of malignant and normal cells were inoculated, only malignant cells proliferated to form a tumour whereas the normal cells failed to survive. We have purified malignant cell populations from mixtures of normal and malignant cells by this procedure[22]. We used three types of immunosuppressed

Table 2 Chromosome analysis of human parent cells and hybrid derivatives

Cell type	Range Expected*	Range Observed	Mean Expected*	Mean Observed
Parent				
Normal fibroblasts	46	45–47	46	46
HeLa D98/AH-2	—	50–64	—	61
HeLa HBU	—	47–66	—	57
Malignant–normal hybrids				
ESH2 6 weeks after fusion	96–110	90–107	107	101
ESH3 4 weeks after fusion	96–110	94–106	107	104
ESH5 4 weeks after fusion	96–110	95–105	107	102
Malignant–malignant hybrid ESH6				
4 weeks after fusion	97–130	95–124	118	110
20 weeks after fusion	97–130	90–114	118	106
ESH6T 20 weeks after fusion†	97–130	95–118	118	107

Counts were based on at least 30 metaphase spreads.

* Estimated range and mean assume the presence of a full complement of chromosomes from the respective parent cells.

† Includes a total of 13 weeks in the mouse followed by re-establishment of tumour cells *in vitro*.

mice in the study reported here, all of which gave comparable results. The mice were (1) thymectomised neonatally and treated with antithymocyte serum; (2) weanlings that had been thymectomised, whole-body irradiated and reconstituted within 2 d with bone marrow or foetal liver cells[23]; and (3) nude mice that require no immunosuppressive treatment because they lack a functional thymus and cannot mount a significant cell-mediated response against foreign antigens[24].

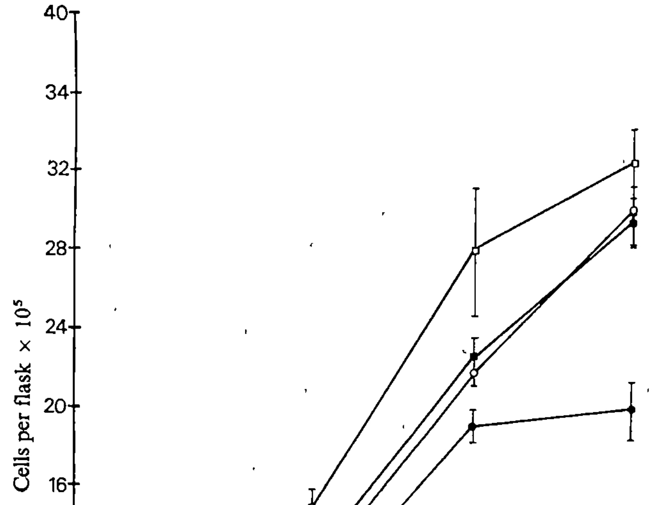
The results of the malignancy assays are presented in Table 3. Clearly only the malignant–malignant hybrid ESH6 retained its malignant properties. The fact that comparable cell numbers of ESH6 and the parent HeLa variants formed tumours is an indication that there was no partial loss of malignancy in the ESH6 hybrid. This was further substantiated by comparing the karyotypes of cells re-established *in vitro* from ESH6 tumours and ESH6 cells grown only *in vitro* for the same time (Fig. 4). The karyological profiles in Fig 3*b* and *c* are very similar, indicating that there was no selection *in vivo* for a malignant subpopulation of the total ESH6 mass culture.

The suppression of malignancy in the malignant–normal cell hybrids seemed to be complete; as many as 1×10^7 cells inoculated failed to produce a tumour. Periodic monitoring of these cell populations during 6 months has yet to reveal a single tumour. It should be emphasised that only mass cultures have been tested. We are examining the malignant traits of a series of clones of different morphologies derived from the malignant–normal hybrid populations.

Malignancy as a recessive trait

The studies reported here clearly demonstrate that malignancy behaves as a recessive trait in human cells, and support the findings of Harris *et al.* who demonstrated suppression of malignancy in mouse cell hybrids. Because of the preliminary nature of this report, it is not possible to conclude whether suppression is related to a specific genetic defect in the malignant cell which is made good by complementation with a normal cell[8] or to a balance of chromosomes carrying information for expression or suppression of malignancy as proposed by Sachs and others[25–27].

Fig. 2 Growth curves of parent and hybrid cell populations. 2.5×10^5 cells were inoculated into T-25 flasks (Falcon). Triplicate samples were taken at each time and counted in a haemocytometer. ●, WI-38; □, D98/AH-2; ○, ESH5; ■, ESH3.



Weiner *et al.*[10,12] found that several different malignant mouse cell lines failed to complement when fused together. This startling finding seems to suggest that malignancy in different cancer cells is due to a defect at the same genetic locus. My studies reported here do not help to clarify this intriguing possibility because the two HeLa variants used for the malignant–malignant fusion presumably originated from the same cancerous clone.

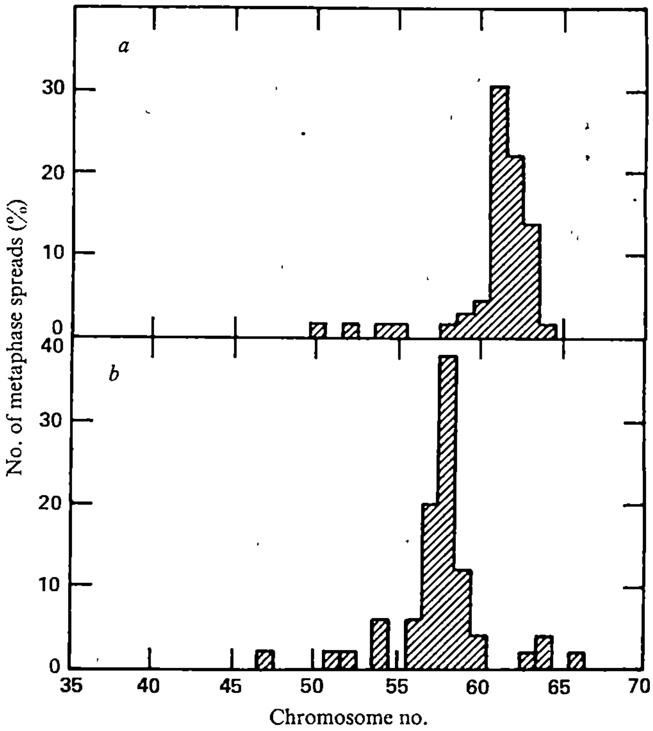


Fig. 3 Modal chromosome number of D98/AH-2 and HBU. *a*, D98/AH-2; *b*, HBU. At least 50 metaphase spreads were counted for each determination.

My results are at variance with those of Croce *et al.*[28] who reported that hybrids between SV40-transformed human cells and mouse macrophages retain the expression of SV40 tumour (T) antigen and are tumorigenic as long as the human C7 chromosome is retained in the hybrid. Loss of C7 was correlated with loss of T antigen and loss of tumorigenicity. Their findings indicate that the SV40-transformed phenotype is under positive control[29]. The fundamental difference in our results may be explained on the basis that Croce *et al.* used human–mouse interspecific hybrids which may involve different regulatory factors. Also, the malignant human cells were transformed by an oncogenic DNA virus, SV40. The viral genetic information necessary for this transformation event may be able to supersede the regulatory control exerted by normal gene(s) which are necessary for the suppression of malignancy.

My studies with malignant–normal hybrids indicate that senescent normal fibroblasts can be rescued by fusion with malignant HeLa cells and attain immortality. Thus senescence of human fibroblasts in culture[30,31] behaves as a recessive trait when fused with HeLa cells, a phenomenon

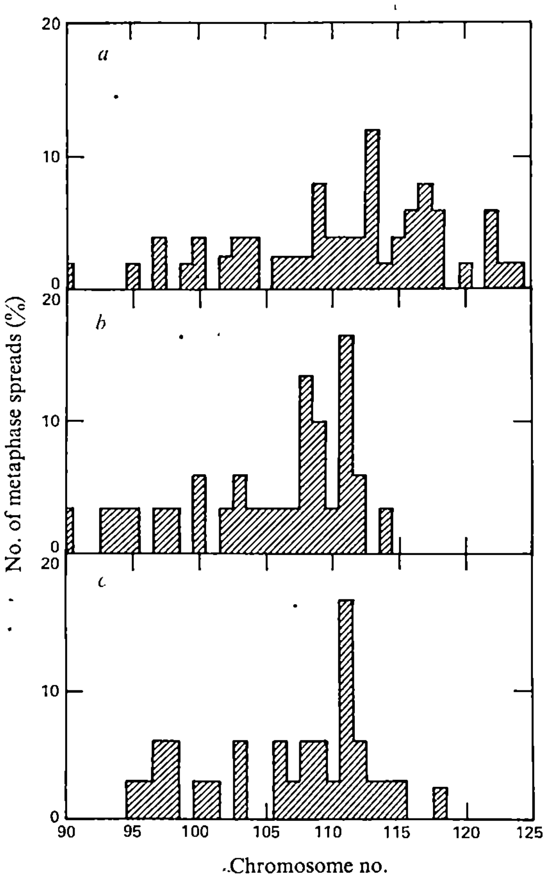

Fig. 4 Modal chromosome number of ESH6 at various times after selection. *a*, 4 weeks after fusion; *b*, 20 weeks after fusion; *c*, 20 weeks after fusion, including 13 weeks in a mouse. At least 50 metaphase spreads were counted for each determination

noted by others[32,33]. But although the malignant–normal hybrids can proliferate indefinitely, they are not malignant. The use of these human–human hybrids may provide a method whereby transformation events can be separated from the event(s) leading to malignancy.

The human–human hybrid cell system has several advantages over the murine or interspecific systems for the analysis of malignancy. (1) Most normal diploid mouse cell strains spontaneously transform into heteroploid malignant cell lines, thus normality is not a stable characteristic of mouse cells grown *in vitro*. Normal human fibroblasts have a stable diploid karyotype and a limited *in vitro* lifespan[31], and have not been shown to transform spontaneously. (2) Many hybrids between malignant and normal mouse cells retain their malignancy when injected into animals[7]. This apparent lack of suppression of malignancy has been shown to be due to rapid chromosome segregation from the hybrid cells. The rapidity of this chromosome loss, in addition to making the initial premise of suppression of malignancy hard to evaluate, renders the identification of specific chromosome(s) controlling this expression extremely arduous. My findings indicate that human cell hybrids have very stable chromosome constitutions which should render the isolation and characterisation of malignant variants easier. (3) Most, if not all, mouse cells contain endogenous RNA tumour virus genomes[35,36], but claims for the presence of human RNA tumour viruses in human cell lines[37,38] have been unsubstantiated and probably represent contamination by viruses from other animal hosts[39]. (4) Certain claims for the suppression of malignancy in mouse cell hybrids have been shown to be due to histoincompatibiity rather than a genetic regulatory element[40] Because human cells are tested in a xenogeneic host, the question of histoincompatibility becomes a moot point since even malignant control cells would be rejected in inadequate immunosuppressive conditions.

Table 3 Assay for malignancy of human parent and hybrid cell populations

Cell lines	No. of cells inoculated into each mouse	No. of tumours/No. inoculated Tx + ATS*	T⁻B⁺†	Nude‡
D98/AH-2	8×10^5	5/6	10/10	6/6
HBU	8×10^5	6/6	9/10	6/6
Normal fibroblast	1×10^7	0/10	0/10	ND
ESH2	1×10^7	0/10	ND	0/6
ESH3	1×10^7	0/10	ND	0/6
ESH5	1×10^7	0/10	ND	0/6
ESH6	8×10^5	5/6	8/10	6/6

ND, Not done.

* Neonatal thymectomy plus antithymocyte serum.

† Thymectomy, whole-body irradiation followed by bone marrow reconstitution.

‡ Athymic nude mice, no immunosuppressive treatment.

Many other malignant–normal and malignant–malignant cell combinations must be tested before we can determine whether the suppression of malignancy reported here is a general phenomenon of human somatic cells If this is the case, it should lead to significant advances in the study of control of malignant expression in humans. It remains to be seen whether non-malignant hybrids derived from cancer cells retain the antigenic identity of their malignant parent. If so, they may be useful in cancer immunotherapy This possibility is strengthened by the fact that unlike mouse cells, human hybrids are chromosomally stable and seem to have their malignant phenotype completely suppressed.

I thank Maria Li and Mark Feinerman for technical assistance I thank Drs J. Schneider, E. Schneider, L. Hayflick and W Munyon for cell lines. These studies were supported by grants from the American Cancer Society and National Institutes of Health.

Directed lipid flow in cell membranes

Mark S. Bretscher

MRC Laboratory of Molecular Biology, Hills Road, Cambridge CB2 2QH, UK

A continuous and rapid oriented flow of lipid molecules in eukaryotic plasma membranes may explain capping of surface antigens.

MEMBRANES of eukaryotic cells exist in several discrete compartments[1]. These include the rough and smooth endoplasmic reticula, Golgi apparatus, the nuclear and plasma membranes and various cytoplasmic vesicles. How these membranes are related to one another is unclear, but structures inside the cell must be responsible for maintaining the high degree of organisation observed in cell sections. Any cellular features or processes which display a unique polar property may tell something about the basis for this organisation. One such process is the capping phenomenon described by Taylor *et al.*[2] in lymphocytes and observed by several groups in other cells[3–9].

Capping of antigens in the plasma membrane occurs when a particular surface antigen is cross linked, usually by specific antibody; the redistribution of these cross-linked antigens can be visualised using fluorescent antibodies. Two types of redistribution are found: the antigens form patches (which are just two-dimensional precipitates in the plane of the fluid membrane[9]) and are seen as discrete fluorescent areas on the cell surface. These patches may then form a cap, seen as a fluorescent crescent which in B lymphocytes occur at the end of the cell remote from the nucleus. Capping, unlike patching, requires metabolic energy and is thus an active process. In lymphocytes, where it has been most extensively studied, capping can be prevented by a combination of drugs which are believed to disrupt or inactivate microtubules and microfilaments—colchicine and cytochalasin B (ref. 10). Furthermore, once the cap has formed, addition of these drugs may enable it to disperse[10]. The main requirement, however, for molecules to be capped is that they be cross linked[2,7,11]; other antigens, or antigens labelled with Fab antibody fragments, do not patch, nor do they cap.

The mechanism of cap formation has remained unclear, although it is generally believed that the surface antigens, once cross linked from outside the cell, are moved to one pole of the cell by cytoplasmic structures which may include microtubules and/or microfilaments[12–15]. Interpretations of capping along these lines become difficult to understand when one tries to consider them at a molecular level. How do the cytoplasmic components recognise that surface antigens are cross linked? Any simple explanation would seem to require that the surface antigens span the cell bilayer, a situation for which there are several precedents[16–19]. There then exist at least two plausible mechanisms for capping: either cytoplasmic components recognise a "new" distribution of those ends of the surface antigens on the cytoplasmic side of the membrane, and somehow select these to be capped. This mechanism is hard to contemplate as the membrane is a liquid and these surface antigens must frequently come close to each other due to Brownian motion. Alternatively, surface antigens could all be allosteric proteins; when cross linked from outside the cell, a conformational change of that part of the antigen on the cytoplasmic side of the membrane could be recognised as "new" by cytoplasmic components, and lead to the selective movement of these molecules to the pole of the cell. There are several difficulties with this hypothesis: (1) Fab fragments which bind to surface antigens might be expected to cause a conformational change—yet capping does not result[2]; (2) apparently any surface antigen can be capped, which would imply a bewildering amount of recognition by cytoplasmic components; (3) lectins, which bind to sugar residues on surface glycoproteins, will cause capping of those molecules to which they bind[7,11], yet it seems unlikely that binding lectins to the carbohydrate portion of a protein would change its conformation.

Here I present a radically different interpretation of the capping process which may have interesting implications for other cellular processes.

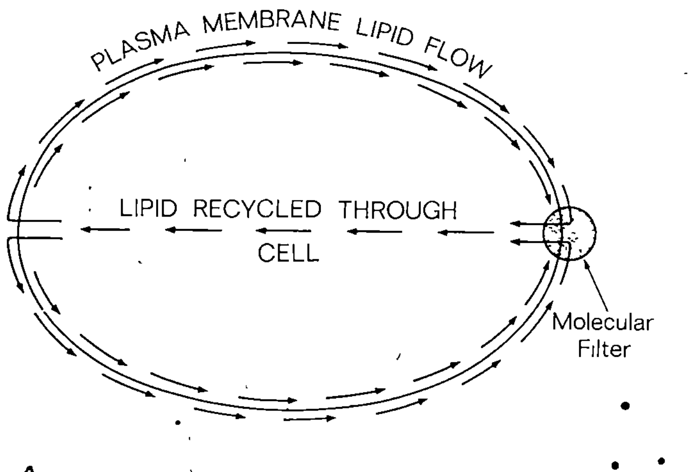
Continuous lipid flow in cell membranes

The hypothesis I wish to put forward is that there is a rapid, continual and oriented flow of lipid molecules in the plasma membranes of motile eukaryotic cells. Lipid molecules are inserted into the plasma membrane from the cytoplasm at certain sites on the cell and are resorbed back into the cytoplasm at different sites on the cell. This is shown schematically for a lymphocyte, in which there seems to be a lipid flow from one end of the cell to the other, in Fig. 1. Addition and removal of lipids presumably occurs through vesicles (see below). Other molecules associated with the plasma membrane do not cycle in this way: they remain approximately randomly distributed in the membrane under the influence of Brownian motion. The precise distribution of membrane proteins may not be quite random: the actual distribution will depend on many factors, including how fast the lipid flow is, the diffusion coefficient of the molecule in question and the length of the cell. But if a very large molecule is lodged in the plasma membrane, its rate of lateral diffusion may not overcome the lipid flow: it will then be swept to that site on the cell surface at which lipid resorption occurs. An example of such a large "molecule" is a set of cross-linked surface antigens. The individual antigens are no longer free to diffuse independently of one another and, if the patch is large enough, they will be carried along *en masse* by the lipid flow to the pole of the cell and will be seen as a cap.

Quantitative aspects of lipid flow

The idea that membranes flow is not new[20–23]. Ingram[24] and Abercrombie *et al.*[25] have observed the directed movement of large particles (such as carbon black) on the dorsal surface of fibroblasts from their ruffling edges to an area over their nuclei. This was interpreted as showing that the surface membrane of

Fig. 1 Schematic diagram of recycling of lipids in a lymphocyte



R386

these cells is flowing. The difference between their interpretation and my proposal is that I believe there is a net flow which is largely confined to lipid molecules—and not membrane recycling which includes all the membrane proteins. In the case of lymphocytes, it seems that once antigens have been capped, their reappearance on the cell surface takes a long time (compared with capping) and requires protein synthesis[26]. In other words, capping does not seem to result from the recycling of surface membrane as a whole: if rapid membrane recycling exists, it must be limited to lipid molecules. Presumably the same holds for fibroblasts.

The rate of movement of particles on fibroblasts has been measured and is about 3 μm min^{-1} (refs 22 and 25). If a similar rate of lipid flow exists on a lymphocyte, then the time taken to sweep a cross-linked antigen on to one half of the cell (which is about 10 μm in diameter) would be about 2 min. This is roughly the time at which the first caps are seen to form on lymphocytes[2], and suggests that the rate of lipid flow in lymphocytes and fibroblasts is similar.

If a lipid flow rate of 3 μm min^{-1} exists across a flat lipid bilayer sheet, we can estimate how this will affect the distribution of individual protein molecules lodged in the membrane. The rate of lateral diffusion of rhodopsin molecules in frog retinal disk membranes has been measured by Poo and Cone[27]: these proteins diffuse at a rate of about 10 μm in 1 min. If the viscosities in disk and plasma membranes are similar, the lateral diffusion of a protein the size of rhodopsin will effectively win out over a lipid flow of 3 μm min^{-1}. There will, however, be a slight difference in concentration of antigens at the two ends of the stream. For a one-dimensional case in an equilibrium situation, the concentrations of a protein (C_a, C_b; a is upstream of b) are given by $C_a/C_b = \exp(-FL/D)$, where F is the flow rate, L is the distance between points a and b in the direction of the stream and D is the diffusion coefficient of the protein. For a flow rate of 3 μm min^{-1}, a diffusion coefficient of 4×10^{-9} cm^2 s^{-1} (for rhodopsin in disk membranes at 20 °C, ref. 27) and L of 10 μm (roughly the length of a lymphocyte), we get $C_b/C_a \sim 3$. Of course, the lymphocyte is a roundish cell so that F cannot be uniform over its surface and the parameters taken for rhodopsin may not be applicable here, especially as the viscosity in the plasma membrane of a cell growing at 37 °C may be somewhat lower than in the frog retinal disk membrane[28]. It is therefore difficult to predict just how great C_b/C_a would be. But if the protein molecule were made much larger, its diffusion coefficient (which is not easily estimated[29]) would decrease and could thereby change C_b/C_a by a large factor because of the exponential relationship between D and C_b/C_a. In other words, as a protein aggregate grows in size, C_b/C_a may increase sufficiently that a patch would be seen to cap.

These calculations simply show that, given the rather crude assumptions made, a lipid flow of a few μm min^{-1} could explain the capping process. They also indicate that surface antigens, or single proteins embedded in the bilayer, might not be quite uniformly distributed over a cell. This might be visible as a non-uniform distribution of particles in the freeze-fracture plane of a large cell, such as a fibroblast.

Implications of lipid flow

The most obvious prediction this model makes is that lipid molecules will not stay in the plasma membrane for long periods. More usefully, it predicts that a surface antigen need not communicate in any way with the cytoplasm to be swept along and thus be capped. Thus, phospholipids or glycolipids—molecules which by their nature only extend half way through the bilayer—should be able to be capped. The most direct way to test this would be to insert a new glycolipid into the bilayer of a cell not possessing that antigenic determinant, and see if that can be capped. This experiment cannot be unambiguous at present since there is no known way of showing that the added glycolipid is indeed properly inserted into the host cell's bilayer, rather than adhering to surface protein. Nevertheless, when such an experiment is attempted[30], the added glycolipid does cap. A better experiment might be to see if antibodies which bind specifically to phospholipids[31] could lead to capping.

There then remain two additional questions I should like to consider. If only lipids are resorbed into the cell, how is this done without concomitant resorption of plasma membrane proteins? A molecular filter would seem to be needed—a special vesicle designed to exclude membrane proteins. The other question is, where do the lipids go after internalisation? If they are fed into the internal membrane pool—the Golgi apparatus or endoplasmic reticulum—how is it that plasma membranes contain high levels of cholesterol (approaching equimolarity with phospholipids), whereas those membranes within the cell contain a low level of cholesterol which is only a fraction of that found in the plasma membrane[32]. In other words, the hypothetical filter I have in mind would remove not only plasma membrane proteins but might also remove much of the cholesterol. A possible candidate for this is the "coated vesicle", which is found in many cell types[33–39] and contains only one major protein, "clathrin"[38,39]. These vesicles are believed to be responsible for resorption of plasma membrane in nerve endings after stimulation of the neuromuscular junction[40]. They contain a small lipid vesicle inside a lattice network of clathrin[38,39]; as the lipid vesicle buds inwards from the plasma membrane, clathrin can be seen to coat the vesicle[33–35,38] and in so doing, might clear away other proteins to give a fairly pure lipid vesicle inside its coat.

Microtubules and microfilaments seem to be implicated in capping and thus in the recycling of phospholipids. How they do so is unclear, although there are hints that one of the functions of microtubules may be to shunt vesicles around[41–44], and microfilaments seem to be needed for various membrane movements such as ruffling[45,46]. The present arguments imply that somehow these fibrillar elements are involved in the directed movement of membranes within the cell.

In conclusion the polar property displayed by many eukaryotic cells in the capping process or in the movement of particles adsorbed on their surfaces can be explained at the molecular level by an oriented and continuous flow of lipid molecules in the cells' plasma membranes. There must be a source and a sink for this lipid flow; the sink is likely to require a molecular filter which removes most of the membrane proteins and perhaps cholesterol from the internalised membrane. This specific resorption process may be achieved by coated vesicles.

I thank Dr Graeme Mitchison for assistance with some of the estimates made here.

Jurassic igneous rocks of the Forties Field

F. G. F. Gibb & R. Kanaris-Sotiriou

Department of Geology, University of Sheffield, Mappin Street, St George's Square, Sheffield S1 3JD, UK

Middle Jurassic volcanic rocks unexpectedly encountered during North Sea drilling operations seem to have oceanic affinities. Though this finding may seem surprising in a suite situated in a continental basin, it can be explained using a plate tectonic model. According to the model, the volcanism developed along a line of incipient sub-crustal rifting during the early opening of the Atlantic. Before crustal splitting occurred, however, the spreading axis migrated westwards and the well documented volcanism of the North-west Tertiary Igneous Province developed.

DRILLING operations in the Forties and Piper areas of the North Sea have unexpectedly encountered basic igneous rocks which seem to be part of a thick volcanic sequence of Middle Jurassic age[1]. As such, they represent a new and previously unsuspected igneous province in north-western Europe. The lavas, which have a maximum thickness of over 740 m, are porphyritic olivine basalts which "tend towards an alkaline affinity"[1]. We report here on the whole-rock geochemistry of the lavas; our preliminary findings are based on material from the Forties Field wells 21/9–1 and 21/10–1.

The material from well 21/9–1 represents a 17-m vertical section comprising (in descending order):

(1) The lowermost 0.65 m of a porphyritic basalt flow (the whole of which is probably not much thicker).
(2) A 2.75-m thick flow of porphyritic vesicular basalt with a brecciated upper surface.
(3) 12.6 m of porphyritic basalt which could be a single flow or as many as three separate flows.
(4) The top metre of a porphyritic vesicular basalt flow of indeterminate thickness.

The section represented by the material from well 21/10–1 is comparatively short, comprising 1 m of porphyritic basalt on top of 0.5 m of porphyritic vesicular basalt, which in turn lies on top of sediments. The change from non- or sparsely vesicular basalt to markedly vesicular basalt may correspond to the junction between two flows, but the exact relationship is obscured by the altered nature of the rocks and the fact that just above the transition the porphyritic basalt is intruded by a 0.5-m thick sheet of vesicular 'dolerite' with chilled upper and lower margins.

Petrography

All of the flows represented in the well 21/9–1 section contain abundant, large phenocrysts of clinopyroxene (Cpx) and pseudomorphs after olivine (Ol). Phenocrysts of plagioclase are present in varying amounts but are much smaller. The pyroxene is virtually unaltered, but the olivine is almost entirely replaced by serpentine, chlorite and carbonate and often considerable amounts of iron oxide. The lavas from well 21/10–1 also contain phenocrysts of clinopyroxene and pseudomorphs after olivine, but differ from those of well 21/9–1 in apparently lacking the plagioclase microphenocrysts and in containing abundant basaltic hornblende. The pyroxene phenocrysts in the lavas from both wells vary in size, but can be a few centimetres across, and exhibit spectacular, discontinuous, oscillatory and sectoral zoning. The mineral chemistry of the pyroxenes is still under investigation, but it is evident from their optical properties that they are augites with significant contents of Al and Ti, and are thus typical of the phenocrysts found in basic igneous rocks of alkaline affinity. This, together with the obviously high original olivine content, led Howitt *et al.*[1] to deduce that the rocks were probably alkali olivine basalts.

The groundmass of all the lavas is fine grained and very altered, but small plagioclase laths or microlites, minute augite crystals and magnetite/haematite grains can be discerned among the chlorite and other alteration products. As is typical of alkaline basaltic rocks[2,3], all of the specimens are more or less altered, particularly with regard to oxidation, which is most marked towards the tops of the flows. The top of the thickest flow in the well 21/9–1 section is so oxidised that it consists almost entirely of haematite. This red 'bole' is suggestive of subaerial weathering and seems to be incompatible with suggestions[4] that the volcanics were subaqueous.

Although the indications are that the North Sea igneous rocks are of alkaline affinity it is difficult to be more precise on petrographic grounds, largely because of their altered nature, so we have investigated the whole-rock geochemistry. A number of samples from each of the flows represented in the two well sections have been analysed for major and trace elements (by a combination of X-ray fluorescence (XRF) and chemical methods) in order to study the systematic chemical variations which exist within and between individual flows (Table 1). More detailed geochemistry will be described elsewhere.

Whole-rock geochemistry

The classification of volcanic rocks on the basis of normative mineralogy becomes increasingly difficult and unsatisfactory as the rocks become more altered. Various methods have been suggested to overcome the effects of alteration, especially oxidation[5–8]. We have followed Thompson *et al.*[9] in reducing the Fe_2O_3 content to 1.5% or 2.0% (for total alkali contents of less than 4% and less than 7%, respectively) before calculating the norm. The representative analyses presented in Table 1 consist of the average compositions of two of the thickest flows from well 21/9–1 (9B, 9C), a typical specimen of lava from well 21/10–1 (11211) and the two samples from well 21/9–1 with the highest and lowest K_2O contents of those so far determined (3395.25, and 3396.5). All are nepheline normative except for the sample with the lowest K_2O content from well 21/9–1, which is only just hypersthene normative. Though this is consistent with alkali olivine basalt affinity, the altered state of the rocks does not permit unequivocal interpretation.

Another method of identifying the parentage of basic

volcanics is to plot them on a total alkalis against SiO_2 diagram (Fig. 1). It is evident that on this criterion the North Sea volcanics are, on the whole, mildly alkaline, with a few more strongly alkaline varieties.

The problems of correctly classifying altered volcanic rocks, especially alkaline types, has been discussed by a number of authors[3,10,11], particularly with regard to identifying their tectonic setting. Probably the most satisfactory method of typifying the North Sea basalts is the TiO_2 against Zr/P_2O_5 plot of Floyd and Winchester[11] which uses 'immobile' elements, thus minimising the effects of any subsequent alteration of the rocks. The North Sea lavas (Fig. 2) fall within the fields of both continental and oceanic alkali basalts and lie outside the fields of tholeiitic basalts. In addition, the suite exhibits the vertical trend characteristic[11] of alkali basalts and atypical of saturated volcanics. Trace element contents, particularly Sr and Rb are also consistent with alkali basalt parentage. The Sr and Rb contents are of the order of 600 p.p.m. and 20 p.p.m. respectively. Typical tholeiites contain less than 150 p.p.m. Sr and only a few p.p.m. Rb, whereas alkali basalts can contain up to 1,000 p.p.m. Sr and 100 p.p.m. Rb (refs 12 and 13). It therefore seems clear that the analysed Jurassic lavas from the Forties Field are mildly undersaturated rocks of alkali olivine basalt parentage.

Geochemical discrimination between alkali basalts from continental and oceanic tectonic settings is notoriously difficult (see Carmichael *et al.*[13]). One possible method is to use the TiO_2–K_2O–P_2O_5 ternary plot proposed by Pearce *et al.*[14]; but attempts to apply this method result in the analyses plotting along the boundary between the two types. Direct comparison of the North Sea lavas with other alkali basalts in terms of major elements reveals that individual analyses can be matched to a remarkable degree with basalts from such diverse tectonic settings as the East African Rift Valley[15,16] and Hawaii[17]. Surprisingly, in view of the continental nature of the North Sea crust, the lavas seem to have more in common with oceanic alkali basalts than with those from continental settings. Indeed, in many geochemical respects, the alkali basalts from Hawaii seem to be the most directly comparable with those from the North Sea. With regard to this occurrence of alkali olivine basalts apparently having oceanic affinities within a continental plate, it is worth considering the structure of the North Sea Basin at the time of the volcanism and its possible relationship to the large scale tectonic pattern.

Plate tectonic development

During the Jurassic the North Sea area was dominated by a series of major troughs, or graben. The volcanic rocks occur close to the confluence of three of these—the Witch Ground, Viking and Central Graben[1]. It has been suggested[18] that this trough system may have originated in Hercynian times but if so there seems little doubt that it was being reactivated during the Jurassic[4]. Tectonically, therefore, the best analogy for the Jurassic North Sea may be the East African Rift Valley where a comparable rift system is developing on continental crust, and the similarities between individual volcanic rocks of the two areas lends some support to this possibility.

The general north–south rifting in the North Sea area during the Jurassic could be connected with the subduction of the Tethys plate below the Russian Platform far to the south-east[4], or, alternatively, it could simply be a result of the stress system developed at continental margins because of differences in crustal density[19]. Neither, however, could account for the thinning[18] of the continental crust, or the occurrence of the igneous rocks, both of which are consistent with high heat flow in the underlying asthenosphere. Whiteman *et al.*[18] have suggested that the North Sea rift systems may be failed arms of plume-generated rrr trilete junctions, but they attribute the rift system in the Forties area to uplift caused by mantle plume activity during the late Carboniferous and early Permian. Consequently, though mantle plume activity could certainly account for igneous activity, the timing is inconsistent with the Middle Jurassic age of the North Sea volcanic rocks and, in any case, there seems to be little evidence other than the rift systems to support the suggestion that plume activity occurred beneath the North Sea area from the Carboniferous to the Cainozoic.

We suggest the following model based on a general consideration of Laurasian global tectonics at the time of volcanism.

During the Lower Jurassic (approximately 180 Myr BP) the Atlantic began to open south of the Azores[20,21]. The spreading axis is generally regarded as being truncated by a transform plate margin running from south of Spain to south of Newfoundland. By the beginning of the Cretaceous the mid-Atlantic spreading axis extended much further north, "possibly as far as the western approaches to the English Channel"[21], and it seems reasonable to presume that this northward extension existed in an embryonic form during the Jurassic. When it matured into

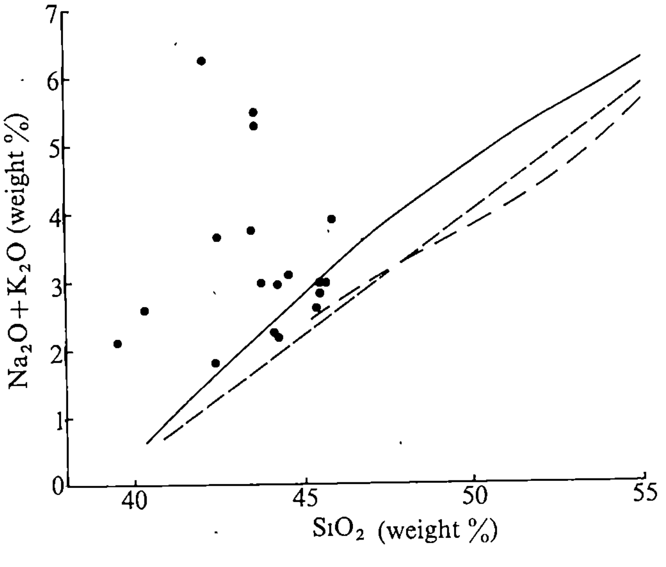

Fig. 1 Total alkalis against SiO_2 plot for North Sea volcanic rocks. Lines denote the division between alkaline and sub-alkaline types: ———, after Irvine and Baragar[6]; — — — —, after Macdonald and Katsura[17]; — · — · —, after Kuno[2].

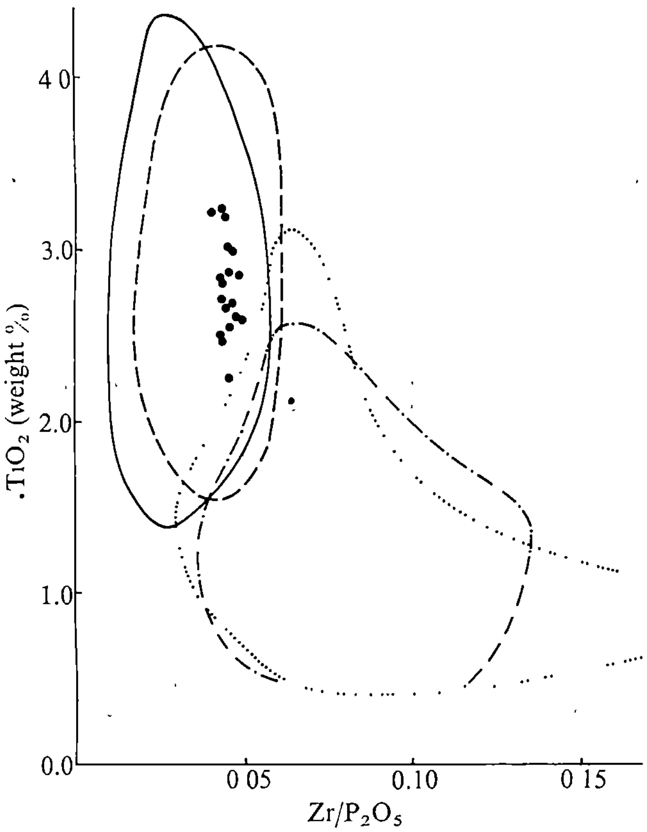

Fig. 2 TiO_2 against Zr/P_2O_5 plot for North Sea volcanic rocks. Field boundaries after Floyd and Winchester[11]: ———, continental alkali basalts; — — — —, oceanic alkali basalts; · · · ·, continental tholeiitic basalts; — · — . —, oceanic tholeiitic basalts.

an active spreading axis this northward extension could have terminated[21] at the edge of the continental crust against the Bay of Biscay–Labrador Sea transform fault. It is generally believed that no spreading axis existed north of this transform fault at least until the late Cretaceous, when it emerged west of the UK continental shelf and offset along the transform fault. If the embryonic spreading axis (or the underlying feature which gave rise to it) to the west of Spain in Jurassic times were projected northwards below the continental crust, it would pass underneath the North Sea, and it could be significant that the North Sea volcanic rocks occur at the intersection of this extension with the Fair Isle–Elbe wrench fault[4]. Since any offset along the Bay of Biscay–Labrador Sea transform fault would be insignificant until new oceanic crust began to be generated by the mature spreading axis, such a linear projection does not seem unreasonable. What is proposed, therefore, is that from its inception during, or possibly before, the Middle Jurassic, the spreading axis north of the Azores (or its underlying parent feature) extended northwards beneath the continental crust at least as far as the North Sea, and possibly as far as the hinge point for the opening of the central Atlantic which was situated in south Norway[20,21]. Activity along this northward extension was insufficient to produce a splitting of the crust but enough to contribute to an approximately east–west tensional regime with consequent thinning of the crust and reactivation of rifting in the North Sea area. Though little or no new crust was generated along this extension (the spreading axis was only just becoming established west of Spain), the uprise of heat in the asthenosphere below the North Sea could have generated the volcanic rocks by the partial fusion of the mantle, with the ensuing magma reaching the surface through the thinned crust along lines of structural weakness—the Fair Isle–Elbe line in this particular case. As the Atlantic continued to spread, the continental crust underlying the British Isles was dragged eastwards by the Eurasian plate as a trailing plate, and the extension of the spreading axis below the continental crust underwent a relative westward migration, becoming more and more offset along the Bay of Biscay–Labrador Sea transform fault. During the Cretaceous this westward migration reached the eastern edge of the Rockall Trough. By the time of Anomaly 24, the migration had moved the spreading axis to the west of the Rockall Bank and the well documented opening of the North Atlantic between Greenland and Europe began.

Our model, though admittedly speculative, involves a deep-seated feature of the type generally associated with the genesis of oceanic volcanic rocks, and that, together with the thinned overlying continental crust, could conceivably account for the nature of the North Sea volcanic rocks. The model is also consistent with a tensional regime in the Jurassic North Sea Basin and its subsequent transition to a compressional regime during the late Cretaceous[4].

We are grateful to British Petroleum Limited for making material available for study, and to Dr F. Howitt for his comments.

letters to nature

Direct observation of pulsar microstructure

HANKINS' observations[1] of pulsars exhibiting structure on time scales as short as a few μs have set stringent requirements on the theories which attempt to explain the pulsar emission mechanism[2,3]. These microstructure observations[1,4,5] were made at low radio frequencies where pulsar intensities are high. To overcome the effects of interstellar dispersion, which effectively 'smear out' the microstructure, Hankins developed a complex computation method. Since the effects of dispersion are less pronounced at higher frequencies, microstructure should be directly observable

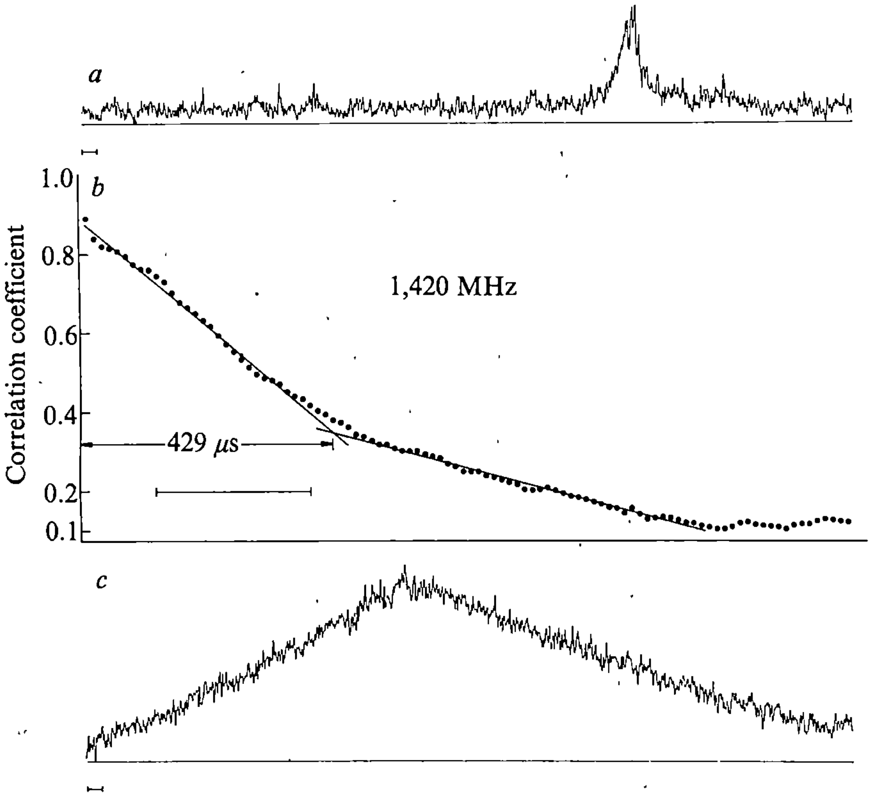

Fig. 1 *a*, A single pulse from PSR1133+16 with a time resolution of 14 μs; *b*, its autocorrelation function; *c*, the associated integrated pulse shape obtained by adding 2,099 pulses. In all of our figures, the time scale is indicated by the 260-μs bars underneath.

using an appropriate bandwidth This letter reports high-frequency observations of PSR1133+16 where the dispersion broadening and the time resolution were short enough to reveal microstructure on a time scale of 14 μs.

We used the 100-m radiotelescope of the Max-Planck-Institut fur Radioastronomie at Effelsberg[6] at an observing frequency of 1,420 MHz, with beamwidth 9′ and antenna performance 1.5 K Jy^{-1} The signal was detected with a linearly polarised feed at the prime focus The first stage of the receiving system was a cooled parametric amplifier giving an overall system noise temperature between 50 K and 65 K, depending on elevation. For pulsar microstructure studies, various filters at the intermediate frequency were available to allow the correct bandwidth to be chosen for the optimum resolution for each pulsar. After detection the signal was digitised by a voltage–frequency converter (with a maximum output frequency of 15 MHz), in conjunction with the pulsar data logger (PDL) This device enables the storage of 1,024 numbers per pulse period, and is controlled by two computers The first, a Ferranti Argus 500, provides Doppler-corrected pulsar period and timing signals. The second, a Honeywell H316, takes the data or buffer storage and transfers them through the Argus 500 computer on to magnetic tape.

A number of pulsars were recorded with various resolutions on November 17 and 25, 1975. Observations of the pulsar PSR1133+16 were made with a resolution of 13 μs. The bandwidth used was 1 MHz, which in view of the pulsar DM of 4.85 pc cm^{-3}, resulted in a dispersion broadening of 14 μs. The data from each pulse were recorded using 1,000 resolution intervals, each 13 μs long. Most of the observations were restricted to the first component of the double-pulse profile.

Our results for both components of PSR1133+16 confirm the general features of the microstructure as described by Hankins[1,4]. Autocorrelation functions (ACFs) of the strong pulses often show the ‘linear’ feature associated with microstructure, extending from near zero lag to a few hundred μs. This is followed by a much broader feature associated with the subpulse width Many pulses lack the microstructure feature in their ACFs which seems to imply either that microstructure is not always an important part of the

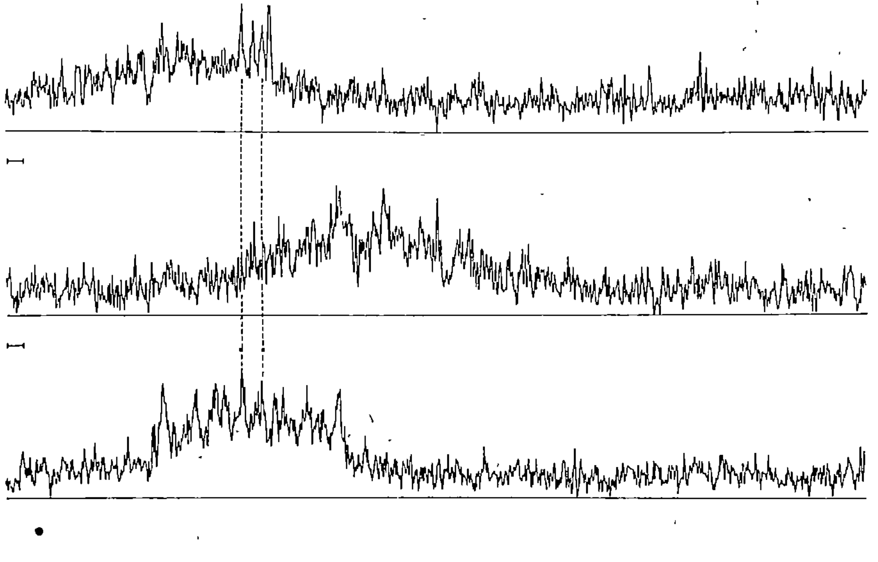

Fig. 2 Three consecutive pulses from PSR1133+16 showing a quasi-periodic behaviour within the subpulses.

emission, or that, if it is present, it is sometimes totally unresolved at 14-μs resolution. Spikes which are comparable in width with our time resolution are rare, however, and seem to be relatively weaker than those reported at 111.5 MHz by Hankins and Cordes[5]. The flux intensity of the strong pulses in our observations reaches a maximum of 200 Jy.

A pulse (taken from the first component of the integrated profile), which shows microstructure, its ACF and the integrated pulse shape obtained from it and 2,099 surrounding pulses are shown in Fig. 1*a*, *b* and *c* respectively.

An interesting feature which appears in some pulses is a quasi-periodic behaviour within the subpulse. Three consecutive pulses showing this behaviour in their ACFs are shown in Fig. 2. The apparent periodicity is 150 μs. Hankins remarked that similar behaviour sometimes appears in PSR0950+08, but to our knowledge it has never before been reported for PSR1133+16. Furthermore, the fact that some peaks occur at the same phase in the two strongest pulses, which have subpulse peaks at different phases, makes it uniquely interesting. Of course, this quasi-periodicity appears in the ACFs as secondary maxima at the lags corresponding to the 'period' and its multiples.

Studies of these observations of PSR1133+16, as well as 20-μs resolution observations already obtained for PSR0950+08 and observations of several other pulsars at resolutions <200 μs are still in progress and should yield further information on what is the basic pulsar emission process.

We thank all of the people who made the PDL a reality, in particular U. Reith and H. Hutfless.

A possible large-scale meridional structure in the helioequatorial solar wind

OVER the past few years observational data for a large-scale meridional structure of the solar wind have been accumulated[1-3]. Space-probe measurements have revealed heliolatitudinal effects at 1 AU, but little is known about the wind flow pattern at small radial distances, just outside the corona. Here we report the existence of a solar equatorial belt, from which few protons are emitted, and we discuss its causes.

We studied the semi-annual variations in solar cosmic ray propagation with the change of heliolatitude of the Earth. The probability of the arrival of solar cosmic rays at the Earth may be used to measure the conditions for the propagation of solar particles in space, between the solar flare and the Earth. This probability is proportional to the ratio of the proton flux (E_p > 10 MeV) to the energy of a solar radio burst (2,800–9,400-MHz range)[4]. A list of proton flares[4] was used to calculate this ratio averaged over 30 d. In Fig. 1*a* the probability *K*, determined in this way, as a function of the Earth's heliolatitude for 1957–63 is presented (182 proton events). One can see that very few solar protons penetrate a certain 'layer' centred on the solar equatorial plane (~ ±2° of heliolatitude). This avoidance ('quiet') zone in the solar particles propagation was found also in the data for 1938–56 and 1965–69. The same effect is seen when events in the northern and the southern hemispheres are analysed separately. Clearly the avoidance zone does not completely 'isolate' one solar hemisphere from the other, so the particles emitted by flares in the northern hemisphere can penetrate into the southern region and vice versa, but the mean flux of solar protons decreases when particles cross the equatorial plane (for details see ref. 5).

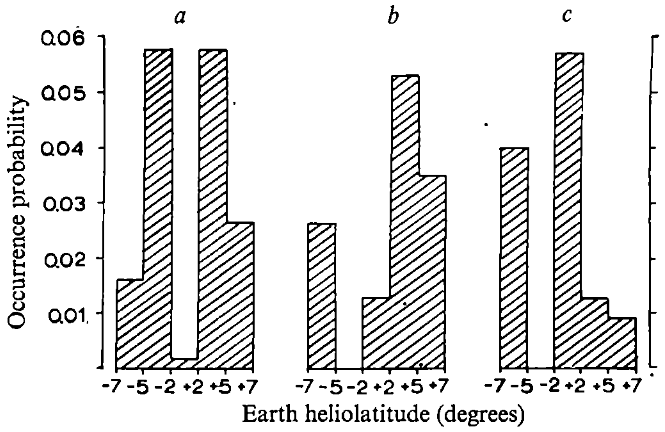

Fig. 1 *a*, The probability of the occurrence of solar cosmic rays at the Earth, *K*, as a function of the Earth's heliolatitude (1957–63). *b* and *c*, The displacement of the avoidance zone of solar cosmic rays in 1965–69; *b*, Events in the northern hemisphere; *c*, Events in the southern hemisphere.

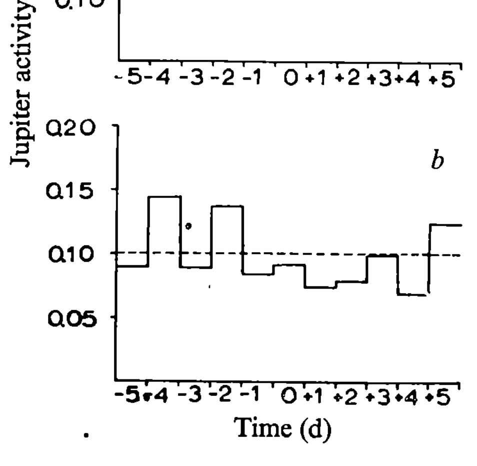
The quiet zone effect was also revealed in the influence of proton flares on Jupiter's decametric radio-burst activity. Some evidence for an association of the period of Jovian activity with the solar type-IV radio bursts was found by Warwick[6]. This correlation was not, however, confirmed later[7,8]. Data from Boulder[9-12] were studied again to search for the effect of solar

Fig. 2 Decametric radio-burst activity of Jupiter after the proton flares (using the superposed epoch method). The ordinate gives the mean indices of Jovian activity. *a*, When the heliolatitude of Jupiter > 2°; *b*, when Jupiter is within the avoidance zone (heliolatitude < 2°).



protons on noise from Jupiter for 1960–71. The indices of Jovian activity were calculated for each day of a 4.5-month period near each opposition (for the indices we adopted the ratio of duration of the storm to the full time of the observation, with weight equal to the importance of the storm). The days when solar proton events as well as solar flares with a type-IV radio burst were observed, were taken as the zero days for the superposed epoch method. Two time intervals were considered separately: first, when the heliolatitude of Jupiter is $> 2^\circ$ and second when this latitude is $< 2^\circ$. It is evident from Fig. 2*a* that Jovian burst activity increases after flares with a delay of 1 d. The effect exceeds 5σ only when Jupiter's heliolatitude is $> 2^\circ$ (see Fig. 2*b*). Thus the avoidance zone probably exists at distances up to 5 AU (ref. 13).

These results suggest that a 'screen' might exist in the solar equatorial plane, probably a region of increased interplanetary magnetic field. It is possible that the particle density increases in the same layer. Such a regularity in the meridional distribution of the particle density near the Sun ($\gtrsim 5\ R_\odot$) has been inferred[14,15]. Some density excess in the equatorial plane may, however, be expected also at 1 AU. A density excess of 20–30% has perhaps been seen by Hundhausen *et al.*[16]. A corresponding decrease of the plasma velocity in the equatorial plane was revealed by the same measurements[16] in agreement with early results[14] and recent cometary data[17]. Some heliolatitudinal changes were also observed in the interplanetary magnetic field (for example in refs 18–20).

Out study therefore strongly suggests that the solar equatorial wind has a considerable meridional structure near the Sun: an annular region of quasi-stationary plasma with an increased magnetic-field intensity may be assumed in the equatorial plane. The angular width of this layer is $\sim 3^\circ$–4° (as it is seen from the Earth). The radial distance from the Sun is $\gtrsim 5\ R_\odot$. This hypothesis is in good agreement with calculations of the dynamics of solar wind expansion[21–24], which predict the existence of a meridional component of the solar wind velocity directed towards the equator at a distance of several $R_\odot$ (inside the critical Alfvén point). The magnetic field lines would be squashed into the equatorial plane (see also ref 25).

The displacement of the observed structure to the south ($\sim 3^\circ$) for 1965–67 was revealed by the finding of a very large N–S asymmetry in the distribution of solar activity[26]. A possible displacement of the lines of wind flow in such an asymmetry was suggested in ref. 27. The location of the avoidance zone is shown in Fig. 1*b* and *c* (for details see ref. 28). The result obtained agrees with the findings of other authors[15,29,30] and with the calculations[33,34] based on the space-probe measurements[31,32].

The authors are very grateful to A. B. Severny for discussions.

Solar constant during a glaciation

THE causes of ice ages are of great topical and scientific interest. Here we review some recent work on the subject, point out some severe objections to postulated mechanisms, and make our own proposal that the driving force is some periodic behaviour in the Sun's interior.

Kukla[1] has revived the Milankovich mechanism for glaciation, and values of the solar constant at the autumnal equinox suggest that the climatic optimum of 6,000 yr ago may be accounted for by a run of warm autumns. If the Milankovitch curve[2,3] is compared with the climatic factors obtainable from magnetically dated deep-sea cores, however, it is clear that this mechanism cannot cause the major glacial cycles (see Fig. 1 and refs 4 and 5) The major variations of the aridity of the land north of Dakar, the trade wind vigour and the ^{18}O glacial stages are in good correlation. There are ~ 8 such cycles down to the 0 7-Myr magnetic date, but, in the Milankovitch curve there are 15 occasions in this period when the summertime radiation at 65°N is significantly below average. At best, the Milankovitch mechanism may be responsible for the minor ripples superimposed on the major trends.

An attractive theory of glacial cycles has recently been proffered by McCrea[6]. He supposes that the Sun passes through a series of very dense dust clouds which border the concave edge of the galactic spiral arms. In a cloud, the Sun accretes matter and its luminosity could increase to high values. McCrea relates these 50,000-yr periods to the glacial stages, supporting Simpson's hypothesis that the warmer Sun provides sufficient precipitation to support a glaciation[7] This must, however, be viewed with suspicion because it is now established that temperatures fell during a glaciation, in the tropics and at the poles Furthermore, geological evidence[8] shows that centres of glaciation were the Scandinavian highlands, the Labrador plateau and other moist mountainous regions. Today these regions receive copious precipitation, yet no continental ice caps grow; probably because they are not cold enough. The McCrea mechanism is essentially one of random occurrence; yet, particularly from core evidence, the climate seems cyclical —crudely sinusoidal, with perhaps systematically increasing amplitude and period for the later cycles[4,5].

I suggest that some solar periodicity is the prime cause of the major climatic cycles, and try here to estimate (using Houghton's radiation curves[9]) the Earth's radiation and heat budget that would be in balance with a glacial climate This leads to a new value of the solar constant which I assume relates to the luminosity of the Sun.

It is difficult to calculate glacial temperatures Wilson and Hendy[10] have reviewed the ^{18}O data and believe that if the equatorial regions fell by 5 °C the polar regions would fall by ~ 14 °C. The extensive work on foraminifera in Atlantic cores by the CLIMAP group[11] shows that 18,000 yr ago the surface waters, from Newfoundland to the Bay of Biscay were colder by 10 °C and that most of the tropical waters were colder by 4 °C. Botanical studies in Europe[12] have established the July 10.5 °C isotherm during the Würm glaciation as running in the general direction

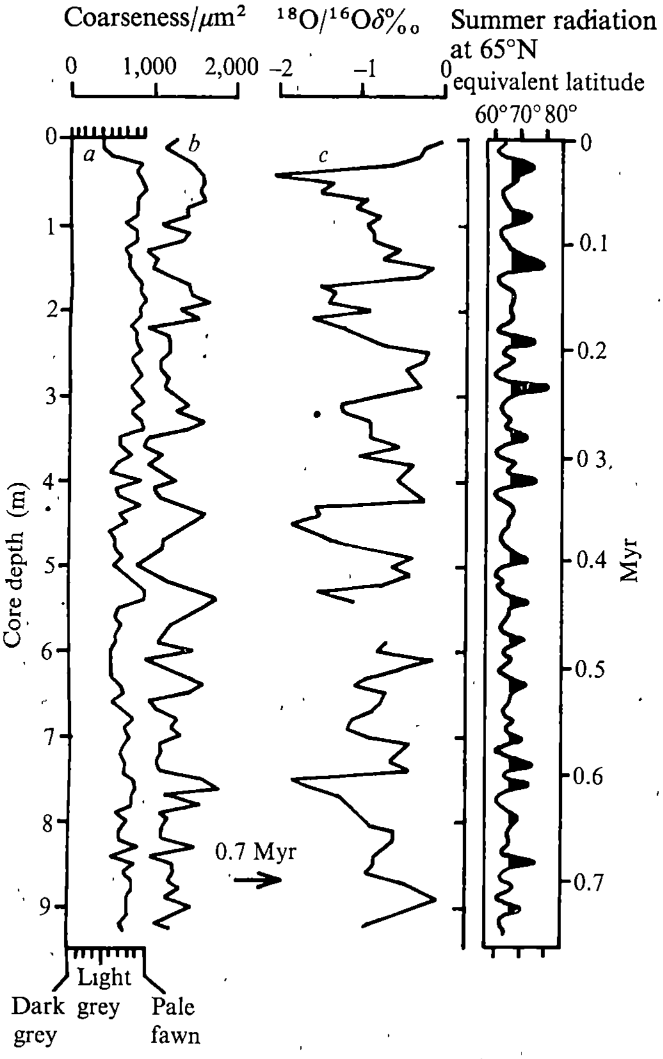

Fig. 1 The comparison between the climate factors down core V23-100 (from 21°18′N, 22°41′W, off the Sahara coast, just north of the Cape Verde Is.) and the Milankovitch curve. *a*, The colour is a measure of vegetation on the Spanish Sahara. The general lack of greyness means that humus (or burnt vegetation) was absent in the soil, that is, desert conditions prevailed throughout the whole time span. *b*, The coarseness is a measure of the size distribution of quartz particles A high value means strong trade winds, capable of transporting large particles. *c*, The ^{18}O deviations from present-day values measure the ice volume and establish the glacial stages. Note that strong winds and a slight increase in aridity occur during glacials.

Bordeaux–Berlin–Warsaw–Moscow. Today this line is the 18.5 °C July isotherm. By determining the degree of racemisation of aspartic acid in fossil bones, Schroeder and Bada[13] have estimated falls of 4 °C for the Mediterranean coast and 5–6 °C for East Africa. Judging drops in temperature from the lowering of the snow line is uncertain, as it depends markedly on precipitation; but assuming no change for Mount Kilimanjaro then an ~ 5 °C fall[8] would be reasonable for equatorial mid-tropospheric air. In estimating the long-wave radiation back to space, I generalise these data and assume surface level falls of 14 °C polewards of 80°N, 11 °C between 80°N and 60°N, 8 °C between 60°N and 40°N, and 5 °C from 40°N to the Equator.

In Fig. 2*a*, annual temperature profiles are shown at regular levels in the troposphere. The present-day ice cap is taken at a mean latitude of 75°N and the glacial ice cap at a mean latitude of 55°N (see ref. 7). This itself suggests a surface fall of 11 °C ~70°N, but a fall of only 6 °C for the mid-tropospheric air. In Fig. 3*a*, Houghton's annual absorbed solar radiations and re-emitted infrared radiations are reproduced (continuous lines), and the total heat flux across the circles of latitude are shown in Fig. 3*b*. Plotting the infrared radiation against the surface level temperature profile (Fig. 4), a linear relationship is obtained from the pole to ~ 20°N; however, against the upper air temperatures (say at 4 km) the empirical relationship is more complex. In the doldrum belt, towering cumulus cloud probably accounts for the 10°N and equatorial points plotting below the straight line. To estimate the infrared radiation to space during a glaciation, I assume that the present-day latitude points can be moved, parallel to the empirical line, by the appropriate temperature fall assumed for that latitude. This will tend to include the effects of the temperature-dependent changes in the concentration of water vapour[14]. The glacial infrared radiations are transferred to Fig. 3*a* as the dashed line.

Before the solar radiation curve can be proportionally reduced to secure a balance, it must be corrected for obvious changes in the planetary albedo. The present-day albedo (the inset in Fig. 3*a*) is redrawn along the dashed curve 1. This assumes that the glacial albedo at 55°N is the

Fig. 2 *a*, Present-day temperature profiles, constructed from mean meridional cross sections (Arctic Forecast Guide, US Navy Weather Research Facility, April 1962). same as that now at 75°N. I think this is an overestimation, and I believe it could not be made any greater. Evidence from the deep-sea core (Fig. 1) suggests that the Spanish Sahara has always remained desert and, if anything, was more arid (had less cloud cover) during glacials. Extending these results to the globe, it therefore seems reasonable to assume that at 30°N the albedo is unchanged, but perhaps at 20°N it could be reduced slightly. The pole and the equatorial regions are assumed to have a constant albedo.

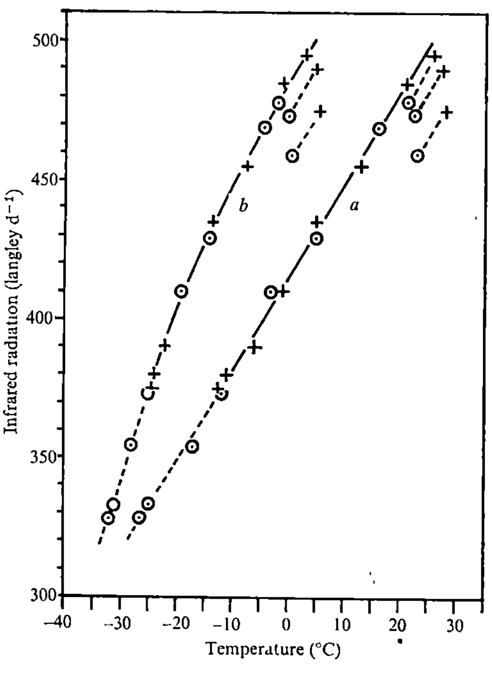
Fig. 4 The relationship between the surface-level temperature profile (*a*), the 4-km profile (*b*), and the infrared radiation emitted back to space at the 10° latitude intervals from the Pole to the Equator. (+, Present-day values, ⊙, the estimated glacial values—see text.)



With this first albedo assumption, the solar radiation curve is replotted (not shown), and then it has to be reduced by 1% to give a balance. The heat flux, across the latitudes, plots (not shown) well above the present-day value, except polewards of 65°N. I feel that the glacial heat flux should be greater than the present flux, but at all latitudes; clearly this first albedo is too high. The second albedo curve is deliberately drawn too low, making 65°N equivalent to 75°N. Balance is obtained with a 4% reduction, but the heat flux plots everywhere just below the present values. Some intermediate albedo is more realistic and I choose curve 3, which gives a balance for a 2.5% reduction; and the heat flux (the dashed curve in Fig. 3*b*) is everywhere greater than the present day. This glacial absorbed solar radiation curve is shown in Fig. 3*a*. If the albedo difference at 20°N is ignored, then there would be a 2% reduction. Assuming that present-day conditions are midway between a full interglacial and a full glacial, then I venture to suggest that the luminosity of the Sun has fluctuated with a 5% amplitude range and period of 10^5 yr.

It may be possible to reconstruct the temperature profiles for a glacial climate. Taking the 4-km profile as an example, the ten latitude points are moved along the empirical curve until they are at the appropriate glacial infrared radiation value, determined from the ground-level line. This gives a drop of 7 °C for the pole and for 80°N, 6 °C for 70°N, but a uniform fall of ~ 5.5 °C for the other points. In our present-day troposphere the average lapse rate of 5 or 6 °C km^{-1} is constant everywhere above 2 km, and does not depend on season. If the same lapse rate persists in a glacial climate, profiles at various heights may be constructed (Fig. 2*b*). A strong inversion between the surface and a height of 2 km appears polewards of 70°N as an annual feature.

It is interesting to compute, from the profiles, latitudinal thermal 'conductivity'. Physically, this would be a measure of the meridional component in the wind and ocean current structure. Using the surface-level profiles, the present-day and glacial conductivities are given in Fig. 3*b*. The high value in the tropics probably relates to the Hadley cell; but in the westerly wind belt, the meridionality of the transporting system is much reduced, and it seems that the glacial westerlies and ocean currents were noticeably more zonal than those of the present day.

It is interesting to note that the CLIMAP results do indicate a displacement of the Gulf Stream south of its present course, as if strong zonal winds directed it, during a glacial, more towards the Azores. Of course, the assumed increase in thermal gradient over the middle latitudes would encourage an eastward vector in the westerlies; and, treating the atmosphere as a heat engine, the whole circulation would have to be more vigorous. Evidence for this increase in vigour is already apparent in the deep-sea core work, some of which strongly suggests enhanced monsoonal activity[4,5]. Perhaps the Azores anticyclone intensifies, moves south-eastwards, and effectively blocks the Spanish Sahara from encroaching westerlies. A simultaneous intensification of the St Helena high would give an added 'push' to the monsoon.

I thank the Lamont–Doherty Geological Observatory for supplying the two cores V23-100 and V19-301 which have provided valuable data points.

Far infrared emission spectrum of the stratosphere from balloon altitudes

WE present here observations of the far infrared emission spectrum of the stratosphere taken with a balloon-borne interferometer from an altitude of 22 km above Churchill, Manitoba, Canada (latitude 58.7 °N, longitude 94 °W) in July, 1974. The instrument was part of a composite Atmospheric Environment Service of Canada gondola whose overall aim was the measurement, by several complementary methods, of the concentrations of minor constituents of the atmosphere and the monitoring of their changes with altitude and time during the flight. Many of the minor constituents of particular interest in the current debate on stratospheric pollution (O_3, H_2O, NO_2, N_2O, NO, HNO_3, HCl, SO_2) exhibit pure rotation spectra in the far infrared and are expected to contribute to the stratospheric emission spectrum. O_2, a well known and well behaved constituent of the stratosphere emits a series of weak magnetic dipole lines in this wavelength region, with intensities matching those of intrinsically stronger ones from less abundant species, and which can be used for spectral normalisation (see ref. 3).

Our preliminary data have been analysed by a method which uses synthetic spectra to allow for the weak O_3 lines and to effect a correct normalisation of the observations to the O_2 lines. The synthetic spectra were produced by a program described by McClatchey *et al.*[1], modified to use the instrumental convolution functions sinc *x* or sinc²*x* more applicable to Fourier transform spectroscopy (see ref. 2), with magnetic dipole transitions of O_2 added.

We used a simple rapid-scanning Michelson interferometer with no phase modulation, which produced interferograms with fringe frequencies for the highest wavenumbers of interest ($\sim 150\ \text{cm}^{-1}$) matching the maximum frequency response of the Ge(Ga) bolometer detector system[5] at Infra-Red Laboratories, Tucson, Arizona (~20 Hz).

The design of the system provided reproducibility between spectra in the wavenumber range 30–130 cm^{-1} to a resolution of 0.2 cm^{-1} at least equal to that of data taken from aircraft altitudes at equivalent resolution by phase modulation techniques[4–6]. Some of the more relevant details of the instrument and of the flight are discussed in the caption to Fig. 1, which shows a composite of two single spectra, displaced vertically to facilitate comparison.

Spectra were produced sufficiently rapidly that adequate height resolution during ascent (about 200 m per spectrum) and time resolution during sunrise and sunset (about 70 s per spectrum) were provided. Spectra could then be averaged if necessary after the flight to produce better signal-to-noise ratios. These spectra agree closely with those from aircraft altitudes[4–6], but with important differences. Strong H_2O lines which dominate most of this spectral region are considerably weaker at balloon altitudes. The O_2 lines, though still easily discernible up to 80 cm^{-1}, are somewhat weaker, particularly when compared with the comparatively strong Q branch emissions of O_3. This is as expected from the distributions of those constituents in the atmosphere. Weak O_3 lines pervade the whole region up to about 70 cm^{-1} and produce much of the small scale structure, making weak emissions from other constituents difficult to distinguish at this resolution. Strong H_2O lines still exhibit considerable emission in the wings of the lines, particularly those at 55, 56 and 88 cm^{-1}. No lines of H_2O other than

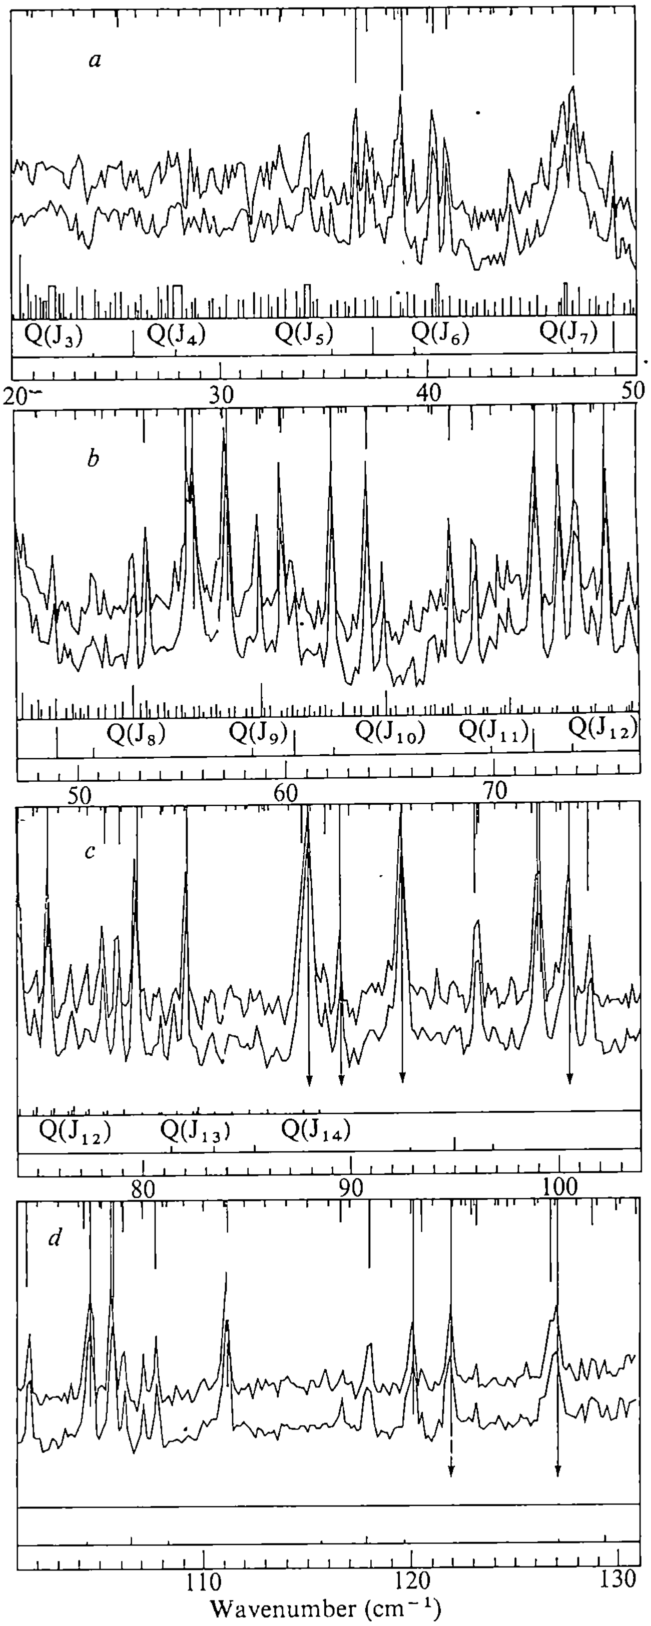

Fig. 1 Two emission spectra of the stratosphere between 20 and 130 cm^{-1} (resolution 0.2 cm^{-1}), taken at a zenith angle of 75°, from about 22 km in the anti-Sun azimuthal direction at 01.05 UT, July 23, 1974 (20.05 LT) *a*, 20–50 cm^{-1}, *b*, 50–75 cm^{-1}; *c*, 75–100 cm^{-1}; *d*, 100–130 cm^{-1}. H_2O line positions and relative strengths are shown above the spectra; O_3 lines and Q branches are delineated immediately below the spectra Magnetic dipole lines of O_2 are depicted below the O_3 line positions. The Ge(Ga) bolometer detector was fed by an *f*/1 5 TPX lens of 25 mm diameter, and was filtered by a mesh filter (at 2 K) a PTFE blocking filter (2 K), 0.4 mm black polyethylene (~100 K) and a TPX window at 253 K. The interferometer beamsplitter was a 12-μm thick Mylar (du Pont).

from the most abundant isotopic species are immediately obvious, nor is there evidence of emission from the dimer of H_2O, even under very careful analysis using synthetic spectra in regions of expected emissions. This finding is contrary to previous reports of aircraft measurements[7,8].

There is little evidence of emissions from other minor constituents in the preliminary analysis of these spectra. A peak is evident on an expanded plot at 37.8 cm^{-1} in the predicted position of a pseudo-Q branch of NO_2 (ref. 9). These emissions have been identified by Harries *et al.*[10] on spectra taken at aircraft altitudes, and a value for the integrated column density has been determined for that altitude. No peak of comparable magnitude to that observed in our spectra is predicted by the synthetic spectrum which includes O_2, H_2O and O_3 emissions. The line strength for this NO_2 emission is poorly known, however, and mixing ratios derived from this line are considerably above those obtained from other instruments on this flight. More definitive identification of the presence of emissions from this constituent at these altitudes must await spectra of higher resolution.

Of the expected HCl emission line positions only two are comparatively free of emission from other constituents, those at 41.6 cm^{-1} and 83.3 cm^{-1}. Expanded portions of the spectra at these wavenumbers indicate excess emission over that expected from weak O_3 lines as indicated by the synthetic spectrum, but it is not possible to say definitively whether emissions originate with HCl molecules. An upper limit to the mixing ratio of HCl on the basis of these data would be several parts per 10^9, considerably higher than the upper limit of 0.18 parts per 10^9, placed on this constituent in the lower stratosphere by Farmer[11] from near infrared observations.

Considerable structure is seen in the spectra between strong lines beyond about 80 cm^{-1} where weak O_3 lines should be negligible, and other molecular species are being examined as sources of these small but significant peaks.

The integrated column densities of H_2O and O_3 were obtained, and from several combinations of lines near to Q branches of O_3 the column densities of H_2O and O_3 above 22 km were determined as $1.1\ (\pm 0.6) \times 10^{18}$ and $5(\pm 2) \times 10^{18}$ molecules per cm^2, respectively. Further analysis of this kind, with careful fitting of data to synthetic spectra, particularly those calculated using multilayer atmospheric models, should yield more precise values of these constituents in the stratosphere. It is apparent, however, that values of line strengths for the magnetic dipole transitions of O_2 are needed to greater precision than are at present available (see ref. 12), particularly at the higher wavenumbers.

We thank Dr W. J. F. Evans, AES of Canada and the National Research Council of Canada for financial support. We also thank the staff of the Churchill Research Range and the balloon launch contractors, Raven Industries.

Lamb waves originating in non-geostrophic perturbations

A LAMB wave is a purely compressional wave mode in an isothermal atmosphere at rest above a horizontal rigid surface[1]. It travels only horizontally, with a phase velocity equal to the speed of sound and its energy density decreases exponentially with height. Bretherton[2] and Garret[3] have concluded that such a mode may exist in the temperature- and wind-stratified atmosphere of the Earth, with its energy mainly located at heights below 30 km. Lamb waves belong to the family of acoustic–gravity waves which, according to Rossby[4] and Obukhov[5], may be excited by non-geostrophic perturbations in a rotating stratified fluid until the fluid has returned to a quasi-geostrophic steady state. Here we report the observation of Lamb-wave generation in the troposphere during a geostrophic adjustment process.

On several days before and after the solar eclipse of June 30, 1973, simultaneous atmospheric and ionospheric observations were made at Tsumeb (19.2°S, 17.7°E) in southern Africa. On July 1, a microbarograph recorded unusually large ground-level pressure fluctuations, which, of course, were not caused by the eclipse. They have periods of ~ 1 h, and take place from morning until evening. Figure 1 shows a digitised form of the pressure record, but it is influenced by the filter characteristic of the microbarograph. Similar fluctuations superposed on the diurnal variations occurred in the Faraday rotation angle of the radio signal of a geostationary satellite and in the maximum electron density of the F2 layer (Fig. 1). The Faraday rotation is a measure of the ionospheric electron content which usually reacts very insensitively to perturbations in the electron gas. The maximum electron density is at a height of ~230 km and was deduced from vertical incidence ionograms which were not, however, available between 1210 and 1515 SAST. Around 1200 and from 1515–1800 SAST, it is particularly obvious that the electron density fluctuations show a strong correlation with the pressure fluctuations. A power spectrum analysis of all records shows two significant oscillations at periods of 90 and 60 min respectively, and each oscillation

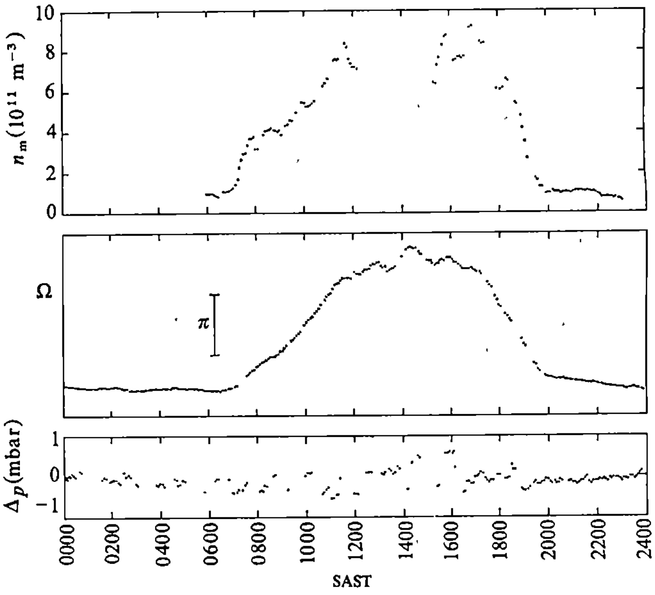

Fig. 1 Ground-level pressure variation Δp, Faraday rotation angle Ω of the 137-MHz radio signal of the geostationary satellite Intelsat IIF3, and maximum electron density n_m against South African Standard Time at Tsumeb on July 1, 1973.

has been isolated by a numerical bandpass filter. The two filters are characterised by centre periods of 90 and 60 min, and half-power widths of 38 and 18 min, respectively. Figure 2, for instance, shows the isolated 90-min oscillations confirming the strong correlation between the tropospheric and ionospheric events.

Additional Faraday rotation records were made at Outjo (20.1°S, 16.2°E) and Okahandja (22.0°S, 16 9°E), at distances ~250 km from Tsumeb. The filtered Faraday rotation data at all three stations show different phase angles, indicating that the oscillations are caused by propagating waves. For both periods, we find northward horizontal phase trace velocities of 220 m s^{-1}. The observed periods and velocities are typical of acoustic–gravity waves which propagate in the neutral gas causing perturbations of the ionised gas by ion–neutral collisions and by enhanced production and loss of ionisation[6,7].

The waves have been traced back towards the south by means of further Faraday rotation records and ionograms taken at several South African stations—additional microbarograms were not available. The 90-min wave could not be detected at Hermanus (34.4°S, 19.2°E), the 60-min wave not at Grahamstown (33 3°S, 26.5°E) Thus we may conclude that the waves were excited at low heights near these stations and could not reach the ionosphere above because their energy propagated on inclined ray trajectories[8]. Both stations are near the southern coast of Africa where, at the time in question, considerable non-geostrophic winds occurred (Fig. 3). Additional weather maps indicate that these winds were strongest during the daylight hours of July 1 The close spatial and temporal coincidence of the observed waves and ageostrophic winds thus confirms the theory that acoustic–gravity waves may originate in non-geostrophic perturbations.

It is reasonable to expect that the atmospheric response to a tropospheric source is dominated by Lamb waves because their energy is mainly located at low heights[9,10]. To test this hypothesis we shall compare our observations with calculated Lamb waves in a realistic atmospheric model. We take the 1972 Mean COSPAR International Reference Atmosphere which, below a height of 25 km, is completed by the 1966 US Standard Atmosphere Supplements. Winds are not taken into account since their meridional components, in particular, are unknown. The electron and ion number densities are described by α-Chapman layers with maximum densities of $4\times10^{11}\,m^{-3}$ at a height of 230 km. The wave-induced perturbations of the neutral and ionised gas are calculated from the linearised hydrodynamic equations including dissipative effects[11]. In Table 1, observed and theoretical results are compared where T=wave period, v=horizontal phase trace speed, r_n=relative perturbation of maximum electron density, r_p= relative perturbation of ground-level pressure, φ=phase difference between r_n and r_p. A calculation of the perturbation of the Faraday rotation angle is not possible for reasons given by Georges and Hooke[12].

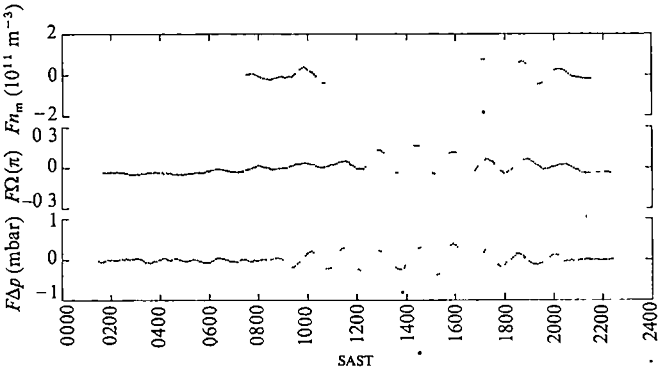

Fig. 2 Filtered records of ground-level pressure, Faraday rotation angle and maximum electron density.

The differences between observed and theoretical values of v most probably arise from the fact that, in deriving v from the Faraday rotation data, a horizontally-stratified ionosphere was assumed. A deviation of only 3° from the horizontal stratification, for instance, would introduce an error of some 100 m s^{-1} in the observed value of v because, at F-region heights, the Lamb waves behave like internal gravity waves with vertical wavelengths roughly five times

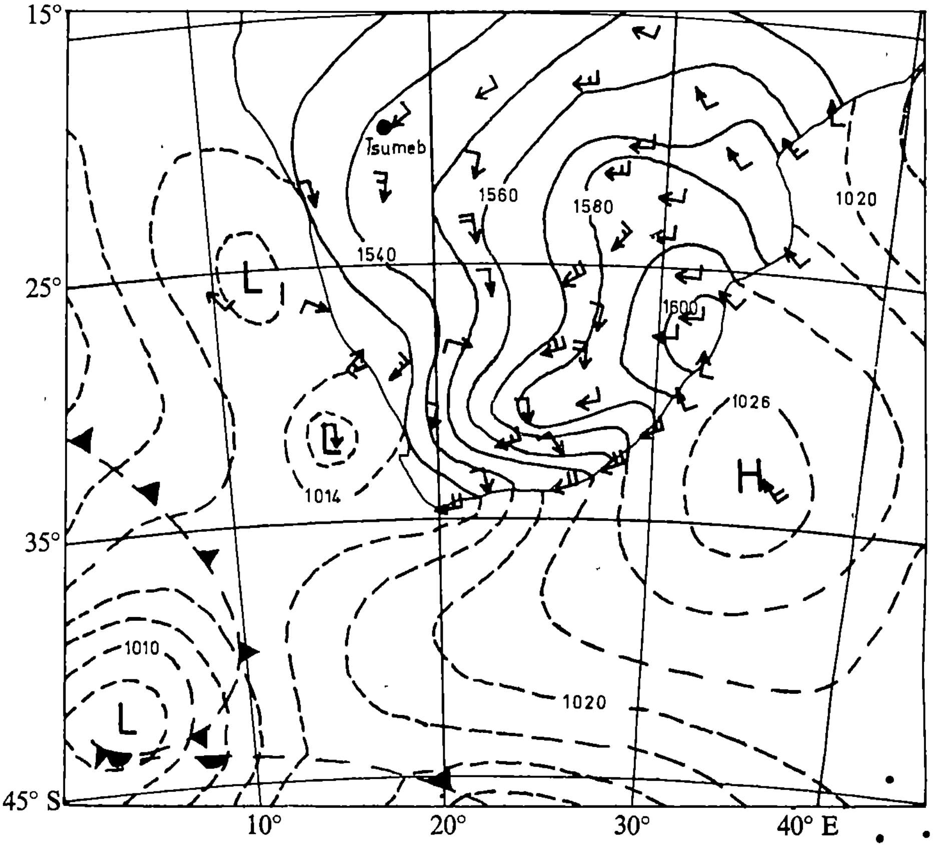

Fig. 3 Weather map on July 1, 1973, 1400 SAST. – – –, Isobars at MSL in mbar; —, contours at 850 mbar (gpm); ←, wind direction, each feather = 10 knots. (From Synoptic Weather Map, Weather Bureau, Republic of South Africa.)

Table 1 Comparison between observed and theoretical results

	$T = 90$ min Observed	$T = 90$ min Theoretical	$T = 60$ min Observed	$T = 60$ min Theoretical
v (m s^{-1})	220	310	220	310
$\|r_n/r_p\|$*	550	700	450	770
φ* (deg)	65	120	75	100

*Observed pressure perturbations are corrected according to the filter curve of the microbarograph. The values of φ have phase ambiguities of $2\pi n$.

smaller than the horizontal wavelengths[10]. The differences between the observed and theoretical values of $|r_n/r_p|$ and φ, on the other hand, possibly come from simplifications in the theory such as neglect of winds, surface friction and diffusion of the ionised constituents. In particular, the last two processes tend to reduce the differences in $|r_n/r_p|$. In spite of the highly magnified wave amplitudes at thermospheric heights, nonlinear effects play no role.

Other acoustic–gravity wave modes that can propagate in our atmospheric model give no better explanation for the observations than the Lamb mode. In particular, they yield values of $|r_n/r_p|$ which differ from the observed data by more than an order of magnitude. This is because other wave modes are ducted primarily in the upper atmosphere whereas the Lamb waves are guided by the Earth's surface[13].

I thank all who supported this investigation by providing observational data.

Ni and Co content of chondritic metal

WE have made a detailed study of the metal phases in some chondrites. Axon and Goldstein have reported[1] microprobe measurements of the Ni and Co contents at the interfaces between contiguous α and γ phases in seven metallic particles of high Co content from Apollo 14 and 15 lunar soils. The three particles of highest Co content had α phase in contact with clear homogeneous γ phases (Fig. 1), whereas the particles of lower Co content (Fig. 1) had Widmanstätten spindles of α phase in a matrix of high Ni γ phase in a manner analogous to that observed in certain Ni-rich ataxite irons. Axon and Goldstein have expressed the view that the Co contents of these particles are "higher than the meteorites of similar structure" and that they must have come from a different source.

In two instances, Olivenza (LL5) and Khanpur (LL5), we have encountered spindle-like exsolutions of the high-Co α phase in a matrix of high-Ni–high-Co γ phase. The α–γ interface values for the two meteorites are plotted together with measured bulk compositions in Fig. 1. It can be seen that the meteoritic metal is similar in structure and composition to the lunar soil particles, although the interface composition of the meteoritic γ phase shows less enrichment of Ni. In terms of the binary Fe–Ni equilibrium diagram, the LL5 metal seems to have γ-phase interface compositions appropriate to ~410 °C, in contrast to the value of ~350 °C observed for the lunar material.

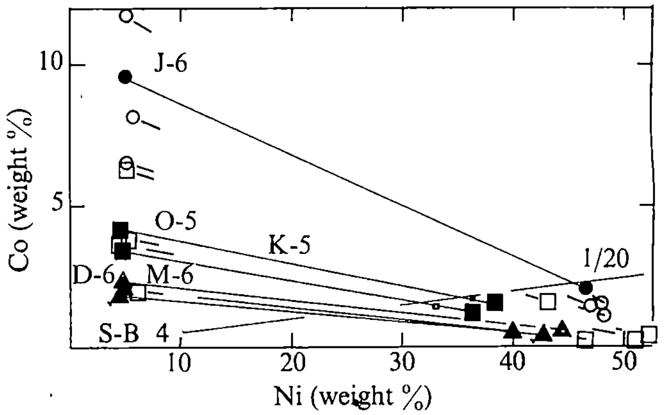

Fig. 1 Interface compositions for α and γ phases in the metal of LL chondrites (solid symbols) compared with high cobalt metal in lunar soils (open symbols). Circles, Clear γ phases; squares, ataxite type structures; triangles = zoned γ phases. J, Jelica; O, Olivenza; K, Khanpur; M. Mangwendi; D, Dhurmsala; S-B, Soko-Banja. Number, petrological grade of LL chondrites.

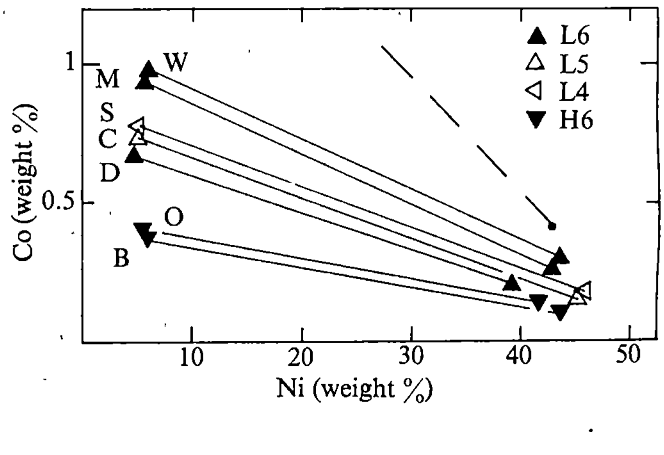
Figure 1 also includes α–γ interface values for Jelica (LL6). In this meteorite the α phase is extremely rare. When the α and γ phases are contiguous in Jelica, however, the γ phase is clear and compositionally unzoned, and in this case the bulk composition of the metal is almost coincident with the reported γ-phase composition. The bulk metal compositions for Khanpur, Olivenza and Jelica have a Co–Ni ratio of 1: 20 (Fig. 1). This represents the cosmic abundance ratio of the two elements. Therefore, the bulk Ni–Co contents of the metal phases in these three LL chondrites are consistent with a Prior's Law relationship in which iron partitions between the metal and silicate phases, whereas the more noble elements Ni and Co concentrate exclusively in the metal. The bulk composition of the metal is first established according to Prior's Law, and the distribution of Ni and Co between the α and γ phases is then controlled by tie-line relationships in the Fe–Ni–Co ternary equilibrium diagram. The lower part of Fig. 1 contains data for Mangwendi (LL6), Dhurmsala (LL6) and Soko-Banja (LL4). In each of these instances the α phase is contiguous with a compositionally zoned γ phase.

None of the samples in Fig. 1 shows visible signs of reheating in the metal phases. They are all observed falls, free from terrestrial corrosion and ablation heating. The silicate portions of these samples have been examined by Sears and Mills[2] who have given details of identification.

Fig. 2 Interface compositions between α and zoned γ phases in L and H chondrites. The broken line represents the lowest line of Fig. 1. W, Wold Cottage; M, Mauerkirchen; S, Saratov; C, Crumlin; D, Durala; O, Ogi; B, Butsura.



The same criteria were used to select an array of H and L chondrites from Sears' and Mills' samples. The results are shown in Fig. 2. The Ni content of the α phase is essentially the same in both Figs 1 and 2, but there is a distinct Co hiatus of about 1% between the LLα (Fig. 1) and the Lα phases (Fig. 2). There is also a marked change in the slope of the Ni–Co tie-lines between Figs 1 and 2, as may be seen from the broken line in Fig. 2, which represents part of the lowest tie-line (Soko-Banja) of Fig. 1.

No metallurgical reheating effects were observed in the samples shown in Fig. 2, but the kamacite (α phase) in both Wold Cottage (L6) and Mauerkirchen (L6) contained minor ε-shock transformation of the type that Axon and Boustead[3] have shown does not alter pre-existing compositions at α–γ interfaces. Within the limits of this investigation, no consistent differences emerged between the petrological grades L4, L5, L6. Any hiatus between the Co contents of α metal in H and L chondrites is, however, much less pronounced than that between L and LL chondrites. In contrast, the silicate compositions seem to show the reverse effect.

Reheating or shock-heating effects were identified in the metal from three of the samples from ref. 2 that are not plotted in Fig. 2. They are: Holbrook (L6), (α=5.8 Ni, 1.15 Co; γ=29.0 Ni, 0.45 Co); Gambat (L6), (2.86, 0.86; 16.2, 0.26), and Tennasilm (L4) (3.98, 0.75; 25.6, 0.25). Lines joining the α and γ compositions in these reheated samples of metal cross the assembly of Fig. 2 at a steep angle. It is noteworthy that the interface data for the metal in these reheated L chondrites are similar to those reported by Goldstein *et al.*[4] for two-phase α–γ or α–plessite structures in metal from Apollo 17 soils.

We thank Dr R. Hutchison (British Museum) and Dr A. A. Mills (University of Leicester) for supplying material. We can provide tabulations of the data on which Figs 1 and 2 are based.

Non-crystallinity and polymorphism in elemental solids

THIS paper shows a universal correlation of the non-crystalline state with polymorphism in elemental solids. This is demonstrated by a map constructed on a plot of the number of polymorphic forms (NPF) against the group number (GN) for all solid elements in the Periodic Table (Fig. 1). From this result, we propose that both the structure and occurrence of a non-crystalline solid are governed by the structures shown by crystalline states of the element.

The number of polymorphic forms was derived primarily from the data given by Eckerlin and Kandler[1], and by Pearson[2]. High pressure polymorphs were included because localised atomic packings in non-crystalline solids may assume the same bonding configurations as these exhibit. The elements with such high pressure polymorphs are As, Ba, Bi, Dy, Ga, Gd, Ge, Mn, rare earths, P, Pu, S, Sb, Si, Sn, Sr, Tb, Te and Yb. Polymorphs with a similar space group were counted just once, since the bonding natures may be almost identical among similar polymorphic structures, for example, B, Ce, Fe, Ga, Li, Mg, P, Pu, S and Te.

The GNs were arranged to give a progression in degree of bonding anisotropy from isotropic metallic bonding to anisotropic metallic bonding, to covalent bonding, to anisotropic semi-metals and back to isotropic metallic bonding.

Non-crystallinity is favoured in elements with a large number of polymorphic forms and a high degree of bonding anisotropy. Therefore the occurrence of non-crystallinity was described by regions with tie lines bounding the non-crystalline elements formed in similar conditions (see Fig. 1). We thus defined five regions distinguished by the most convenient, or least stringent, conditions for formation. Elements located on the boundary between two regions are best assigned to the lower numbered region.

In region I, non-crystalline solids can be prepared simply by quenching from the liquid state. This region contains the elements S, Se, P, As, and B.

In the upper part of region II, non-crystalline solids can be obtained by vapour, electrolytic or sputter-deposition near room temperature (elements such as C, Si and Ge). For the lower part of the region, Sb, Bi, Te, Fe and Ni require much lower deposition temperatures, ranging from liquid nitrogen to liquid helium temperature. Nickel and Fe were put in region II since they become amorphous in conditions similar to those for Te, Sb, and Bi.

For region III, non-crystalline solids can be formed only by vapour or sputter deposition at very low temperatures (near liquid helium temperature). Region III is defined by metallic elements Mn, Pu, Dy, La, Hf, V, W, Re, and Pd, and semi-metals Pb, Sn, Ge, and Tl. This region includes transition metals with GN from 4b to 8. Bonding characteristics for transition elements do not, however, change as much as the GN indicates, and therefore the occurrence of non-crystalline phases should be more dependent on the NPF than on the GN. Normally, the stability of the non-crystalline solids in region III is enhanced by impurities, thinness, and substrate conditions[3,4]. We therefore expect that a number of elements on the boundary between regions III and IV, such as Pb, Tl, Pu, Dy, La, Ce, Sm, Yb, U, Np and I to form non-crystalline phases under favourable conditions.

Non-crystalline solids are difficult to form for elements in region IV. Formation requires deposition at very low temperatures in the presence of stabilising factors including contamination and thin film effects, or favourable substrate surfaces. With the scant data available, region IV tentatively includes all group 2a and 3b elements at the left hand of the map. The elements Al, In, Zn, Cd, Hg, Cu, Ag and Au make up region 4 on the right hand of the map. Future work on elements in this region may require extra attention paid to the characterisation of the non-crystalline states as well as the control of experimental conditions, especially for the reported amorphous phases of Al, Be, Zn, Cd, Ag and Au.

There is no evidence for the occurrence of non-crystalline phases in Na, Cs, K and Rb, which make up region V. Because of the isotropic bonding characteristics and small number of polymorphs in group 1a, we believe these elements will not form non-crystalline solids.

This good correlation of polymorphism with the occurrence of elemental non-crystalline solids demonstrates that certain structural aspects of the crystalline state are relevant to the non-crystalline form. We therefore postulate that the structure of a non-crystalline solid is composed of a finite number of bonding states (or polymorphic bonding) with the same bonding characteristics (length, angle, and energy) exhibited by the polymorphs.

It is more reasonable to expect that crystalline state bonds exist in an amorphous solid rather than random packing arrangements. For each thermodynamically stable crystalline structure, there will be a limited number of bonding configurations constituting the lowest free energy state. The formation of non-crystalline phases, however,

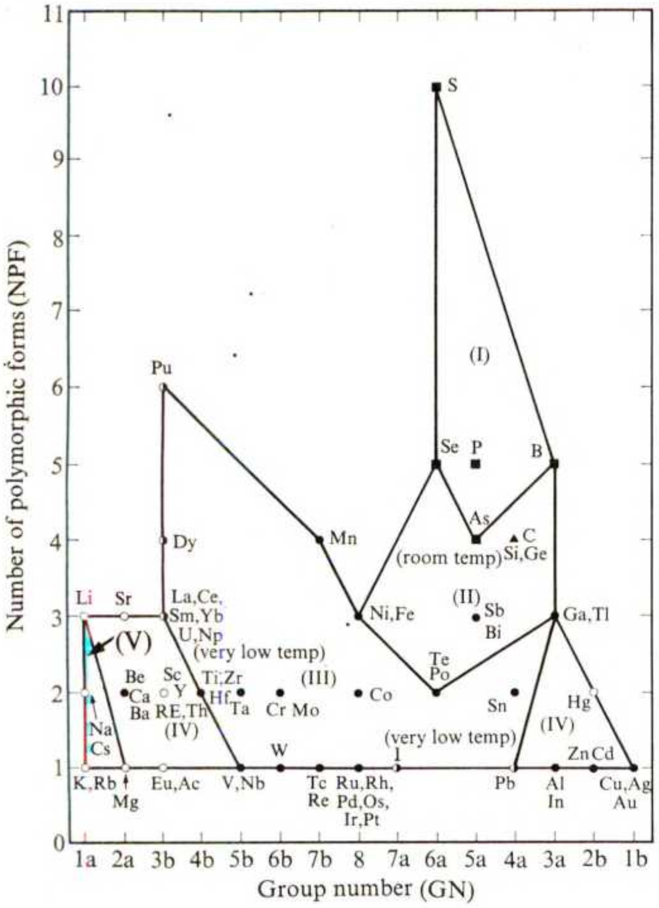

Fig. 1 Map showing the occurrence of elemental non-crystalline solids as correlated with the number of polymorphic forms (NPF) and group number (GN) of all the solid elements in the Periodic Table. The boundary lines are assigned to group elements conveniently into five regions representing the trend of formation conditions. The ease of formation of non-crystalline solids is illustrated by: ■, quenching from the liquid; ▲, formation by chemical or physical vapour deposition near room temperature; ●, formation by vapour deposition at low temperatures; half-filled circle, no data available, but we believe these can be formed in conditions similar to the ● data; and ○ no data available.

usually involves rapid quenching from high energy states (liquid or vapour) to prevent the forming of the lowest free-energy states. Instead, the atoms relax into a number of allowable bonding configurations separated by localised energy barriers. These allowable bonding types are those exhibited in the polymorphic structures. Therefore elements which have a large number of polymorphic forms will have a large number of available bonding states (energy minima) to accommodate the rapid relaxation process. The polymorphic bonding configurations would explain the low configurational entropy of non-crystalline phases as measured in Si and Ge[5]. The effect of GN on the occurrence of a non-crystalline phase can be understood in a similar context. Minimisation of the free energy by crystallisation becomes more unlikely as bonding anisotropy is increased from metallic bonds to covalent bonds, because of an increased 'jamming' probability.

Several recent observations support our concept of polymorphic bonding in non-crystalline solids. Structural models based on computer-simulated random packing give better agreement with diffraction results when variable bond lengths are allowed rather than single bond distances[6,7]. The optical properties of amorphous silicon are more consistent with the bondings in the high pressure tetragonal polytype than with the diamond structure[8]. Moreover, the fact that there can be more than one 'polytype' for an amorphous material, as in arsenic, in itself means that the non-crystalline state is characterised by specific bond types.

We are grateful to Dr R. D. Nelson for discussions. This work is supported by the Division of Physical Research, US Energy Research and Development Administration.

An early Ordovician vertebrate

HETEROSTRACAN fishes are the oldest known fossil vertebrates, and well preserved examples are frequently found in rocks of late Silurian and Devonian age, but in older rocks their remains are fragmentary and rare. Their oldest occurrence yet described is in the Harding Sandstone, Colorado (middle Ordovician[1,2]), where two genera occur; one of these has subsequently been recognised in marine limestones of similar age from Ontario, Canada[3].

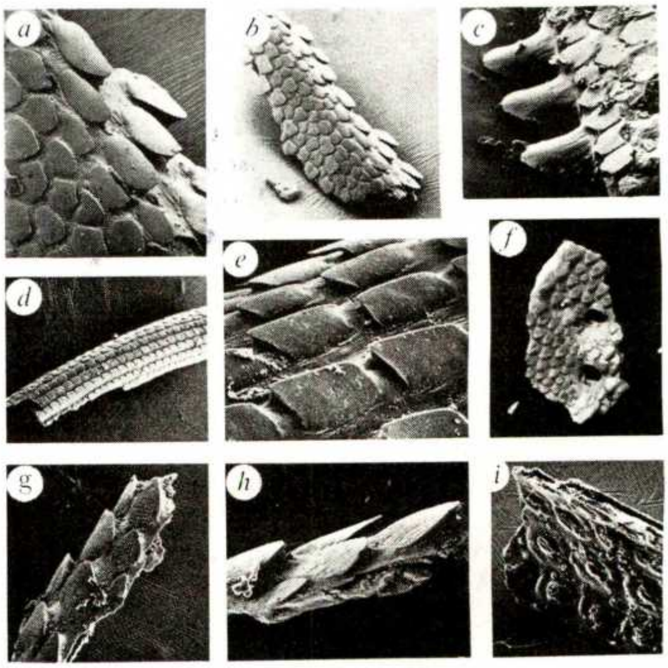

Fig. 1 Fragments of *Anatolepis heintzi* (*a*–*f*, *i*) and *Anatolepis* sp. (*g* and *h*) from the early Ordovician Valhallfonna Formation, northern Spitsbergen. *f* Was taken with a light microscope, the others with a scanning electron microscope. *a* and *b*, Holotype, PMO NF 3263/1 (× 54 and × 18, respectively), showing typical scale types with smooth external surfaces; *c*, PMO NF 3263/2, part of spine-like fragment (× 36), with transformed scales at edge; *d* and *e*, PMO NF 3263/3, elongate, U-shaped fragment with rhombohedral external scales (× 18), and detail (× 180); *f*, fragment with obliquely orientated, circular perforations, PMO NF 3263/4 (× 18); *g* and *h*, PMO NF 3263/5, fragment of second species of *Anatolepis* with grooved scales; *g*, from above (× 30); *h*, lateral view (× 94.5); *i*, inner surface of a fragment, PMO NF 3263/6 (× 54), showing low tubercles perforated at tip, and trilaminate structure at broken edge.

During the search for phosphatic microfossils from the early Ordovician Valhallfonna Formation, northern Ny Friesland, Spitsbergen[11], we recovered numerous small fossils which are identified as fragments of the earliest heterostracan, indicating that the earliest vertebrate occurrence predates that of the Harding Sandstone by about 20 Myr.

Whereas deposits containing later heterostracans were laid down in freshwater or brackish conditions[4], the earliest sediments are regarded as fully marine, indicating that the vertebrates had their origin in the same medium as other major metazoan groups[5,6]. The only recorded occurrence of vertebrate remains supposedly pre-Middle Ordovician are some small thelodont denticles—termed *Palaeodus* and *Archaeodus*—from the early Ordovician of the Russian platform[7]. These specimens are lost, and doubt has been cast on their authenticity (ref. 3 and S. Turner, personal communication). The Middle Cambrian problematicum *Eoichthys* Bryant[8,9] is regarded as unlikely to be vertebrate; indeed it was later[10] not considered as such by its original author.

The present finds were part of residues obtained by dissolving limestones in acetic acid, which otherwise include conodonts, chitinozoa[12], trilobites, brachiopods and radiolaria[13]. The associated fauna indicates a shallow shelf, fully marine environment, with a well oxygenated, soft, muddy sea floor, populated by a variety of benthic trilobites[14]. Vertebrate remains have been recovered from two horizons: 90–100 m from the base of the Olenidsletta Member and 30–50 m from the base of the Profilbekken Member. The former occurrence is with graptolites indicating an Arenig (early Ordovician zone of *Didymograptus hirundo*) age, the latter slightly younger, possibly earliest Llanvirn.

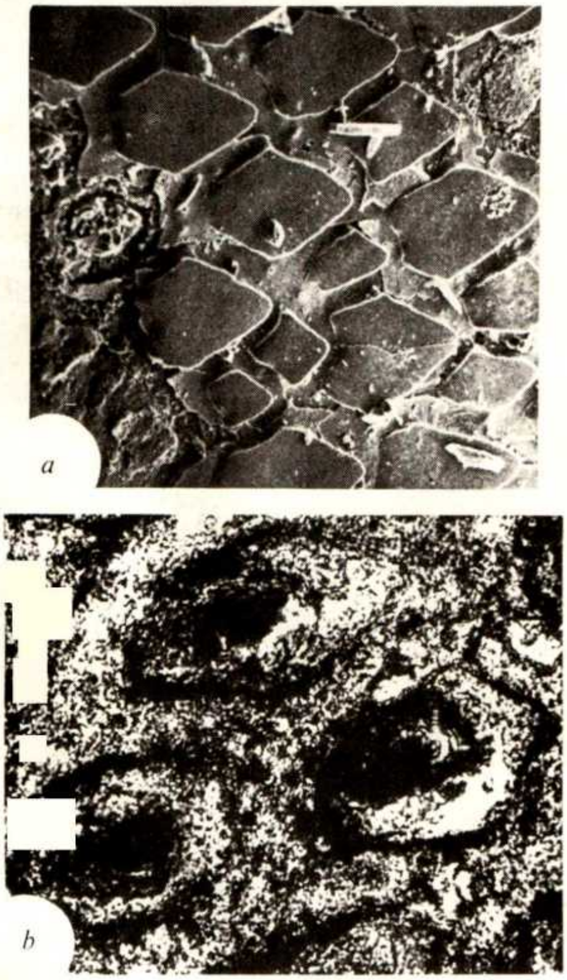

Fig. 2 *Anatolepis heintzi a*, PMO NF 3263/7 (× 300). Scanning electron microscope photograph of part of fragment showing circular structures beneath each scale; *b*, PMO NF 3264 (× 1,600), light microscope picture of similar fragment to *a*, photographed with transmitted light to show circular aspidin structures in middle of scales (NF 15, Fig. 10).

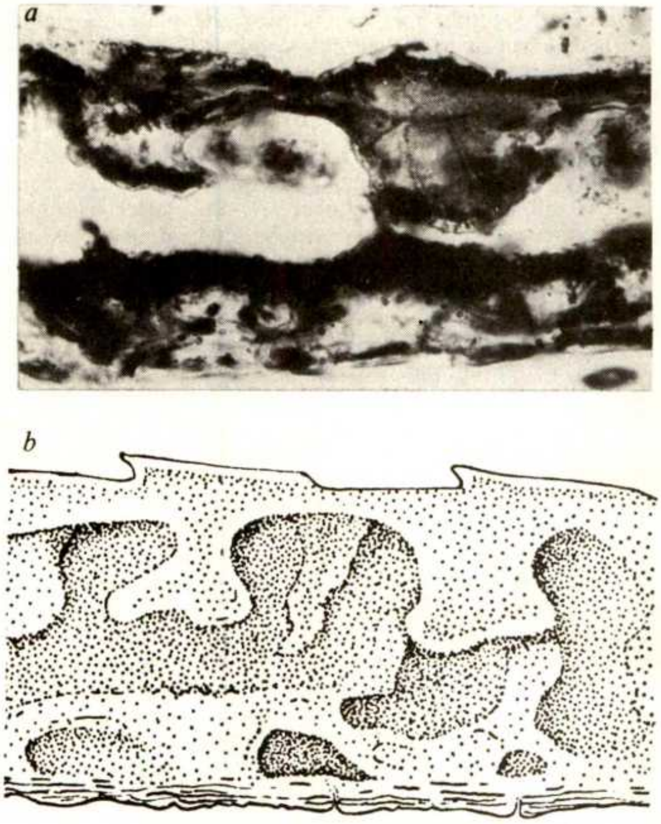

Fig. 3 *Anatolepis heintzi. a*, Photograph of thin section of PMO NF 3262 (×750), showing external scales, basal lamellar layer, intermediate cavernous aspidin layer. *b*, Generalised reconstruction of *Anatolepis* bone (×750).

The specimens range in length from 1 to 2 mm, and one or more edges are invariably frayed, suggesting that the fragments are parts of larger plates. Analysis by X-ray diffraction shows that fragments are composed of apatite but the possibility of the hydroxyl (OH) radical being present (in small amounts) cannot be eliminated. The outer surfaces of the plates are covered with minute, smooth, elliptical to rhomboidal scales 25–150 μm long; the larger scales are concentrated at the edges of the fragments, where they are frequently more or less imbricated. Plates are frequently 'doubled over' at the edges with larger scales (Fig. 1*a* and *b*), such fragments possibly being from the perimeter of the animal (and if this is so, indicating a dorsoventrally flattened overall shape). The inner surface of the plates carry tubercles of two sizes; the larger of these are perforated at their tips, these perforations presumably being the sites of dermal nerves or blood vessels (Fig. 1*i*).

Apart from flat or slightly curved fragments or 'edge' pieces, there are two particularly interesting fragments which, being covered with similar scales, are referable to the same animal. One is a spine (Fig. 1*c*) in which some of the scales are extended to form blades. The other fragment (Fig. 1*f*) includes small, circular openings, each equipped with a small lip externally and doubtless representing original openings in the exoskeleton. Since several groups of early agnathans had separate gill openings it is tempting to assume that these perforations represent the openings into the gill pouches, but they may also be pores into the lateral line system.

The plates are remarkably thin (70–100 μm) and delicate, and this explains why larger fragments have not been recovered. In section the structure of the plates is similar to that described for other heterostracans[15,16], with a basal lamellar layer, an outer, probably dentinous, layer carrying the rhomboidal scales, the two separated by a spongy 'aspidin' layer (Fig. 1*j*, Figs 2 and 3): the latter easily tears during sectioning. Both *Astraspis* and *Eriptychius* from the Harding Sandstone are much more robust and have completely different external tubercles—the latter variously lobate, frequently with broad, subparallel raised ridges, the former with hemispherical, radially grooved tubercles. External tubercles of both these genera have more than twice the average diameter of those of the new material from Spitsbergen. Because of these differences we propose a new name for the species described here—*Anatolepis heintzi* gen. et sp. nov. The type species is named after the late Professor Anatol Heintz, who contributed much to the study of early fishes. A distinctive second species, with minutely grooved external scales (Fig. 1*g* and *h*), has been recovered (one specimen only) from the lower horizon.

More material, preferably still *in situ* on the bedding surfaces, is needed before an attempt at a reconstruction of the whole animal can be made. The fragments alone are of interest because they prove that heterostracans were already present in the earliest part of the Ordovician (500 Myr ago) and show that they were then certainly Marine. They also indicate that the thicker armour of the middle Ordovician forms is likely to have been secondary[17]. Material at hand shows no evidence of cyclomorial growth[18] or fusion of smaller tesserae[19], and it is possible that skeletisation occurred all at once in *Anatolepis* rather than by fusion of individual tubercles. If such fusion occurred it may have been in an ancestor of Tremadocian or Upper Cambrian age. Our discovery may stimulate examination of acid residues of pre-Ordovician age for the remains of still earlier vertebrates.

Do nocturnal rodents run more efficiently at night?

An animal's activity is perhaps the most obvious physiological parameter influenced by circadian rhythms. Nocturnal animals move about and do their foraging during their hours of darkness. This higher level of activity is also synchronised with a higher basal metabolic rate as well as body temperature[1], and may also be reflected in metabolic needs for (the increased) locomotion occurring during the active period. Since the animal is using more energy simply to maintain its basic needs, there may also be a higher energy requirement for moving about. We have examined this, and have found that the increased basal rate persists as the constant difference (at different speeds), between the day and night performances of gerbils.

Three male gerbils (*Meriones unguiculatus*, weight 62–85 g; average 71.7 g) were purchased from local pet stores, and fed rat food and water *ad libitum* supplemented with seeds, fruits and vegetables. Between 20 and 26 h before each run their food was removed. The gerbils were placed on a 12-h light (0600–1800) and 12-h dark (1800–0600) cycle two weeks before the experiment. The animals were run under ordinary room light for the light runs and under dim red lights for the dark runs (the lighting conditions seemed to have no effect on their running ability). Running took place on a treadmill 40 cm long and 10.5 cm wide enclosed in a Lucite box (13×15×50 cm) kept at 20–22 °C, and the gerbil's speed was measured by timing revolutions with a stop-watch; it could be maintained to within ±5%. Oxygen consumption was measured on a Beckman model F-3 oxygen analyser calibrated to within ±0.005% O_2 (1% of full scale deflection) by lowering the pressure within the measurement cell. Room air was pulled into the chamber at a rate of 226 l h^{-1} (STP) ±3% giving a 75% turnover of the air in the chamber in 3.6 min (assuming complete mixing). The chamber was kept at a slight negative pressure, ensuring that all the air exhaled by the animals would be drawn into the oxygen analyser. After the gerbils had run for at least 20 min at each speed and were running well, data were taken for each 10-min period when the deflection of the oxygen analyser trace showed an oxygen variation of no more than ±0.005%. Oxygen consumption was calculated by multiplying the air flow by the change in oxygen concentration. This value was then multiplied by 1.0425, on the assumption of a respiratory quotient (*R*) of 0.84, which would give a maximum ±4.25% error for *R* values of from 0.70–1.0 (ref. 6). In fact, the *R* value probably did not vary appreciably, since

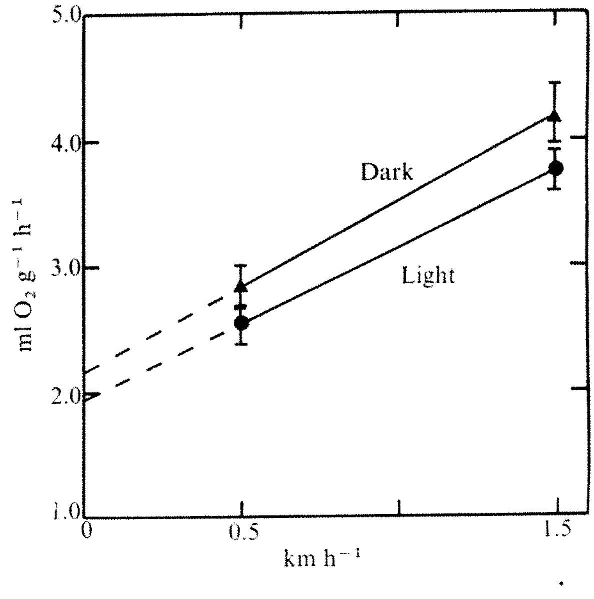

Fig. 1 Oxygen consumption of gerbils running during their dark (▲) and light periods (●) at 0.5 and 1.5 km h^{-1}. Vertical bars with horizontal caps indicate ±2 s.e.m.; there was no overlap of the means ±2 s.e.m. The lines joining the means are extrapolated to the *y* intercept. The slope for the dark period running is 1.35 ml O_2 g^{-1} km^{-1} (s.e.m. =0.140); for the light period it is 1.21 ml O_2 g^{-1} km^{-1} (s.e.m. =0.107).

the animals were all in the same nutritional state during their runs.

For both running speeds used here (0.5 and 1.5 km h^{-1}) the oxygen consumption of animals running during their dark period was significantly higher than when they ran during their light period (Fig. 1). It takes more energy to run a given speed during the dark (active) period. The increments in oxygen consumption for the 1 km h^{-1} difference in speed between 0.5 and 1.5 km h^{-1} were, however, about the same, and were below those predicted for quadrepedal mammal of that size. The increment was 1.35 ml $O_2\ g^{-1}\ h^{-1}$ in the dark period, and 1.21 ml $O_2\ g^{-1}\ h^{-1}$ in the light period, compared with predicted value of 1.52 ml $O_2\ g^{-1}\ h^{-1}$ for a 72-g mammal[2]. The *y* intercepts of the lines (2.17 and 1.94 ml $O_2\ g^{-1}\ h^{-1}$) are in good agreement with the predicted value of 2.04 ml $O_2\ g^{-1}\ h^{-1}$ (ref. 2).

The oxygen consumption data may be interpreted as if the resting requirement is higher during the dark period but the metabolic increase needed for running is the same during either period, in agreement with measurements of activity and metabolism in rats during dark and light periods[3]. Lizards and mammals of the same weight also show the same metabolic increments for running, even though the lizard has a much lower basal oxygen usage[4].

Splitting the metabolic levels shown in Fig. 1 into a resting and a running component shows that the increment from running will be about the same whether the running occurs during the light or the dark period. Then, since the time of the day the animal chooses to run a given distance will affect neither the metabolic increment due to running nor the total resting oxygen consumption, the total oxygen consumption over a 24-h period will be the same. Whatever other advantages may accrue to the gerbils as nocturnal animals, such as safety from predators or decreased evaporative water loss during the cooler night periods[5], there is no metabolic adaptation for more efficient running when the animals run the most.

Increased incidence of triploidy in embryos derived from mouse eggs fertilised *in vitro*

FERTILISATION *in vitro* has now been achieved in several mammalian species, including rabbit[1], mouse[2], golden hamster[3], rat[4], and man[5]. The possibility exists that the technique may increase the incidence of chromosomal anomalies through any of several mechanisms including meiotic disturbance in the oocyte associated with superovulation, fertilisation by two or more sperm as a result of a high sperm concentration and/or a change in the natural block to polyspermy, altered conditions of competition between sperm with normal and abnormal genomes, and disjunctional irregularities during early cleavage of the fertilised egg. To determine whether any of these possible types of abnormality are of real significance will require extensive investigation. As yet the limited published data from human[6,7] and rabbit[8] embryos are either too few to be useful or lack control observations. We have therefore made a cytogenetic study of the incidence of triploidy in mouse embryos following fertilisation *in vivo* and *in vitro* and have found a highly significant increase in triploidy in the *in vitro* group.

Care was taken in both series to arrange that the eggs fertilised were 'fresh' (that is, non-aged). In both groups, eggs were from 2–3 months old (C57BL/10×CBA) F_1 females with sperm provided by outbred TO males. All of the females were induced to superovulate with 5 IU pregnant mare's serum (PMS) (Gestyl, Organon), followed approximately 48 h later by 5 IU human chorionic gonadotropin (HCG) (Pregnyl, Organon). For fertilisation *in vivo* HCG was administered 12–13 h before the estimated time of natural ovulation. Females were paired with males and examined for vaginal plugs the following morning; the day of finding a plug was taken as day 1. For fertilisation *in vitro*, females were killed 13 h after HCG administration and their unfertilised eggs were immediately mixed with sperm. Thus, in both groups the eggs were the same approximate age at the time of association with sperm.

Table 1 Chromosomal analysis of mouse embryos derived from superovulated eggs fertilised *in vivo* and *in vitro*

	40	±40	±60	Triploidy (%)
In vivo days 3 and 4	162	17	5	2.7
In vitro 72-h culture	124	26	22	12.8

Experiments using the same *in vitro* system have indicated that sperm–egg union is complete within 1.5 h of gamete mixing (unpublished), a time which correlates well with *in vivo* studies indicating that sperm penetration can be detected within 1 h of mating[9,10].

Whittingham's medium based on Tyrode's solution[11] with 0.5 mM pyruvate was used for fertilisation *in vitro*. The medium for fertilisation contained 32 mg ml^{-1} bovine serum albumin (BSA, Armour); that for culture contained 4 mg ml^{-1} BSA. The preparation of the medium and dishes for experimental use followed the methods of Hoppe and Pitts[12]. A sperm suspension was prepared by gently forcing the contents of two epididymides into the medium under paraffin oil with watchmakers forceps. After 20 min allowed for dispersal, a 1 : 9 dilution of the suspension giving a final concentration of 1.5×10^6–3.0×10^6 ml^{-1} was used for fertilisation.

Eggs were released directly into the sperm and incubated at 37 °C for 3–6 h, then washed and cultured in droplets of medium under oil. After 72 h, embryos were at the 8–16-cell stage, and at that time the medium in the droplet was changed to one containing 10^{-8} M vinblastine sulphate (Velbe, Lilly) prepared in culture medium. Following incubation for a further minimum period of 3 h, chromosome preparations were obtained from the embryos.

In the experiments the mean *in vitro* fertilisation rate was 77.7% (two-cell/total eggs), and 89.6% of these two-cell embryos reached the 8–16-cell stage used for chromosomal examination. If cultured further, rather than being fixed, 80–90% of embryos would have been expected to form blastocysts, according to previous experience. Further, offspring of both sexes have been obtained after embryo transfer[13].

Naturally mated females were injected on days 3 or 4 with 0.1 ml Velbe (1 mg ml^{-1}), and killed 2–5 h later to allow the recovery of embryos. The embryos of both *in vivo* and *in vitro* groups were placed into 1% sodium citrate for 8 min, transferred to acid-cleaned slides, fixed rapidly with 3 drops 3 : 1 methanol–acetic acid and air dried (ref. 14, and E. P. Evans, personal communication). The preparations were stained with toluidine blue for cytogenetic analysis. Analysable preparations were obtained from 33% of the 528 embryos in the *in vitro* series and from 44% of the 414 embryos in the *in vivo* series.

The chromosomes were counted in all suitable blastomeres at mitotic metaphase (Table 1). The majority of counts were confidently either 40 or 60. No attempt was made to sex the embryos by identification of the Y chromosome. Some of the counts shown in Table 1 as ±40 may have been genuine aneuploids but no instances of $2n/3n$ chimaerism or levels of polyploidy higher than $3n$ were identified. The difference between the frequencies of triploidy recorded in the *in vivo* series (2.7%) and the *in vitro* series (12.8%) is highly significant ($\chi^2=11.47$, $P < 0.001$).

The mean frequency of triploidy among 3.5-d embryos derived from naturally ovulated eggs of 6 non-silver mouse strains was 0.9%, according to data given by Beatty[15]. The mean frequency in the exceptional silver strain was considerably greater, reaching 9.5% in one series. In an investigation of 1,359 preimplantation embryos from naturally ovulated (C3H×101)F_1 females, 13 (1.0%) were triploid (E. P. Evans, personal communication). The latter embryos were obtained following morning matings and the eggs are therefore likely to have aged for several hours before fertilisation. Estimates of the frequency of triploidy among the preimplantation embryos of naturally mated, superovulated mice are 0.3% (ref. 16), 1.2% (ref. 17) and 1.8% (P. A. Neighbour, personal communication), in addition to our own figure of 2.7%. We have been unable to find an estimate of the contribution of superovulation itself to the incidence of triploidy in the mouse, which would require comparison with data from the embryos of matched, naturally ovulated and fertilised females.

Estimates ranging from 1.2% to 8.5% polyspermy in superovulated eggs fertilised *in vitro* have been derived from data obtained using Swiss mice[18,19]. No control data from natural matings were provided so it is not possible to say anything about the significance of these figures. High frequencies of polyspermy have been recorded in superovulated eggs of the golden hamster fertilised *in vitro*, for example by Barros *et al.*[20], but such eggs have not been cultured past the two-cell stage[21]. All of these estimates were based on the number of pronuclei or sperm heads within the vitellus. Such observations provide no assurance that a synkaryon will result or that the egg will cleave. They cannot, therefore, have the same validity as counts of chromosomes at mitosis for the estimation of the proportion of resulting morulae that are triploid.

Counts of chromosomes have been reported in 26 human blastocysts obtained following *in vitro* fertilisation[6,7]. All were said to have been diploid or approximately diploid. In view of the small number studied, these data are of limited value in excluding abnormalities of ploidy.

The explanation we favour for the striking rise in the incidence of triploid embryos following fertilisation *in vitro* is dispermy. This could be related either to a much higher sperm concentration *in vitro* than *in vivo*[22] or to an alteration of the mechanism that normally prevents polyspermy. Disturbance at the second maturation division, leading to an increased frequency of digyny is also possible. The frequency of digynic triploidy, however, is unlikely to be great since the proportion of eggs with second polar bodies at the time of transfer to the culture medium is closely correlated with the proportion later observed to cleave (unpublished). A marker chromosome experiment to discriminate between these possibilities is in progress.

We thank Drs C. E. Ford and R. D. Barnes for discussions and suggestions. G.R.P., a visiting worker at the Clinical Research Centre, was a member of the MRC External Scientific Staff during the course of this investigation.

Spread of antibiotic-resistant plasmids from chicken to chicken and from chicken to man

THE natural ecology of *Escherichia coli* and its infectious plasmids is not understood, although there is suggestive evidence that animals may serve as reservoirs for *E. coli* found in humans[1,2]. Investigation in this area becomes additionally important in view of the practice of introducing plasmids with pieces of foreign DNA into *E. coli*[3,4]. During an examination of the effects of antibiotic-supplemented animal feed on flora of farm animals and human personnel (ref. 5 and S.B.L., G.B.F. and A.B.M., unpublished), a study was initiated to determine if *R* plasmids and their *E. coli* hosts were naturally transferred among chickens and from chickens to human handlers. Our results illustrate the spread of antibiotic-resistant organisms from chicken to chicken and from chicken to man.

We used a temperature-sensitive chloramphenicol-resistance gene as a marker to identify a particular plasmid. *Escherichia coli* D1-7 (ref. 6), carrying *R222*, was treated with nitrosoguanidine[7] and a mutant expressing temperature sensitivity to chloramphenicol was selected from the surviving bacteria. The temperature-sensitive chloramphenicol-resistance property was easily transferred to other hosts. This finding indicated its presence on a plasmid. This mutant plasmid, designated *pSL222–6*, expressed resistance to chloramphenicol, tetracycline, sulphonamides and streptomycin at 32 °C, but at 42 °C did not express chloramphenicol resistance. *pSL222–6* was transferred by conjugation into two morphologically distinct *E. coli* isolated from chickens. An inoculum containing a mixture of the two recombinant bacteria was introduced directly into the intestines of four chickens by means of a tube placed in the cloaca. The chickens were caged separately and fed tetracycline-supplemented feed (Pfizer; tet-feed) to enhance colonisation with this tetracycline-resistant *E. coli*.

A repeat inoculation was carried out 4 d later although subsequent analysis showed that already at this time all

*Does not include inoculated chickens placed in cages A and C; chickens in cages A and B were fed tet-feed; C and D received normal feed.

of the faecal *E. coli* isolated from these chickens were resistant to chloramphenicol at 32 but not at 42 °C. Two chickens were then placed in two cages each containing 50 chickens. One cage (A) was placed on the tetracycline-supplemented feed; the other (cage C) was not. Two other cages containing chickens with (B) and without tet-feed (D) were also maintained in the barn at about 50 feet from the experimental cages. In this way, the effect of tet-feed on the spread of the marked plasmid from inoculated chickens to other chickens could be evaluated.

Samples of faeces were taken weekly using a sterile swab (Handi-Swab, Fisher) from the cloaca and cultured on MacConkey agar plates at 30 °C. These master plates were then replica plated on to MacConkey agar containing chloramphenicol and incubated at 30 and 42 °C. Table 1 illustrates the spread of the mutant plasmid from the initial two chickens to the rest of the animals in these cages. After 2 months, *E. coli* with temperature-sensitive chloramphenicol resistance were detected in 14% of chickens in cage A. Of particular note was the finding of *E. coli* with this particular *R* plasmid in faeces of 24% of chickens in a distant cage (B). None of the bacterial samples from chickens in cages not placed on tet-feed (C and D) demonstrated the mutant *R* plasmid.

Since only the plasmid was marked in this first experiment, a second study was carried out to determine whether the plasmid was being spread by way of the host bacterium. Plasmid *pSL222–6* was introduced into a mutant strain of chicken *E. coli* resistant to nalidixic acid (Nal^R). (*Nal* resistance is not normally found among *E. coli* in chicken gut flora.) The Nal^R *E. coli*-bearing *pSL222–6* were introduced by cloacal inoculation into four chickens previously fed tet-feed. These chickens were placed in a cage of 18 chickens also eating tet-feed and excreting organisms resistant to tetracycline, and the presence of the doubly marked *E. coli* followed (Table 2). After 1 week, 7 of the 18 chickens were excreting Nal^R *E. coli*, all of which showed temperature-sensitive chloramphenicol resistance. By 5 weeks these *E. coli* were detected in all the chickens in the cage. Spread was more rapid than in the previously described experiment. About 20–30% of *E. coli* in the flora of these animals was Nal^R (*pSL222–6*).

Over a two-month period faeces from eleven family members living on the farm and three laboratory workers responsible for the sampling of the chickens were tested for the presence of *pSL222–6*. On two occasions the plasmid was detected in human faeces. The first occurred in the faecal sample from the 12-yr-old son of the farm owner; 2 d after he had cleaned the cage in which chickens harbouring *E. coli* with this plasmid were housed, 78% of the coliforms in his faecal flora were resistant to chloramphenicol and this resistance was temperature sensitive. The *E. coli* also showed resistance to streptomycin and sulphonamides, but not to tetracycline. These resistances were not transferable. A similar non-transferable tetracycline-sensitive segregant of *pSL222–6* was found in *E. coli* from chickens in the cleaned cage. The presence of a plasmid in this *E. coli* was verified by the identification of a fast-moving peak of labelled DNA in an alkaline sucrose gradient (data not shown). Furthermore, other plasmids of the same incompatibility group (FII) were unstable when conjugated into this *E. coli*. This finding indicated the presence of a plasmid of the same incompatibility type as *pSL222–6*. Since typing of *E. coli* was not possible and the *E. coli* were not marked we could not determine whether the organisms were of human or chicken origin.

The second human host observed excreting *E. coli* with *pSL222–6* was an animal handler. One week after she had sampled chickens inoculated with the Nal^R *E. coli*-bearing *pSL222–6*, her faecal flora showed the presence of temperature-sensitive chloramphenicol-resistant *E. coli*. These *E. coli* were also resistant to nalidixic acid. All three other resistances on *pSL222–6* were also present. In conjugation the resistances in this *E. coli* were transferred together.

Subsequent faecal specimens from these two individuals 3 and 5 d after the initial sample did not reveal the presence of these particular organisms. Neither individual was taking antibiotics. Since only faecal swabs were examined, further studies would be necessary to determine whether these organisms were present to small extents in their intestinal tracts.

Our results demonstrate the spread of resistant organisms from chicken to chicken and from chicken to man. In studies of 1-d-old chicks, Smith[8] found *E. coli* from one group of chickens in faecal samples from a second group of chickens within 2 d of their being mixed in a cage. In the present study spread of the mutant *R* plasmid and Nal^R *E. coli* was detected in adult chickens in the same and distant cages. The mechanism of spread, whether by air or on the clothes of the feed handler, is not known. Cage-to-cage spread of bacteria is probably a common occurrence in a farm environment, followed by subsequent spread of plasmids and bacteria among the chickens in the cage.

In the light of our findings, transfer may also occur among other animals and between other animals and man. In the absence of direct contact and of selective pressure, such as that exerted by antibiotics, the frequency of spread is probably small. The subsequent transfer of animal *R* plasmids to human *E. coli* in the intestine, however, could occur[9] especially if the recipients were taking an antibiotic related to resistance determined by an *R* plasmid[10]. Although as few as 10^4 organisms can produce colonisation of the human intestinal tract[11] most studies *in vivo* have indicated that more than 10^6 bacteria need to be ingested[12,13]. This seems too many to have been ingested without their

Table 2 Spread of newly introduced R^+ *E. coli* among chickens

	Week 0	Week 1	Week 3	Week 4	Week 5
Number of new chickens excreting Nal^R *E. coli* (*pSL222–6*)	4	7	3	2	2
Accumulated number of chickens excreting Nal^R *E. coli* (*pSL222–6*)	4	11	14	16	18

Four chickens excreting Nal^R *E. coli* bearing temperature-sensitive chloramphenicol-resistant *R* plasmid *pSL222–6* were introduced into a cage of 18 chickens previously fed tetracycline and excreting tetracycline-resistant *E. coli*. Spread of Nal^R *E. coli* was followed by replica plating initial faecal samples, from MacConkey agar plates, on to (1) MacConkey agar + chloramphenicol at 30 and 42 °C; (2) MacConkey agar + nalidixic acid (30 μg ml^{-1}) at 37 °C. All Nal^R colonies were temperature sensitive for chloramphenicol and vice versa.

knowledge by the two individuals in this study. The results suggest a different route of entry or a different culture medium for the ingested bacteria, for example, by way of the nasal passages to sputum to the gastrointestinal tract.

These data bear on the widespread use of antibiotics in veterinary and medical practice and on the proposed use of *E. coli* as a vehicle in genetic engineering experiments. Further studies on the conditions affecting transfer and mixing between animal and human bacteria will be important in evaluating the consequence of antibiotic-resistant bacteria in animals in contact with man.

Thermostability studies for investigating non-electrophoretic polymorphic alleles in *Drosophila melanogaster*

ON theoretical grounds it is generally believed that most structural genes have common isoelectrophoretic alleles[1–3]—polymorphic alleles that cannot be discovered by electrophoresis—but there is no direct evidence for this. Methods that might be used to search for such structural variability (involving, for example, thermostability or kinetic studies) have not often been adopted as screening procedures though they have been used to compare already identified electrophoretic alleles. This is not only because such methods are often unsuitable for screening purposes. Even when a screening method can be applied, its efficiency in revealing existing structural variability is not known *a priori*, not even approximately, as for electrophoresis. Moreover, this unknown efficiency is presumably very low because although electrophoresis, being a separation technique, separates the products of two alleles in heterozygotes, other screening procedures only pick up the combined products which may or may not show an intermediate characteristic. It would usually be extremely difficult to distinguish between the three types. Thus, for any enzyme for which such a method is available, a two-step procedure seems convenient: (*a*) to test it on already known structural (electrophoretic) alleles of that enzyme, and if it turns out that it is efficient (*b*) to use the method in a search for structural isoelectrophoretic alleles. It must be assumed that these two types of structural differences are, on average, equally likely to affect the parameter being studied.

Drosophila melanogaster provides convenient material for such an approach because it is easy to synthesise isogenic lines for whatever gene has been mapped. In this way all relevant comparisons can be made between homozygotes for the alleles being studied. Phosphoglucomutase (PGM) depends in *D. melanogaster* on a single autosomal gene (3: 43.6) (ref. 4) with two common, Pgm^{A} and Pgm^{B}, and several rare electrophoretic alleles, Pgm^{C}, Pgm^{D}, Pgm^{E} and Pgm^{F} (ref. 5). Therefore this gene is quite suitable for this purpose. Thermostability is relatively simple to study, even for homogenates of a single fly. Two procedures were used to evaluate the thermostability of the various allelic PGMs studied: (1) incubation of two aliquots of a homogenate of several *Pgm* isogenic flies at two temperatures followed by electrophoretic analysis and (2) incubation at two temperatures of two slices of a starch gel after electrophoresis of an homogenate of a single fly followed by the addition of the PGM-staining mixture[6]. Temperature and time of incubation were decided empirically.

Figure 1 shows that our technique enabled us to classify any PGM band as heat resistant (R) or heat sensitive (S) on an alternative basis. Moreover, since heterozygous individuals were found in which the product of one *Pgm* allele was resistant and the product of the other *Pgm* allele was sensitive, we conclude that this property depends on the *Pgm* structural gene.

Presumably, there were available for heat-sensitivity studies several possible rare *Pgm* alleles because, besides those variants which are electrophoretically different, variants with the same electrophoretic behaviour but different in origin—if they are rare—are likely to be structurally different. Table 1 shows a large heterogeneity as regards heat sensitivity between both electrophoretically different *Pgm* alleles and rare alleles with the same electrophoretic behaviour but different origins. Moreover, as it might be expected, the latter heterogeneity was not found within the same population. It therefore seems reasonable to compute as certainly or probably distinct alleles any two *Pgm* rare variant alleles differing from each other in electrophoretic behaviour or origin, respectively. Of 16 such variant alleles 10 turned out to be R (5 Pgm^{C} and 5 Pgm^{D}) and 6 S (2 Pgm^{C}, 3 Pgm^{E} and 1 Pgm^{F}). Conclusive

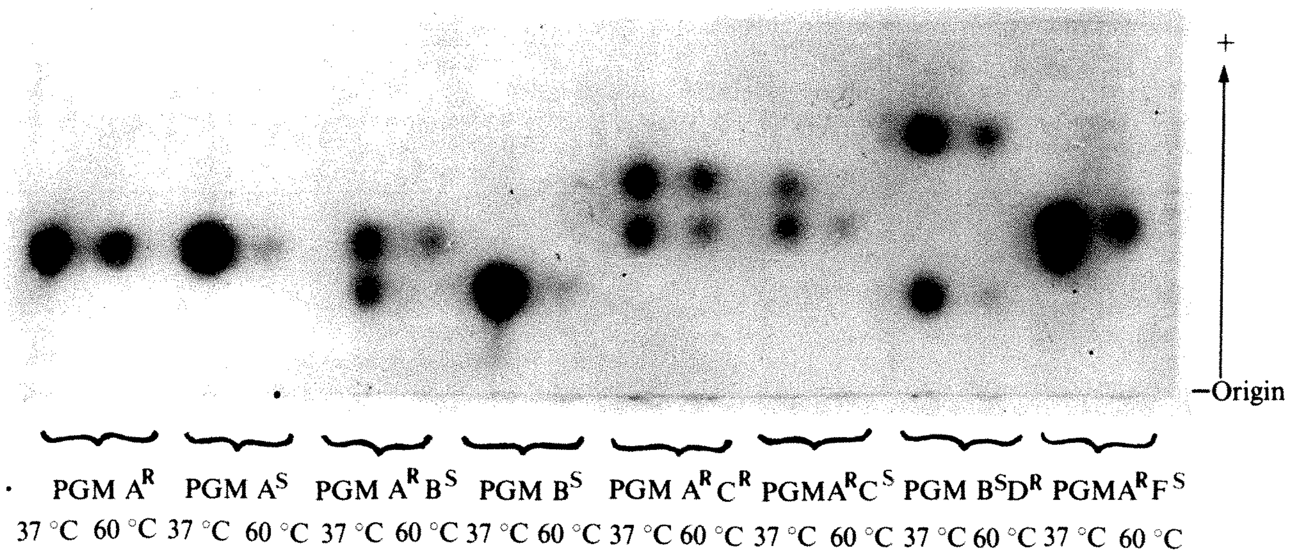

Fig. 1 Heat-sensitivity behaviour of various *Pgm* alleles. In the first procedure, for each strain to be examined 50 adult flies were homogenised in 1 ml of Tris-maleate buffer, *p*H 7.4, 10^{-3} M, diluted with 4 ml of the same buffer, centrifuged at 3,000*g* for 15 min and the clear supernatant subdivided into two aliquots which were incubated in a waterbath for 15 min, one at 37 °C and the other at 60 °C. Both were then analysed by the standard electrophoretic technique[6]. Every strain was classified on the basis of four replicated experiments. In the second procedure, for each fly to be analysed the homogenate (40 µl) was electrophoresed by the usual method. At the end of the electrophoretic run the starch gel was cut into two slices, which were transferred into thin plastic envelopes. One was dipped for 15 min in a waterbath at 37 °C, the other at 60 °C and then stained. By both these methods a given electrophoretic PGM band was classified in a clear cut way as a heat-resistant band (PGM R) or as a heat-sensitive band (PGM S) according to whether or not its PGM activity was detected after the treatment at 60 °C.

evidence that the heat-sensitivity behaviour of each PGM electrophoretic band depends on the corresponding *Pgm* structural allele is presented in Tables 2 (first procedure) and 3 (second procedure). It seems that the phenotype for heat sensitivity of each PGM band travels with the electrophoretic phenotype of the same band and is restricted to it (*cis–trans* effect). Therefore its genetic site(s) must be at the *Pgm* structural gene.

It was thus possible to search for a further polymorphic heterogeneity of the *Pgm* structural gene besides the electrophoretic one. For this purpose we determined the heat-sensitivity phenotype of common electrophoretic *Pgm* alleles derived from a laboratory and two natural populations. These alleles were tested, by the first procedure, in either the homozygous or heterozygous state as isogenic or TM2 balanced lethal stocks, respectively (Table 4). The previously homogeneous Pgm^{A} allele was split into two common isoelectrophoretic alleles, $Pgm^{\mathrm{A \cdot tr}}$ and $Pgm^{\mathrm{A \cdot ts}}$ in all samples examined. The Pgm^{B} allele seems so far to be homogeneous. Therefore a new type of structural heterogeneity of the *Pgm* gene has been discovered. This increases considerably the estimate of the degree of identified variability of this gene. For example, the degree of heterozygosity of the Castellaneta population increases from 0.17 based on the electrophoretic variation only (Pgm^{A}: 0.906; Pgm^{B}: 0.083; all the *Pgm* rare alleles: 0.011)[5] to 0.30.

Bernstein *et al.*[7] and Singh *et al.*[8] have reported common isolectrophoretic alleles of xanthinedehydrogenase in 11 species of the virilis group of *Drosophila* and octanoldehydrogenase in *D. pseudoobscura* with different thermostabilities. But they have not shown (1) that the heat-sensitivity phenotype is different in different allelic products of

Ranna (Sicilia)	67	45	2	—	20

Estimates of gene frequencies (obtained by multiplying the relative frequencies of heat-resistant and heat-sensitive alleles in each electrophoretic class by the gene frequencies of the corresponding electrophoretic alleles):

Castellaneta
$Pgm^{A,tr} = p_1 = 0.832$ } $P = 0.906$
$Pgm^{A,ts} = p_2 = 0.074$
$Pgm^{B,ts} = q = 0.083$
Pgm rare (pooled) $= r = 0.011$

Ranna
$p_1 = 0.907$ } $P = 0.947$
$p_2 = 0.040$
$q = 0.041$
$r = 0.012$

p, q and r are the estimates previously obtained by considering the electrophoretic phenotypes only[5]. p has been split further into p_1 and p_2 according to the relative frequencies of $Pgm^{A,tr}$ and $Pgm^{A,ts}$ alleles.

*Each of these genes was tested either as an isogenic line homozygous for that gene or as a balanced lethal stock in which that gene was heterozygous with a *TM2* chromosome carrying a *Pgm* allele with a known electrophoretic and heat-sensitivity phenotype.

†We propose to indicate the heat sensitivity of the *Pgm* electrophoretic alleles or phenotypes by adding to their name a superscript, *tr* and *ts* corresponding to thermoresistance and thermosensitivity, respectively.

the structural gene studied in appropriate heterozygotes, and, as a necessary consequence of this, (2) that the heat-sensitivity phenotype is transmitted together with a certainly identified structural phenotype (for example, electrophoretic). Therefore their evidence seems to be incomplete because it has not been excluded that the observed heat sensitivity phenotypes were due to a different gene. For example, the thermostability of the autosomal enzyme adeninephosphoribosyltransferase, in man is greatly influenced by the sex-linked hypoxanthineguaninephosphoribosyltransferase (HGPRT) deficiency[9]. Nevertheless it seems likely that those alleles exist because situations such as HGPRT deficiency are probably not common and, on a theoretical basis, many structural genes are expected to have polymorphic isoelectrophoretic alleles.

Nude mice from homozygous nude parents show smaller PFC responses to sheep erythrocytes than nude mice from heterozygous mothers

THE congenitally athymic mouse which is homozygous for nude (nu/nu), compared with the phenotypically normal heterozygote (+/nu) or the normal mouse (+/+) is severely deficient in its plaque-forming cell (PFC) response to sheep erythrocytes (SE)[1,2]. The minimal response of the nude is generally attributed to a deficiency of thymus-derived helper cells which are essential for a full PFC response to thymus-dependent antigens such as SE[1–3]. The amount of helper activity (T cell or T-cell-like) that nude mice may receive from their mothers is of concern in several laboratories[4–9], since most nude mice obtained routinely are born of phenotypically normal (+/nu) mothers that have T cells. There is debate about the relative importance of T-cell precursors observed in nude mice[10], which may be stimulated to express T-cell antigens by soluble factors[11], and the equally important possibilities that nudes may receive T cells and/or soluble factors *in utero* from their normal +/nu mothers or from their +/nu or +/+ littermates or from the colostrum of +/nu mothers[12]. The results of studies designed to resolve this issue remain equivocal[4–13]. There is a need[12] for studies with nude mice born of homozygous nude parents (nu/nu ♀ × nu/nu ♂) and raised by nude mothers to minimise the possibilities of transfer of functionally mature T cells *in utero* or the transfer of T cells or T-cell-like factors by the colostrum. So far this criterion has been difficult to meet since nude mothers from most common mouse strains were poorly fertile or could not raise their young[14].

In initial experiments using NIH strain nude mice, we compared the 4-d PFC responses of nude mice of the following parentages, nude (nu/nu) mothers × nude (nu/nu) fathers (type I), heterozygous (+/nu) mothers × nude fathers (type II), and type I offspring, foster nursed by +/nu mothers (type III). The breeding and husbandry of these nude offspring is to be detailed elsewhere. Briefly, the NIH nude mouse colony was established in the summer of 1972. The initial stock was received on a BALB/c background. The *nu* gene was next established into the N: NIH(S) outbred stock of mice, which has a very high reproductive performance. Breeding at this stage was conventional, that is, heterozygous (nu/+) females with homozygous (nu/nu) males yielding 50% homozygous offspring. In the second stage the nu/nu progeny was established and maintained in a specific pathogen-free (SPF)

Table 1 PFC responses of NIH strain nude mice from nude mothers and heterozygous mothers to sheep erythrocytes

Type of nude		Type of mothers		Cells per spleen	PFC	
		Born to	Nursed by	(× 10^6)	per 10^6 cells	per spleen
I	Mean ± s.e. for 10 mice	nu/nu	nu/nu	126 ± 7	1.4 ± 0.09	174 ± 11
II	Mean ± s.e. for 10 mice	+/nu	+/nu	197 ± 16	12.8 ± 3	2,652 ± 701
III	Mean ± s.e. for 6 mice	nu/nu	+/nu	153 ± 9	6.1 ± 0.5	932 ± 105

Plaque-forming cell (PFC) responses to SE of type I nude mice (homozygous nude mothers) and of type II nude mice (heterozygous +/nu, phenotypically normal mother) and type III (homozygous nude mothers, but foster nursed by +/nu mothers) are compared. The fathers in all cases were homozygous nudes. Each mouse was injected intravenously with 4 × 10^8 SE and the direct PFC count per spleen or per 10^6 acid-resistant splenocytes was estimated for individual mice by the localised haemolysis-in-gel assay described before[15,16]. Cells per spleen were estimated electronically in the Fisher Autocytometer-II. Thymus tissue was not visible in nude mice of this study.

Table 2 *In vitro* PFC responses to sheep erythrocytes by splenocytes from NIH strain nude mice and the effect of dibutyryl cyclic AMP

Type of nude splenocytes cultured		Dibutyryl cyclic AMP	Splenocytes recovered after 4 d in culture (× 10^6)	PFC detected after 4 d of culture	
				per 10^6 recovered splenocytes	per culture
I	Mean ± s.e. for 10 seriate cultures	–	10.6 ± 0.3	3.7 ± 1.8	42 ± 6
I	Mean ± s.e. for 5 seriate cultures	+	12.5 ± 0.8	32.6 ± 5.6	417 ± 95
II	Mean ± s.e. for 10 seriate cultures	–	9.6 ± 0.4	16.5 ± 2.5	153 ± 17
II	Mean ± s.e. for 5 seriate cultures	+	12.6 ± 3.2	24.2 ± 1.6	371 ± 17

Comparison of *in vitro* plaque-forming cell (PFC) responses of dispersed spleen cells from type I nude mice and type II nude mice to sheep erythrocytes (SE) after 4 d in culture. The effect of dibutyryl cyclic AMP (1.5 μM per culture of N^6, O^2-dibutyryl adenosine-3′-5′-cyclic phosphate, Calbiochem) on similar cultures are compared. Type I splenocytes (31 × 10^6 per culture) and type II splenocytes (29 × 10^6 per culture) were cultured in the presence of 2 × 10^6 SE as antigen in modified Marbrook chambers as described before[16]. The number of cells and the number of PFC were estimated as stated in the legend for Table 1.

environment by hysterectomy and foster nursing on previously established germ-free (GF) mice. This environment consists of an SPF open room barrier facility, requiring that all supplies which enter be sterile. Movement of personnel who enter is closely controlled and personnel wear sterile garments, including face masks and gloves. The rooms and animals are monitored for infectious bacteria and viruses. No evidence of infectious viruses has been found. This includes scrutiny for mouse hepatitis virus (MHV), to which nude mice are extremely susceptible In these conditions, survival of homozygotes to 28 months was achieved. In the third stage, 30 pairs of homozygous matings were established as soon as animals were available. It was important to scrutinise the colony continuously and to separate individuals suggestive of sterility and lactation-failure. By these procedures, the total number of homozygotes weaned from homozygous mothers is not much smaller than that for heterozygous mothers. Our experience is that homozygous mothers weaned an average of 9.2 offspring during their reproductive life compared with an average of 12 by heterozygous mothers.

The PFC responses of type I nudes (PFC/spleen) were 15 times less than those of type II nudes (Table 1). The difference estimated on a per cell basis (per 10^6 cells) was approximately tenfold. Type III nudes, which were produced by foster nursing type I nudes on T-cell positive, +/nu mothers showed PFC responses that were four to five times greater than type I nudes (Table 1).

In spleen cell cultures (Table 2), type I nude mouse PFC responses were similarly less than those of type II nudes. Dibutyryl cyclic AMP which exerts a T-cell like helper effect[15] augmented tenfold the PFC culture responses of type I spleen cells, raising them to approximately the control level of type II cultures not exposed to the compound.

These data show that nude mice from homozygous nude parents are more immunologically deficient with respect to their ability to activate antibody-forming cells than the more conventionally bred nude mice derived from heterozygous mothers. The greater PFC responses observed in nude mice borne by nude mothers, but nursed from birth by heterozygous foster mothers are consistent with the suggestion that athymic nude mice receive T-cell help from heterozygous mothers. Further clarification of the possible roles of both T cells and soluble T-cell-like factors awaits isolation and identification of the cells and factors. The status of T-cell precursors in nude mice described here remains to be evaluated.

Suppression of adoptive antibody responses by addition of spleen cells from agammaglobulinaemic chickens "immunised" with histocompatible bursa cells

THE report that T cells from patients with common variable hypogammaglobulinaemia can suppress immunoglobulin synthesis by B cells *in vitro*[1] implies that some forms of hypogammaglobulinaemia could, at least in part, be maintained by a patient's own T cells. Blaese *et al.*[2] described a phenomenon of "infectious agammaglobulinaemia" in line 6 chickens (USDA Regional Poultry Research Laboratory, East Lansing) which seems to represent an ideal laboratory model for the human disease. Transfer of agammaglobulinaemia with spleen cells has now also been observed consistently in strain FP and SC chickens[22]. The mechanism whereby recipients of cells from an agammaglobulinaemic donor are rendered agammaglobulinaemic is, however, difficult to analyse in such a long term *in vivo* system. Thus, further examination of the phenomenon would be greatly facilitated by a short term assay to allow better identification of the target cell.

We describe here a transfer system in which the suppressor activity of spleen cells from agammaglobulinaemic chickens on the adoptive immune response of normal spleen or bursa cells is assayed in neonatal irradiated recipients. The target system used is the antibody response to *Brucella abortus* (BA), which is thymus independent[3] and readily detected in recipients within 1 week of bursa cell transfer[4]. Using this 1-week assay, we have found that spleen cells from bursectomised (BX) donors interfere with an adoptive anti-BA response only when they are taken from BX animals previously injected with bursa cells.

Donor and recipient birds were of strains FP (B15/B21) and SC (B2/B2) (Hy-Line International). BX birds were obtained by *in ovo* injection of 3.75 mg testosterone propionate (Elkins–Sinn) on day 11 of gestation, followed by intraperitoneal injection of 4 mg cyclophosphamide (Mead–Johnson) on the day of hatching, and 3 mg on each of the 2 subsequent days[5]. Sera of BX birds were tested for Ig by double diffusion in agar, using rabbit antiserum to chicken Ig to detect readily Ig at 1% normal 8-week serum level.

Some BX birds of the FP strain were injected intravenously with 2×10^7 male bursa cells 6–13 d before being killed. For the SC strain, the injection schedule was more varied (Table 3). Chicken Ig (mixture of IgM and IgG, prepared as described[6]) was injected subcutaneously with Freund's complete adjuvant (FCA).

Table 2 Effect of pretreatment of suppressor cells on inhibition of adoptive immune response, FP strain

Bursa-immune BX spleen (4×10^7)*	Pretreatment of BX spleen†	Mean $\log_2$ agglutinin serum titres in recipients ± s.e.‡ Day 7	Day 14

*On day 0, recipients injected intravenously with 4×10^7 bursa cells from 6-week-old donors, 2×10^8 BA, with or without 4×10^7 viable spleen cells from a BX donor; this BX donor received 2×10^7 bursa cells intravenously on day −13 (experiment 4).

†Mitomycin (50 μg ml^{-1}) 15 min at 37 °C, anti-T or normal rabbit serum (1/90) and C (1/18) 37 °C for 1 h.

‡Anti-BA agglutinin titres determined on sera taken on day 7; recipients were reinjected with BA on day 7 and bled on day 14.

§$0.2 < P < 0.3$.

Recipients were either injected with 4 mg of cyclophosphamide intraperitoneally on the day of hatching and treated with 500 r. whole-body ^{138}Cs γ irradiation (Gammator M. Radiation Machine Co.) or they received 500 and 800 r. on days −2 and −1, respectively. On the day of transfer, day 0, donor cell suspensions were prepared in 0.165 M phosphate-buffered saline containing 0.2% bovine serum albumin and, in the case of bursa cell suspensions, heparin (2 μg ml^{-1}). BX spleen cells (6.7×10^6 cells per ml) were treated with rabbit anti-T serum[7] or normal rabbit serum (NRS) (1/90) and young guinea pig complement (C) (1/18) for 1 h at 37 °C. Treatment with mitomycin was for 15 min at 37 °C at 10^7 cells per ml. BX spleen donor cells (4×10^7 viable) and target bursa or spleen cells (4×10^7) were mixed just before injection into leg veins of recipients (six to eight per group). The BA antigen was also added immediately before injection (approximately 2×10^8 washed dead bacteria). Anti-BA agglutinin titres were determined on sera taken 1 week after transfer, and in some cases on sera taken at 2 weeks after a second BA injection on day 7. The day-14 sera (minimum of four chickens per group) were also analysed after exposure to 0.1 M mercaptoethanol in order to measure 7S antibody titres[8]. Experiments lasting 2 weeks were possible as control animals injected with antigen alone on days 0 and 7 gave no appreciable responses.

The results in Table 1, obtained in the FP strain, show

that BX spleen, injected together with either bursa or spleen cells from 6–12-week-old normal chickens, did not inhibit responsiveness of normal cells. But when spleen cells were taken 1–2 weeks after intravenous injection of 2×10^7 bursa cells into 3–4-month-old BX chickens, they caused a considerable reduction of the adoptive antibody response (Tables 1 and 2). Injection of fewer bursa cells (2×10^6, experiment 3) was somewhat less effective but still seemed to immunise the BX donors much better than did 2×10^6 spleen or thymus cells. The lack of immunisation with thymus cells suggested that bursa cell-specific antigen rather than antigen determined by minor histocompatibility loci was responsible for the immunisation effect. The age of the BX chicken at which immunisation with bursa cells could be effected was not determined precisely, but in one experiment (not in Tables 1 and 2) such an immunisation proved ineffective in a 2-month-old BX chicken. Other attempts to immunise BX chickens were made using chicken-Ig in CFA; these had no effect (experiment 2, Table 1). This suggested that Ig molecules, as present in serum, did not constitute the moiety against which BX spleen cells were reacting. The fact that the inhibitory effect on bursa and spleen cells occurred in recipients which obviously had circulating maternal IgG (ref. 9) supports this conclusion. Further efforts towards identification of the bursa cell antigen included an experiment (not in Tables 1 and 2) in which immunisation with 4×10^6 paraformaldehyde-treated (30 min at 4 °C, $5+10^6$ cells and 0.1 g ml^{-1}) bursa cells failed.

Since bursa cells from young chickens generally give a higher adoptive response to BA than do spleen cells[4], experiments to characterise the effector cell further were performed with bursa cells as the target. "Bursa-immune", BX spleen cells still reduced the immune response after exposure to mitomycin ($P<0.05$ compared with $P<0.01$ for untreated cells, Table 2). In addition, the effector cell in the BX spleen was largely eliminated by treatment with rabbit anti-T but not by NRS+C, suggesting its T-cell nature (Table 2). Thus, the BX spleen cell responsible for this phenomenon seems to be a T cell which, after recent immunisation with its target cell, does not need to proliferate to inhibit B cells. For prolonged maintenance of B-cell suppression in recipients, however, the untreated or NRS-treated BX spleen cells were more effective than were the mitomycin-treated (compare day 14 with day 7 results, Table 2).

Several of the recipients in experiment 4 which showed no anti-BA on day 14 after transfer of bursa cells + "bursa-immune" BX spleen still failed to produce anti-BA 4 weeks later and had no detectable Ig in their sera. This latter observation suggests strongly that the phenomenon studied here is analogous to that described as "infectious agammaglobulinaemia" by Blaese *et al.*[2] and Palladino *et al.*[22].

As mitomycin-treated cells were effective, an experiment was performed in which a 5 and a 9-month-old FP chicken —birds which were undergoing and which had undergone complete involution of the bursa—were injected with bursa cells and used as spleen donors 1 week later. We reasoned that natural involution of the bursa might be caused by an immune response to bursa antigens occurring at a later age. Mitomycin was required since adult spleen cells would otherwise transfer their own anti-BA response. The mitomycin-treated cells from these spleens did not reduce the ability of bursa cells to give adoptive anti-BA responses. This approach, therefore, was discontinued.

Results with the SC strain were much less striking than those with the FP strain (Table 3). Immunisation with neither bursa nor with spleen cells caused a rapid appearance of bursa-inhibitory activity in the spleen cells of agammaglobulinaemic donors. A longer interval after immunisation with bursa cells may have been needed, as suggested by the results of experiments 7 and 8. The later (day 14) bleedings in experiment 8 indicated that both 19S and 7S anti-BA antibody formation were suppressed. There was also a decreased response in a later bleeding taken in experiment 6 (not shown in Table 3). In this experiment, the day 14 data were very similar to those in experiment 8, but loss of several control recipients precluded appropriate analysis.

Experiments by Palladino *et al.*[22] have also shown that transfer of agammaglobulinaemia was obtained more readily in FP strain than in SC strain, although inhibition of antibody formation could be demonstrated in both. It was further observed in our laboratory that FP chickens give far better delayed hypersensitivity reactions to protein antigens than do SC chickens, suggesting a much more responsive T-cell system in the FP strain. The results reported here suggest that the difference between the FP and SC strains noted by Palladino *et al.* was due to a variation in T-cell reactivity and not to a difference in B-cell mass, since a uniform dose of target cells was used in our experiments. The more readily demonstrable BX spleen immunity to bursa cells in the FP strain may also be related to the relative ease in the FP compared with the SC strain with which agammaglobulinaemia can be obtained (unpublished).

The antigen to which the splenic T cells of BX chickens respond is unknown. Candidates include (1) Ig in a form peculiar to the B-cell surface (IgD analogue)[10]; (2) viral antigen which might normally be expressed on bursa and B cells only[11,12], and (3) any other surface antigen unique to B cells[7,13] in the resting and/or activated state. This is reminiscent of the conclusion of Jacobson *et al*[14] that the target antigen on cells in long term, T-cell mediated[15] allotype suppression could not be Iglb in the same form as it is in the circulation. This phenomenon in mice, applying to a subpopulation of B cells, seems strikingly similar to that of transferred agammaglobulinaemia in chickens, where all B-cell function becomes suppressed. It has also been suggested that suppressor cells have a role in the maintenance of long term allotype suppression of rabbits[16].

Since the suppression of antibody production in our studies as well as in those of Palladino *et al.*[22] and Blaese *et al.*[2] results in agammaglobulinaemia of recipients, the phenomenon is not likely to be antigen specific. Tada and Takemori[17], however, have noted that even in studies on antigen-specific T-cell suppression of the immune response, the susceptibility of B cells to the specific suppressive influence seems to differ depending on the stage of differentiation of B cells and/or on the class of Ig they synthesise.

The lack of tolerance to an organ which was removed during ontogeny and reintroduced later in development was described originally for the hypophysis in tadpoles[18]. The observation that immunity to bursa cells can be induced in chickens deprived of bursa early in ontogeny may similarly be ascribed to a lack of tolerance to tissue (bursa)-specific antigens. The development of immune T cells, in this case called suppressor cells, may then represent the normal mechanism of cytotoxic cell development such as is observed to minor transplantation antigens[19] and to tumour antigens[20,21].

We thank Melvin Bell and Pedro Sanchez for assistance. *B. abortus* was given by Dr C. E. Watson, USDA National Animal Diseases Laboratory, and mitomycin C was obtained through the courtesy of Dr H. B. Wood Jr, National Cancer Institute. This work was supported by grants from the US Public Health Service.

Modification of fibrosarcomas and squamous cell carcinomas of mouse skin using various tissue extracts

RECENT attention has focused on the possibility of utilising (or mimicking) aspects of mitotic processes in the control of cancer. Bullough, Rytömaa and others used preparations of mitosis inhibiting proteins (chalones) to produce remissions (total in some cases) in a number of tumour tissues[1–3]. These chalone preparations were shown to be tissue specific. Only epidermal chalone worked on epidermal tumours. Liver extracts prepared in the manner of epidermal chalone extracts gave no remissions in epidermal tumours[4]. Melanocyte chalone was necessary for remissions in melanomata[5] and granulocyte chalone was successful in the treatment of chloroleukaemia[6]. We report here remissions resulting from the treatment of chemically-induced fibrosarcomas and squamous cell carcinomas of the skin in mice using extracts of various mouse tissues. We also report the presence of mitosis-inhibiting protein in these extracts.

Excised whole skin, liver or tumour, frozen in liquid N_2 and minced, was homogenised with 0.14 M NaCl–0.14 M phenol in a Waring Blender for 15 h at 4 °C. After centrifugation for 2 h at 2,500 r.p.m., the supernatant, combined with 5% sodium dodecyl sulphate in 45% EtOH, was stirred for 24 h at 4 °C, then centrifuged (1 h, 2,500 r.p.m.). The resulting supernatant was transferred to a new tube and again centrifuged (1 h, 2,500 r.p.m.). The final supernatant was combined at 4 °C with an equal volume of cold 95% EtOH and the precipitate collected.

One portion of the extract obtained from whole skin was treated with α-chymotrypsin to remove protein. A second portion was treated with deoxyribonuclease and ribonuclease to remove nucleic acids. Analysis, using modified Dische techniques[7], of the extracts showed that the percentage DNA tripled after chymotrypsin treatment relative to the untreated skin extract and, after deoxyribonuclease–ribonuclease treatment, was one-sixth that of the untreated skin extract. Each of the five extracts (the three tissue extracts and the two treated skin extracts) were suspended in sterile 0.9% saline (100 μg extract per 0.05 ml) for injection.

Fibrosarcomas and squamous cell carcinomas were induced in male BALB/c mice through three injections each

Table 1 Percentage remissions for all animals

‡Tumour size measurements not made.

of 100 μg (in 0.05 ml linseed oil) of either 9,10-dimethylbenzanthracene or benz(*a*)pyrene spaced over a period of 2 weeks. Tumours were developed for 3 months and then the animals were screened. Those with very large tumours (larger than about 10 cm^3) and those showing no tumour development were excluded (in the environmental control group no evidence of spontaneous tumour formation was observed). Tumours were then inoculated with 5–100 μg injections (over a 1-month period) of one of the extracts. Effects of the extracts on tumours were monitored by size measurements. Selected animals were killed and tissue samples examined by the Department of Pathology, College of Medicine, University of Kentucky.

Untreated fibrosarcomas and squamous cell carcinomas showed no spontaneous remissions. Injection into tumours of extract or of 0.9% saline produced uniform minimal mechanical damage. The injection of 0.9% saline alone produced no remissions. Subcutaneous injection of tumour extract or of skin extract into healthy animals produced no apparent effects, establishing the absence of any general cytotoxic material in those extracts.

In two separate experiments, with separate preparations of the whole (untreated) skin extract and with separate animal populations similar effects on tumours were noted (Tables 1, 2 and 3). For all animals in these groups (both those with fibrosarcomas (FS) and those with squamous cell carcinomas (SCC)) the percentage of animals showing remissions one month after initiation of treatment with skin extract were 53% (n=28) and 48% (n=40). For animals with SCC, the percentage remissions were 73% (n=15) and 88% (n=16). For animals with fibrosarcomas, the percentage remissions were 31% (n=13) and 21% (n=24). The smaller percentages observed for animals with FS could result from the difficulty in reaching all parts of the tumour with the extract. FS were larger than the SCC, and may have been too large to treat in some cases—sizes at treatment initiation ranged up to 10 cm^3. The percentages fall after the first month, suggesting that the effect of the skin extract may be temporary and/or that a longer period of treatment may be necessary. The animals with continuing remissions had smaller tumours initially.

Table 3 Percentage remissions for animals with fibrosarcomas

Group*	No. of mice	Percentage remissions		
		1 month	2 months	3 months
(1)	13	31	‡	‡
(2)	24	21	8	0
(3)	7	14	0	0
(4)	8	0	0	0
(5)	10	25	10	10
(6)	5	0	0	0

*Groups as in Table 1

†Percentage of each group still in remission 1, 2 and 3 months after treatment was started.

‡Tumour size measurements not made.

The liver extract produced remissions in 47% (n=19) of all mice treated with liver extract (Table 1). The liver extract produced remissions in 67% (n=12) (Table 2) of the animals with SCC and 47% (n=7) (Table 3) of the animals with FS. If the extraction of skin and liver yield the same products, then these percentages for the liver extracts, which are similar to those for the untreated skin extract, indicate a lack of tissue specificity in the extract actions. Tumour extract produced delayed remissions only (0% 1 and 2 months after treatment initiation for both FS and SCC; 33% (n=12) for all animals 3 months after treatment; 57% (n=7) 3 months after for SCC; and 0% (n=5) after 3 months for FS) (Tables 1, 2, 3). The reason for these delayed remissions is uncertain, but it may be that the remission-producing protein in the tumour extract is present in a decreased amount.

Treatment of tumours with skin extract reacted with nucleases produced remissions in percentages (56% (n=18) for all animals; 75% (n=8) for SCC; 25% (n=10) for FS) (Tables 1, 2, 3) similar to those observed following treatment with the unreacted skin extract. Skin extract treated with chymotrypsin, however, yielded markedly reduced remission percentages (21% (n=14) for all animals; 50% (n=6) for SCC, 0% (n=8) (Tables 1, 2, 3), suggesting that the active component in the skin extract is protein.

An experiment measuring the uptake of ^{3}H-thymidine into cultures of mouse ear in Hank's medium demonstrated the presence of a mitosis-inhibiting substance in untreated skin extract. This material may or may not be the same material which affects tumours.

We wish to thank the American Cancer Society and the Department of Chemistry, University of Kentucky for their support of this work.

Mediation of retinoic acid-induced growth and anti-tumour activity

VITAMIN A (retinol) is a nutrient essential for vision, growth, reproduction and proper differentiation of epithelial tissue[1]. Some retinol is oxidised to retinoic acid (vitamin A acid) *in vivo*[2], but if an animal is provided with retinoic acid in place of dietary retinol, it can only partially substitute for the missing retinol; vision[3] and reproduction are impaired[4]. Sporn *et al.*[5] have described two systems for evaluating the activity of retinol, retinoic acid, and their analogues *in vitro*. One measures the ability of such compounds to promote growth by determining RNA, DNA and protein levels after addition of the test compound to epidermal cell cultures derived from newborn mouse skin; the other measures ability to reverse metaplasia of the epithelial cells of trachea explanted to organ culture from vitamin A-deficient hamsters. Retinoic acid is active in both systems.

In addition, retinoic acid and an aromatic analogue of the acid have been shown to reverse metaplasias of mouse skin induced by application of carcinogenic drugs and expressed as papillomas and tumours[6]. The molecular mechanism(s) by which retinoic acid or retinol control growth and differentiation, as well as the mechanism of their carcinostatic ability, is still unknown but may involve the specific cytoplasmic binding proteins we have discovered for retinol and retinoic acid The cellular retinol-binding protein binds retinol *in vitro*[7] and *in vivo*[8], is present in many tissues, and exhibits binding affinities for *cis* isomers of retinol which parallel the growth-promoting activity of these isomers in the whole animal[9]. The cellular retinoic acid-binding protein binds retinoic acid *in vitro* with high specificity and is present in normal rat[8] and human organs[10] as well as some human cancers[11]. The two proteins have been separated physically and purified 1,000-fold from rat testis[8]. There has also been a preliminary report of a retinoic acid-binding protein in embryonic chick skin[12].

In our investigations into the mechanism(s) of action of retinol and retinoic acid we have examined newborn mouse skin, hamster trachea, and chemically induced papillomas of mouse skin for the presence of the cellular retinoic acid-binding protein. In addition, using extracts of mouse skin papillomas, human breast tumour, and a 1,000-fold purified preparation from rat testis as sources for the binding protein, we have examined its relative affinity for some ring analogues of retinoic acid (Fig. 1). In all cases we find that the binding characteristics of the protein towards the analogues correlate with the activity of the compounds in the assay systems of Sporn *et al.* as well as with reported tumour-inhibiting activity.

Newborn mouse skin, adult mouse skin, mouse skin papillomas induced by treatment with 7,12-dimethylbenz(*a*) anthracene and croton oil[6], hamster trachea, and human breast tumour were homogenised in 0.05 M Tris-HCl, *p*H 7.1, and soluble extracts prepared as described previously[8]. A preparation of cellular retinoic acid-binding protein, purified 1,000-fold from rat testis as described before, was also used[8].

The binding protein was detected and its affinity to various analogues was determined as described earlier, using radioactive retinoic acid and sucrose gradient centrifugation[8]. The binding affinity was assessed by competition experiments and expressed as percentage inhibition (percentage decrease) of binding of radioactive all-*trans* retinoic acid observed when the competing analogue was present in a 100-fold molar excess over the ^{3}H-retinoic acid[8]. Details of the determination are presented in Table 1.

Analysis of extracts of newborn mouse skin and of hamster trachea revealed a peak of radioactivity in the 2S region of the sucrose gradient, indicating the presence of cellular retinoic acid-binding protein. It was also established that the mouse skin papillomas have a high level of the binding protein, quantitated as described previously[8], (860 pmol of ^{3}H-retinoic acid bound per g wet tissue) compared with control skin of mice of comparative age (56 pmol ^{3}H-retinoic acid bound per g of wet tissue). This difference may be due to an increase in the numbers of a cell type which normally contains this binding protein, or due to an altered expression of the genome. We have also found that several malignant human tumours (breast and lung) contained the cellular retinoic acid-binding protein but it was not detectable in normal tissue from the same organ of the same patient[11].

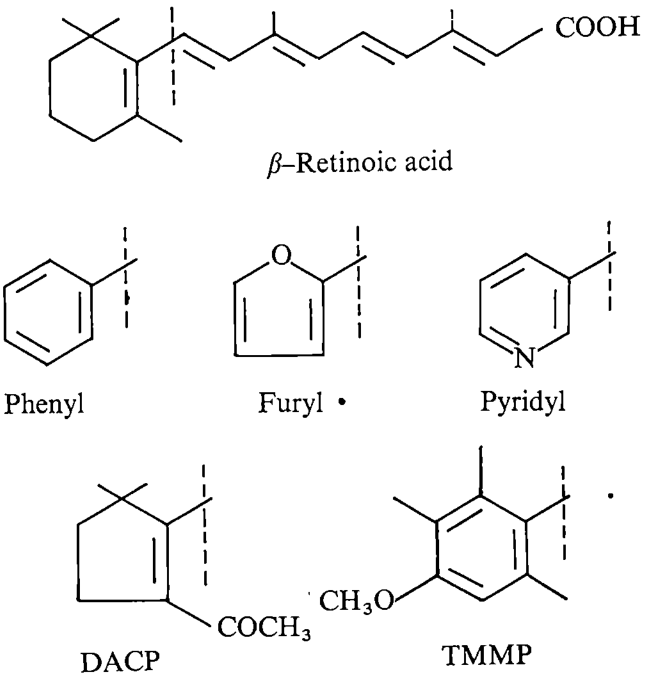

Fig. 1 Structures of β-retinoic acid and analogues with ring modifications.

The presence of this binding protein suggests that the protein might mediate the action of retinoic acid. This contention is strengthened by the affinity which the cellular retinoic acid protein exhibits, independent of the source, towards analogues of retinoic acid. Both the dimethylacetyl-cyclopentenyl (DACP) and trimethyl-methoxyphenyl (TMMP) analogues of retinoic acid are effective competitors for the binding of retinoic acid (Table 1). The phenyl, furyl and pyridyl analogues were less effective competitors in the order listed, with presumably decreasing affinities. These results correlate well with the ability of these compounds to promote growth in epidermal cell cultures derived from mouse skin and to reverse the metaplasia of hamster trachea induced by vitamin A deficiency as shown by Sporn *et al.*[5]. These authors noted that DACP and TMMP had marked activity in their systems, whereas the phenyl analogue had minimal activity and the furyl and

Table 1 Percentage inhibition of binding of all-*trans* ^{3}H-retinoic acid to cellular retinoic acid-binding protein by analogues of retinoic acid

Compound	Rat testis binding protein (%)	Mouse papilloma binding protein (%)	Human breast tumour binding protein (%)
All-*trans* retinoic acid	100	100	100
DACP analogue	100	100	100
TMMP analogue	100	100	100
Phenyl analogue	42	36	36
Furyl analogue	34	16	24
Pyridyl analogue	22	0	0

The preparations, made to 0.3 ml with 0.05 M Tris, *p*H 7.1, were incubated with 1×10^{-7} mmol radioactive all-*trans* retinoic acid (1.37 Ci mmol^{-1}) in the absence and presence of 1×10^{-5} mmol unlabelled retinoic acid analogues shown in Fig. 1. Each compound was added in 5 µl ethanol containing 1 mg ±-α-tocopherol ml^{-1}. Incubation mixtures whose protein concentration was below 1 mg ml^{-1} also contained 0.3 mg myoglobin and 0.3 mg purified bovine serum γ-globulin fraction. After incubation in the dark at 4 °C for 5 h, 0 2 ml of a charcoal–dextran solution was added with agitation After 5 min the charcoal–dextran was removed by centrifugation and 0.2 ml of the supernatant liquid was layered on a 5–20% linear sucrose gradient and centrifuged at 148,000*g* for 20 h. The gradients were collected in twenty fractions and the radioactivity of each fraction determined. Binding to the cellular retinoic acid-binding protein was indicated by a peak of radioactivity in the 2S region of the gradient.

pyridyl analogues seemed to be devoid of activity, compared with retinoic acid.

The apparent affinity of the cellular retinoic acid protein towards the TMMP analogue is of particular interest in that administration of the ethyl ester of this compound, or retinoic acid itself, is effective in preventing induction of mouse skin papillomas. These compounds can also cause the disappearance of the papillomas once induced[6].

The DACP analogue of retinoic acid is reported to block the ability of 3-methylcholanthrene to induce hyper- and metaplasia of prostate epithelium[13]. We have not examined this tissue for presence of the binding protein but we note, as have others[12], that the DACP analogue binds effectively to the protein.

It has been suggested that the reversal of metaplasias induced by vitamin A deficiency and by chemical carcinogens by retinoic acid and its TMMP analogue may be similar phenomena[14] The striking similarity between the binding affinity of the cellular retinoic acid protein for retinoic acid analogues and the growth-promoting as well as anti-tumour activity of these analogues suggests, circumstantially, that the action of retinoic acid in these instances could be mediated by this cellular protein.

Furthermore, the results reported here, as well as those reported earlier for cellular retinol binding protein[8], suggest that evaluating analogues of retinol and retinoic acid for their ability to bind to cellular retinoic acid or retinol-binding protein may be a useful preliminary screening step to identify those with potential growth or anti-tumour activity. Conversely, screening tumours for the presence of binding protein may indicate possible responsiveness of the tumours to treatment by such compounds

We thank Dr P. W. Trown for samples of mouse skin papillomas and untreated control skin. We also thank Hoffmann-La Roche for providing the analogues of retinoic acid and ^{3}H-retinoic acid. This work was supported by grants from the US Public Health Service.

Nutrient-dependent arrest of fibroblast growth is partially reversed by insulin but not fibroblast growth factor

REINITIATION of the growth of quiescent, non-transformed fibroblasts in tissue culture is achieved by addition of serum[1,2] or low concentrations of certain polypeptide hormones[3–6]. These agents which are thought to interact primarily with the surface of the cell[4] presumably require a second signal to be transmitted to the interior. An increase in the intracellular "availability" of low molecular weight nutrients has been suggested to fulfil such a role[7,8]. Mouse fibroblasts placed in different media depleted in certain low molecular weight nutrients reversibly ceased growth in either the G_1/G_0 phase (phosphate, histidine plus glutamine deprivation) or at random (methionine, leucine) in the cell cycle[9,10]. We have found that insulin and other agents stimulated these cells (except those arrested by leucine depletion) to synthesise DNA and divide, whereas fibroblast growth factor (FGF) which normally initiates cell growth in quiescent cultures arrested predominantly by serum depletion of the medium[5,6] was ineffective. This suggests a possible differential basis for their normal mode of action.

Swiss mouse 3T3-4A fibroblasts· in medium containing 10% serum cease growing mainly because of the exhaustion of serum growth factors. Addition of low concentrations (50 ng ml^{-1}) of FGF initiated approximately 40% of these cells to synthesise DNA whereas addition of similar concentrations (50 ng ml^{-1}; Table 1, 250 ng ml^{-1}; not shown) of insulin alone yielded only a small increase. When added with FGF, however, insulin substantially increased the number of cells synthesising DNA, in agreement with previous reports[11,13]. Addition of the original concentration of phosphate (Table 1), glucose or amino acids[14] (not shown) had no effect. This showed that the cultures were completely dependent on the addition of macromolecular components in serum for the reinitiation of cell growth.

CALCUTTA

Fig. 1 Time of induction of DNA synthesis and cell division. Cultures were plated in medium containing 1/100 of the normal phosphate concentration and grown as in Table 1(2). After 3 d insulin (100 ng ml^{-1}) (●) or normal concentrations of phosphate (△) in DEM was added and cultures were exposed for 3 h to ^{3}H-thymidine (3 μCi ml^{-1}) at 3 μM after varying times. The indicated time represents the mid-point of the 3-h exposure to ^{3}H-thymidine (– – –). The c p.m. recorded represent two-thirds of the total radioactivity incorporated into DNA per culture Cell numbers per Petri dish were also recorded (—).

Non-growing 3T3-4A cultures were also obtained by reducing the phosphate, glutamine plus histidine, methionine or leucine concentrations to respectively 1/100, 1/25, 1/25, 1/100 of that present in normal medium. Complete removal of any of these essential nutrients led to cell death within 24 h. Addition of FGF, at 50 ng ml^{-1} (Table 1) or up to 250 ng ml^{-1} (not shown) barely increased the number of radioactively labelled nuclei or the number of cells Addition of hydrocortisone with FGF was also without effect (Table 1). Addition of 250 ng ml^{-1} of insulin alone, however, initiated substantial increases in DNA synthesis (50–60% radioactively labelled nuclei) and in cell numbers in cultures starved for phosphate and histidine plus glutamine (Table 1). Insulin's growth-promoting effect occurred at concentrations from 10 ng ml^{-1} reaching a maximum at about 100 ng ml^{-1} (not shown), while the time required to induce DNA synthesis and cell division was similar to that observed on restoration of the full phosphate concentration

Swiss mouse 3T3-4A cells were plated in 2.5 ml of 10% dialysed foetal calf serum and Dulbecco's modified Eagle's medium (DEM) and grown for 12 d (5 d at confluency 0.94×10^5 cells per 3.5 cm dish). (1), As previously described (ref. 6). For the nutrient-depleted cultures 3×10^4 cells were plated into 10% dialysed foetal calf serum and DEM containing 1/100 of phosphate (2), 1/25 of histidine and glutamine (3), 1/25 of methionine (4) and 1/100 of the normal leucine (5) concentrations. After 3 d the cells reached final densities of 1×10^4–8×10^4 per dish. For phosphate and histidine plus glutamine-deprived cultures 93% to 94% of the cells stopped in the G_1 phase of the cell cycle, whereas cultures starved of methionine and leucine mainly ceased growth randomly[10]. Then 50 ng ml^{-1} fibroblast growth factor (FGF), 250 ng ml^{-1} insulin (50 ng ml^{-1} in (1))(I), 20% dialysed foetal calf serum or the normal concentration of phosphate (2), histidine plus glutamine (3), methionine (4), leucine (5) were added. The initial concentration of phosphate in DEM was added to (1) (*). The fraction of cells with radioactively-labelled nuclei and the cell numbers per 3.5-cm dish were recorded as described previously[6]. For autoradiography the cultures were exposed to 3 μCi ml^{-1} ^{3}H-thymidine at 1 μM from 8 to 36 h after additions throughout the entire DNA synthetic period in synchronised cultures. The percentage of cells with radioactively-labelled cell nuclei on addition of 0.5 μg ml^{-1} hydrocortisone (HC) was (1) HC alone 4%; FGF+HC, 40% (2) HC, 8%; FGF+HC, 11%; HC+I, 44%; FGF+HC+I, 60% (3) HC, 5%; FGF+HC, 10%; HC+I, 30%; FGF+HC+I, 70% (4) HC, 7%; FGF+HC, 8%; HC+I, 30% (5) HC, 8%; FGF+HC, 9%; HC+I, 20%. Serum was dialysed for 3 d against 10 volumes of isotonic saline with six changes at 4 °C. It then contained less than 1% of the amino acid concentrations present in the original preparations as determined in the amino acid analyser. In cultures where phosphate or histidine plus glutamine had been completely removed from the medium addition of insulin had no effect.

(Fig. 1). Similar results were obtained with quiescent 3T3-4A cells or human diploid fibroblasts[16] exposed for 3 d or 5 d respectively to 1/100 of the normal glucose or phosphate concentrations. Addition of 250 ng ml^{-1} of insulin doubled the number of cells by 40 h without any increase in the controls (not shown). In 3T3-4A cultures deprived of methionine and leucine, insulin induced only 30% and less than 10% increases in cell numbers and radioactively labelled nuclei respectively (Table 1). Addition of 20% dialysed foetal calf serum or the missing nutrient, initiated the majority (60–90%) of the cells to synthesise DNA and divide in all cultures.

The following control experiments (not shown) suggested that a contaminant[16] was not responsible for insulin's growth-promoting effects. (1) Both 250 ng ml^{-1} of EDTA-dialysed or non-dialysed insulin preparations initiated 30–50% of the phosphate or glutamine plus histidine-starved 3T3–4A cells to synthesise DNA and divide. (2) Extensively boiled insulin or insulin digested with papain bound to beads were completely unable to initiate DNA synthesis and cell division in similar conditions. In the case of other hormones, preparations of ovarian growth factor[17] at 100 ng ml^{-1} increased the incorporation of ^{3}H-thymidine into DNA 10-fold and approximately doubled 3T3 cell numbers when added to quiescent cultures maintained in low phosphate (Table 2) or 1/25 of the normal glutamine (not shown) concentration. Hydrocortisone at 0.5 μg ml^{-1}, oxytocin, vasopressin, glucagon and prolactin (not shown)—all at 50 ng ml^{-1}—had no effect, whereas prostaglandin E_1 at 30 μg ml^{-1} abolished the capacity of insulin to initiate cell division (Table 2).

Insulin may exert its growth-promoting effect by increasing the intracellular transport of the limiting nutrient[7,8] since it predominantly increases uptake rates of the A (sodium-dependent) amino acid transport systems and not the L (sodium-independent) system[18] in various tissues[19]. The A group includes glutamine, histidine, and methionine while the L group includes methionine and leucine[19]. Also EGF and insulin stimulate α-aminoisobutyrate uptake in cultured human fibroblasts[20]. Direct changes in transport rates *per se* cannot solely explain the ability of insulin to initiate cell growth in cultures partially deprived of phosphate, since the same concentrations of FGF and insulin stimulate approximately the same increase in phosphate uptake in medium containing 1/100 of the normal phosphate ion concentration[13].

Here we have shown that insulin, unlike FGF, can initiate DNA synthesis and cell division in fibroblast cell cultures whose growth is completely dependent on the concentration of a number of limiting nutrients. Conversely, FGF initiates substantial increases in DNA synthesis and cell division in cultures allowed to become quiescent without artificial depletion of the culture medium, whereas insulin at the same low concentration has little effect. Thus the hormonal regulation of cell growth in cultures depleted of low molecular weight nutrients differs from that in cultures essentially deprived of serum. This suggests that growth-controlling polypeptide hormones may be divided into at least two distinct classes; those which depend for their action on general changes in certain intracellular nutrient concentrations and those which require additional intracellular signals for their mitogenic activity.

Table 2 Specificity of the initiation of cell growth in phosphate-deficient medium

Additions	^{3}H-DNA (c.p.m. $\times 10^{-5}$)	Cell no. ($\times 10^{-5}$)
None	0.25	0.69
Insulin	2.16	1.12
Oxytocin	0.17	0.82
Vasopressin	0.18	0.95
OGF	2.06	1.24
Hydrocortisone	0.22	0.45
Insulin+PGE$_1$	0.32	0.64

Cells were grown as described in Table 1(2) and after 3 d in medium containing 1/100 of the normal phosphate concentration either 50 ng ml^{-1} of insulin, oxytocin, vasopressin, 100 ng ml^{-1} ovarian growth factor (OGF), 0.5 μg ml^{-1} hydrocortisone, or 30 μg ml^{-1} prostaglandin E_1 (PGE$_1$) were added as indicated. PGE$_1$ was added 10 min before insulin. The c.p.m. of ^{3}H-thymidine incorporated into DNA and the number of cells were recorded as described in Fig. 1 except that the radioactive-labelling time was from 8 to 36 h after additions. Restoration of the normal concentration of phosphate yielded 1.36×10^5 cells.

We thank Dr R. Dulbecco for advice, support and criticism of the manuscript, Dr D Gospodarowicz, Salk Institute for gifts of fibroblast and ovarian growth factors, Dr J. Pike, UpJohn Company for prostaglandin E_1, and Nancy Neyhard for technical assistance. This work was supported by a Jane Coffin Childs Memorial Fellowship to D.K.

A surface-active agent involved in PVC-induced haemolysis

MANY different forms of PVC powders are manufactured, the variety of the polymers depending on the initial constituents in the reaction mixture. Suspension homopolymers and paste (emulsion or microsuspension) polymers form 91% of the total PVC produced in the US. The latter products range in particle diameter from 0.5 to 30 µm and generally have ionic detergents added during their manufacture, whereas suspension homopolymers have no ionic detergent and are of larger particle diameter (60–180 µm). A preliminary investigation[1] had shown that some forms of PVC particles produced haemolysis *in vitro* and it was suggested that this effect was due to some residual component of the preparation (not vinyl chloride monomer) located on the surface of the particle. The following data support these findings and suggest that the surface-active factor is ionic detergent, used in the manufacture of the paste polymers.

A range of PVC samples was tested for haemolytic activity; fourteen of these were obtained from normal production processes and were used without further treatment; eight samples were specially prepared so that the associated detergent and other factors were different in each case; and a further four samples (20–23) were normal production materials which had been subsequently treated with components (other additives) of the reaction mixture. The results shown in Table 1 are for representative samples of the different types of PVC preparation. Suspension homopolymers have no haemolytic activity unless experimentally treated with detergent (compare samples 19 and 3). A considerable mass of this type of polymer is necessary to produce a significant haemolytic action, and the detergent, its relative concentration and the presence of other additives are also critical factors (compare sample 19 and samples 9 and 8).

All the paste polymers of normal commercial origin or those experimentally produced showed some haemolytic activity although this was low when the detergent code C (a derivative of a sulphated oleate ester) was present (samples 12, 20, 21 and 23). Particularly strong haemolytic potential was found for PVC paste polymers containing code B detergent, sodium dodecyl benzene sulphonate (samples 10, 14 and 18) and in two samples of unknown composition. Paste polymers containing the detergent sodium lauryl sulphate (code A) produced significant haemolysis but were not as active as samples containing detergent B. The haemolytic activity of paste polymers with code A detergent was dependent on: the particle size of the PVC sample (samples 17 and 7 at 10 mg exposure); the total concentration of the detergents associated with the particle surface (samples 15 and 7); and the presence of additives and other detergents (samples 7, 20 and 22).

It has been reported previously[1] that PVC-induced haemolysis could be markedly reduced if the sample was first washed with water or saline and that once removed, the surface-active factor was too dilute or did not retain activity in solution. The present studies have, however, indicated

Table 1 Haemolytic potential of different PVC samples

PVC sample code number	Sample description	Particle size (µm)	Detergent code	% Haemolysis produced by 5 mg	10 mg	20 mg	50 mg
3	SH (NP)	60–120	Absent	—	1	—	1
8	SH (EP)	60–120	B	—	1	—	2
9	SH (EP) low detergent	60–120	A	—	1	—	3
19	SH (EP)	60–120	A†	5	7	13	83
5	Vinylchloride–Vinylacetate copolymer	60–180	Absent	—	0	—	0
7	Paste polymer (NP)	0.5–30	A†	10	99	—	90

10	Paste polymer (NP)	0.5–30	B	100	97	—	—
14	Paste polymer (EP)	0.5–30	B	99	100	—	—
18	Paste polymer (EP) plus sulphosuccinate	0.5–30	B	100	98	—	—
24	Paste polymer (NP)	Unknown	Unknown	99	99	—	—

Haemolysis experiments were carried out as described previously[1] in quadruplicate.

SH, Suspension homopolymer; NP, in normal production; EP, experimentally produced; A, sodium lauryl sulphate; B, sodium dodecyl benzene sulphonate; C, sulphated oleate ester–sodium or potassium; †, at least two additives present; *, single additive present. PVC sample codes are Chemical Industries Association identification numbers.

that some samples (10, 14, 18 and 24) still retain haemolytic potential after washing in buffered saline and that the first wash from 3 of these samples (10, 18 and 24) retains haemolytic potential (45–100%). It is possible that after centrifugation, some very fine particles of PVC remain in the wash material and so account for the haemolytic activity in the wash. Diameter size distribution data suggest that 30–50% of particles in some samples are below 2 μm. The results obtained by further processing the wash material through a 0.2-μm filter before testing for haemolytic potential would support this hypothesis. The wash from one sample (18) still produced 100% haemolysis after passage through the 0.2-μm filter although this effect was reduced to 4% by passage through a 0.01-μm filter. It could also be argued, however, that detergent in the washings binds to the Millipore filter thus reducing the haemolytic potential of the filtered washings.

Most of the paste polymers containing the detergent sodium dodecyl benzene sulphonate (10, 14 and 18) retained high haemolytic activity (75–100%) after washing in saline, an effect particularly pronounced with sample 18 which also contained sulphosuccinate. This effect was not found with PVC samples containing sodium lauryl sulphate (10–20%) which is more readily solubilised. The haemolytic potential of the former samples, however, was totally reduced if they were first treated with ethanol.

Thus, in summary, it is evident that suspension PVC homopolymers have little, if any, haemolytic potential, whereas paste or emulsion powders produce haemolysis probably due to the presence of ionic detergent on their surface. The extent of reaction of these latter PVC polymers is dependent on their particle diameter and size distribution, the concentration and type of detergent and the presence of other processing additives. The results also indicate that certain detergents such as sodium dodecyl benzene sulphonate form a tight association with PVC particles and in this form they are highly reactive membrane-lytic agents. The physiological implications of the above findings are as yet unclear and therefore need assessment by further experimentation.

We thank members of the Chemical Industries Association for assistance in obtaining and identifying the above samples. R.D. thanks the MRC for financial support.

Pioneer neurones in an insect embryo

INSECT sense organs are produced by small groups of specialised epidermal cells[1]. The receptor neurones differentiate at the surface, so developing sensory axons grow inwards from the epidermis to the central nervous system (CNS). How do they find their way? During larval life the axons of newly differentiated sense cells combine with those of neighbouring receptors and thus are guided to the nearest branch of a peripheral nerve which carries them to the CNS[2]. At metamorphosis the axons of adult sensory neurones reach their central destination by growing along persistent larval nerves which are associated with the developing imaginal disks[3–5]. Thus with pathways to the ganglia already established, growth along existing nerves ensures the delivery of each generation of sensory axons to within a few hundred micrometres of their central targets.

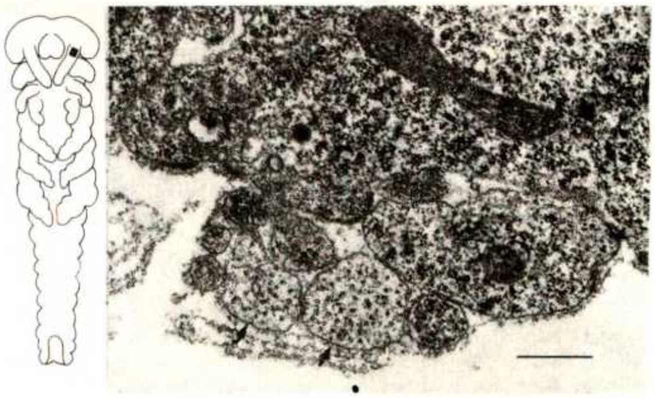

Fig. 1 One of two pairs of axons (arrowed) seen in transverse section through the base of the antenna at the level indicated in the inset. At 105 h of embryonic life at 30 °C. Scale: 1.25 µm.

Just how the connection between the surface and the CNS is first established, whether by an outgrowth of nerves from the centre or by pioneering axons which grow inwards from the surface has never been shown, although some descriptions of embryonic development imply that the first axons to enter the developing appendages are growing outwards from the CNS[6,7]. Presumably these early centrifugal axons would provide a route for the later differentiating sensory fibres to follow in growth to the centre. Here, however, I report observations on the embryonic nervous system of *Locusta migratoria* which show that the first pathways between the epidermis and the central ganglia are formed by axons which grow inwards from peripheral neurones which differentiate early in embryonic life.

Before it rotates round the egg at blastokinesis[8] the locust embryo consists of a segmented band of cells lying on a bed of yolk with its ventral side uppermost. The ganglia develop as a strip on either side of the midline and the base of each appendage is a focus which axons must pass on their way inwards or outwards from the CNS. Timed embryos (30 °C) from a laboratory culture of *Locusta* were processed for electron microscopy[8] and transverse sections were cut through the base of the antennae and the limb buds to look for the early appearance of peripheral nerves.

An initial search revealed that from 110 h of embryonic life onwards, two pairs of axons appear at the base of the antenna (Fig. 1). Where do these axons come from and are they growing into or out of the CNS? Serial sections cut parallel to the long axis of the antenna show that each pair of nerves is produced by a pair of neurones at its distal tip (Fig. 2). From 95 h onwards the two cells of each pair put out processes which grow together to the base of the antenna and enter the embryonic deuterocerebrum. Further series of sections in both planes confirm that there are no other axons in the antenna at this stage, so the two pairs of distal neurones initiate the development of the antennal nerve. During subsequent development the axons of differentiating receptors accumulate about the two sets of pioneering fibres to form two bundles of nerves in the lumen of the antenna. Although the first pairs of axons are naked, the developing bundles become enclosed in the sheathing process of glial cells which appear at intervals along the antenna.

Slightly earlier in development, single pairs of axons appear at the base of each of the three thoracic limb buds. As in the antenna, each pair of nerves is produced by a pair of peripheral neurones. In the limb bud the single pair of cells lies at the anterior margin of the distal end of the lumen (Fig. 2) and from 90 h onwards both of these neurones put out processes which grow inwards to the CNS. Fifteen hours later the two nerves with an expanded growth cone enter the embryonic neuropile from the base of the limb bud (Fig. 3). Further series of sections confirm that these two axons are the first nerves to appear in each of the limb buds, so in the legs as in the antennae, the route from the epidermis to the CNS is pioneered by the ingrowing axons of twin peripheral neurones.

These early differentiating neurones are significant cells in the development of the nervous system. They form the first pathway from the surface to the centre, establish a framework for later innervation and contribute the first peripheral axons to the developing neuropile. During post-embryonic development ingrowing axons which fail to find a peripheral nerve trunk become lost between the epidermis and the basement membrane[2]. The pioneering embryonic fibres reach the central ganglia independently of existing nerves. The axons of the antennal neurones grow directly to its base, but the axons of the limb bud neurones consistently follow a less direct route, which carries them from the anterior half of the distal end of the limb (Fig. 2) over the ventral surface of the leg to the posterior half of its base, where they enter the neuropile (Fig. 3). This indirect route suggests that the path to the CNS is determined not simply by the orientation of the parent neurones but by an interaction between the growing axons and extrinsic cues in the limb bud. The sheathing cells are obvious candidates for a system of signposts. They occur consistently at intervals along the developing appendage and seem to provide a series of stepping stones between the tip of the limb and its base. The last of these cells occurs shortly before the point at which the axons are launched into the developing ganglion (Fig. 3).

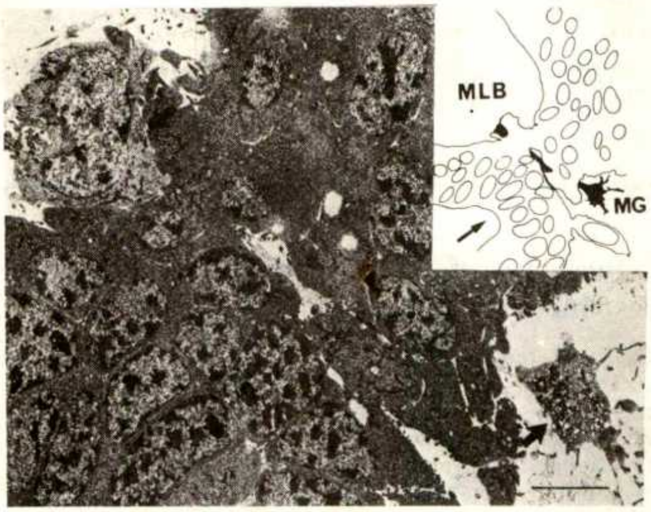

Fig. 3 Inset: camera lucida drawing of 1-μm section of growth cone entering embryonic metathoracic ganglion (MG) from the base of the metathoracic limb bud (MLB) at 105 h of embryonic life. Arrow points anteriorly. Electron micrograph shows part of the same area resectioned for electron microscopy. Notice large sheathing cell (arrowed top left) and expanded growth cone (arrowed bottom right) formed by the terminal expansion of the two axons. Scale: 4 μm.

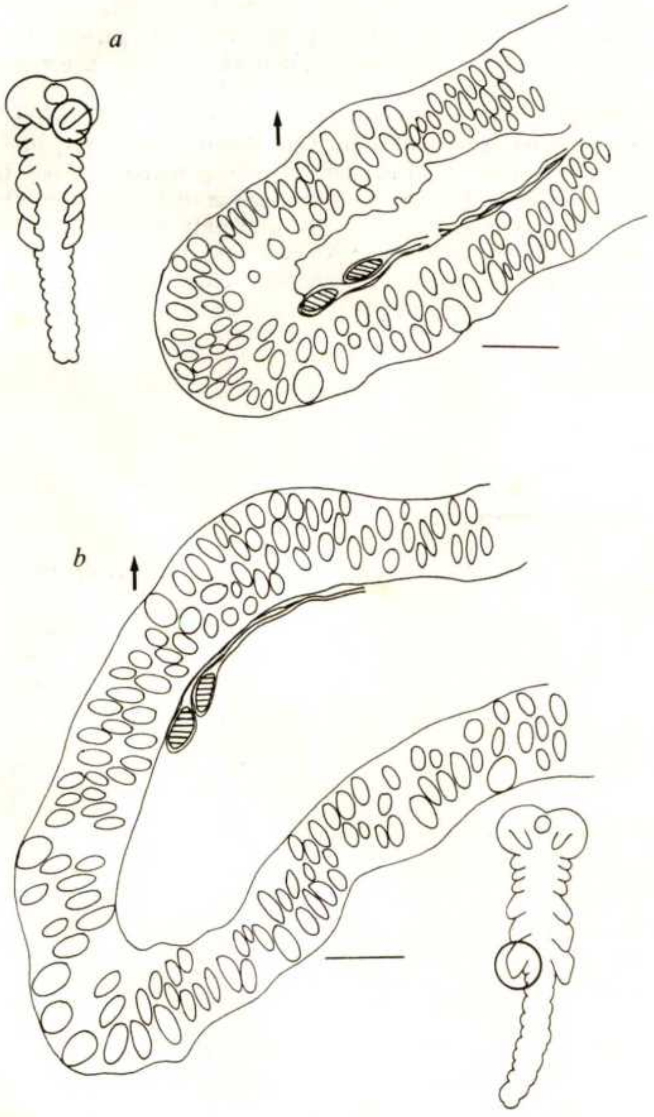

Fig. 2 *a*, One of two pairs of antennal neurones at 100 h of embryonic life. This pair lies on the ventral surface of the antennal lumen, the second pair on the opposite dorsal surface. *b*, Limb-bud neurones from the left metathoracic leg at 95 h of embryonic life. Both camera lucida drawings of 1-μm plastic sections. Arrows point anteriorly. Scales (both): 25 μm.

At the stage at which the peripheral neurones first appear, differentiating central neurones are beginning to put out axons within the ganglia (C.M.B., unpublished) so the pioneer sensory fibres enter the CNS at a crucial stage in its development, when early differentiating ganglion cells lay the foundations of the future neuropile. Perhaps it is fortuitous that similar pairs of cells make the first peripheral pathways in both the antennae and the limb buds. Alternatively an equivalent ground plan may be established in different ganglia by fundamentally similar patterns of growth which reflect the segmental composition of the nervous system. In view of the influence of sensory innervation on the development of insect interneurones[10] and the apparent inductive effect of ingrowing retinal axons on virgin ganglion cells in *Daphnia*[11] it is likely that the early appearance of sensory axons in the embryonic neuropile will be important in determining its structure as well as the distribution of later arriving sensory nerves. This too is now open to experiment.

I thank Nan Cowan for technical assistance and Andrew Jackson for help at the beginning of this work.

Influence of efferent retinal fibres on responsiveness of ganglion cells to light

EFFERENT retinal fibres originating in the nucleus isthmo-opticus[1,2] of the pigeon have been shown, by electron microscopy, to terminate directly on amacrine cells[3]. These findings support the notion of a centrifugal control, originating at the brain, on the retina. Centrifugal fibres exist in several other non-mammalian species[4], but their precise site of termination in the retina has not been determined. In the turtle, stimulation of centrifugal fibres at the level of the optic nerve has a powerful excitatory effect on amacrine cells since it produces a large, "all-or-none" excitatory postsynaptic potential (e.p.s.p.)[5]. Such excitation is in turn transmitted to ganglion cells[5] through the extensive connections between amacrine and ganglion cells[6,7]. Thus ganglion cells are influenced both by the visual input through photoreceptors and other retinal cells, and by a centrifugal input possibly mediated by amacrine cells alone. We describe here some preliminary results concerning the interactions between these two inputs to the ganglion cells.

We used eye-cups of turtles (*Pseudemys scripta elegans*) to which an optic nerve stump 1 cm long was left attached to stimulate both centrifugal fibres and ganglion cell axons. Because there are no reliable criteria to distinguish ganglion from amacrine cells based on their responses to light[5,8], ganglion cells were identified by recording intracellularly their antidromic response to stimulation of optic nerve fibres. A detailed description of the preparation and of the equipment used for intracellular recording is given elsewhere[5].

In more than 50% of ganglion cells, from which intracellular recordings were obtained, illumination of their receptive field (600–800 μm radius) produced photoresponses characterised by a transient depolarisation which did not show any appreciable centre-surround antagonism. These cells were selected for our experiment. Figure 1*a* shows the intracellular responses of a ganglion cell illuminated for 20 ms with a spot (left) and an annulus (right). It seems that the depolarising response maintains approximately the same time course irrespective of the area and pattern of illumination. The antidromic response of the same cell to stimulation of the optic nerve is shown in Fig. 1*b*. Here the spike response (marked by the arrow on the second line) to a single-shock stimulation of the optic nerve (0.5 ms, 2 mA) follows a direct spike produced by injecting outward current through the recording microelectrode. When the interval between the two spikes was reduced progressively, the antidromic response eventually disappeared because it collided with the direct spike travelling orthodromically along the same nerve fibre (Fig. 1*b*, third line). The collision interval found in this cell conforms with the values calculated from conduction times (about 12 ms) and refractoriness (about 8 ms).

When a train of stimuli is applied to the optic nerve, current intensities subthreshold for the antidromic response result in slow, graded, depolarising potentials. Graded responses of ganglion cells to stimulation of the optic nerve with a single shock are usually seen only with very high stimulus intensities (more than twice the threshold for the antidromic response)[5]. The greater efficacy of the low intensity, high frequency nerve stimulation to elicit synaptic

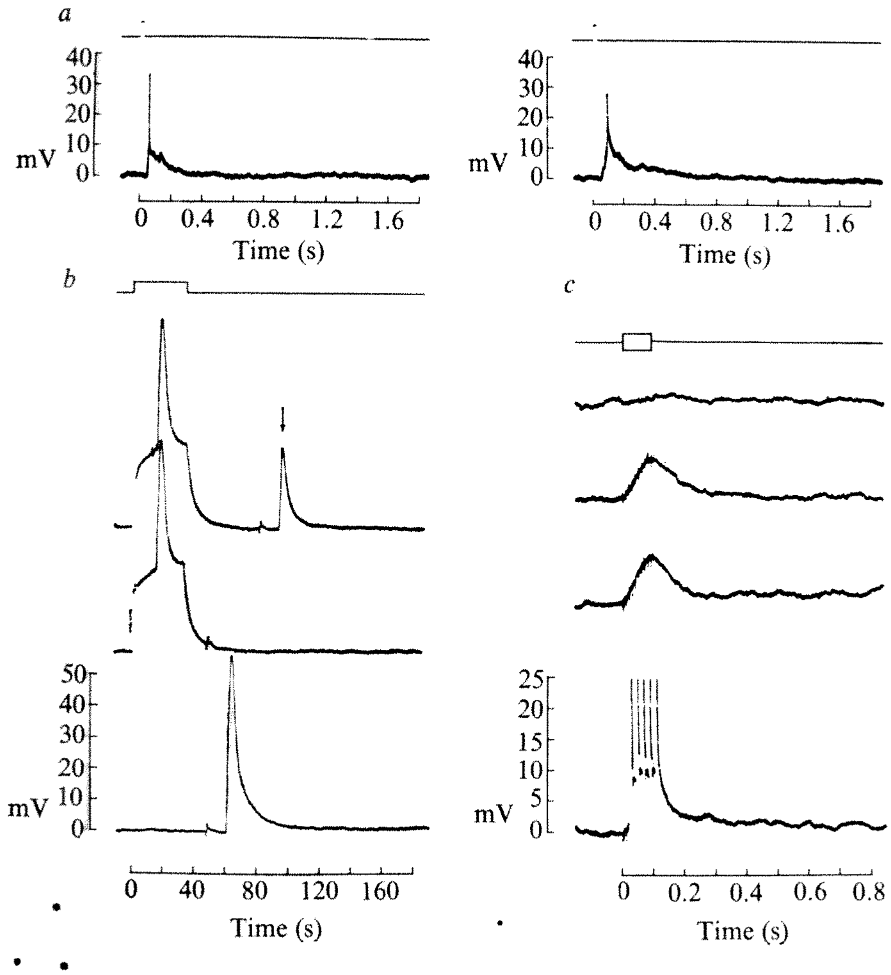

Fig. 1 Intracellular recordings from a ganglion cell in the turtle retina. *a*, Responses to illumination of a circle of 100 μm radius (left) and of an annulus of 180 μm and 1,000 μm inner and outer radius, respectively (right). Zero time coincides with the flash indicated on the first line. *b*, Collision between the antidromic action potential (marked by the arrow on the second line) produced by optic nerve stimulation (0.5 ms, 2 mA) and the direct spike induced by artificially depolarising the cell membrane (third line). The injection of intracellular current is indicated on the first line. In the second line the antidromic action potential fails to invade the cell soma, but is fully developed when not preceded by the direct spike (fourth line). *c*, Ganglion cell responses to repetitive stimulation of the optic nerve (100 ms, 100 per s, 0.1 ms). The stimulus artefact is shown in the first line. The stimulus intensities used, for the responses from top to bottom, are 1.0, 1.5, 1.8 and 2.0 mA, respectively.

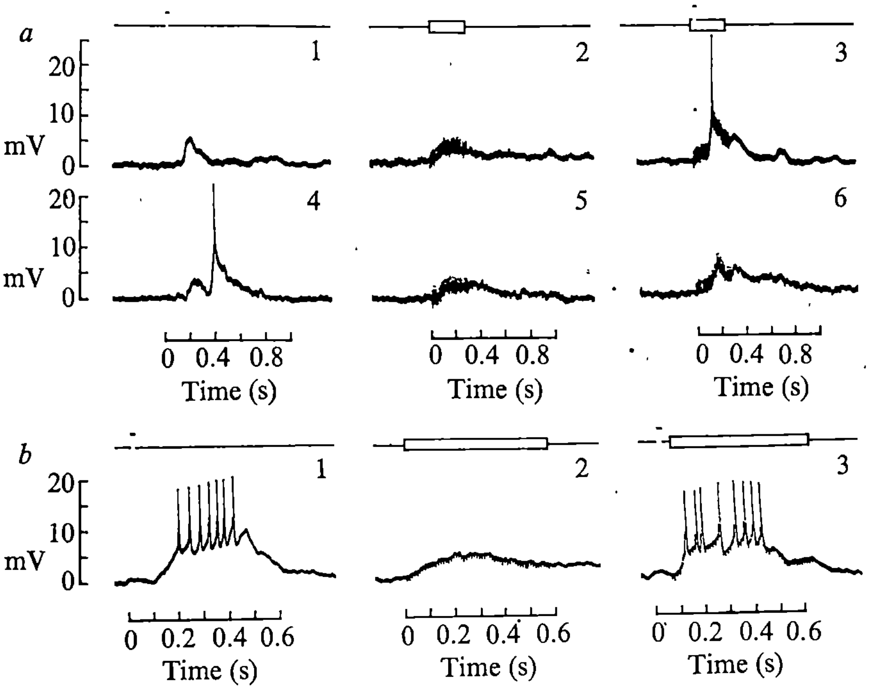

Fig. 2 Interaction between the ganglion cell responses to illumination and to stimulation of efferent fibres. *a*, Same cell as in Fig. 1. *a*1, Slow depolarisation produced by low intensity (4.8 log units of attenuation) illumination of a spot. The light stimulus is indicated in the first line. *a*2, Response to a train of stimuli (300 ms; 100 per s; 0.1 ms; 1.3 mA) applied to the optic nerve (the stimulus artefact is indicated in the first line). *a*3, Ganglion cell response to the combined visual and electrical stimulation. *a*4, Slow potential with a superposed spike produced by low intensity illumination of an annulus (3.6 log units of attenuation). *a*5 and *a*6, as in *a*2 and *a*3. *b*, Recordings obtained from a different ganglion cell. *b*1, Responses to a low intensity (3.6 log units of attenuation) illumination of a spot. *b*2, Response of the same cell to low intensity stimulation of the optic nerve (560 ms; 100 per s; 0.5 ms; 1.4 mA). *b*3, Ganglion cell response to the combined visual and electrical stimulation.

responses is probably due to a process of spatio-temporal summation by which progressively more low-threshold centrifugal fibres are recruited. If the strength of the repetitive stimulation was increased, the threshold for the antidromic response was eventually reached (Fig. 1*c*, fifth line). Thus, two distinct inputs to the same ganglion cell can be distinguished: one originating from photoreceptors excited by light (Fig. 1*a*), the other from activity in the centrifugal fibres (Fig. 1*c*).

The graded depolarisation produced by efferent fibres should affect the responsiveness of ganglion cells to a concomitant photic stimulation because of the resulting change in membrane excitability. Furthermore, since the influence of the centrifugal fibre on ganglion cells is mediated by amacrines[8], ganglion photoresponses may be affected differently according to whether the visual input is conveyed from photoreceptors directly through bipolar cells, or through a more complex pathway involving amacrine cells. These two transmission mechanisms are likely to be activated when the photoresponses are elicited in central or peripheral regions of ganglion receptive fields, respectively[9,10].

Figure 2*a*1 shows a graded depolarising response to a 20-ms illumination of a 100-μm radius spot centred on the recording electrode. High frequency, low intensity stimulation of the optic nerve produced the response shown in Fig. 2*a*2. By combining the two stimuli, the light-induced depolarisation seems to reach the threshold for an action potential (Fig. 2*a*3). On the contrary, a spike obtained by illumination of the periphery of the receptive field (Fig. 2*a*4) would not occur if a graded depolarisation were simultaneously produced by stimulation of the nerve (Fig. 2*a*6). On some occasions the response to the nerve stimulation may, at least partially, add to the annulus-graded photoresponse, but in these instances the centre photoresponse is always greatly enhanced. When centre illumination alone produces a repetitive spike discharge (Fig. 2*b*1), the centrifugal fibre stimulation may decrease the latency of the spike response (from about 200 to 100 ms) and slightly augment the discharge (Fig. 2*b*3). The centrifugal effects are mostly evident on photoresponses to low intensity illumination of either the centre or the periphery: when intensities 1.6–2.4 log units above threshold are used, the photoresponses are modified only slightly.

These results can be interpreted by assuming that a synaptic convergence at the level of the amacrine cells of the centrifugal input and the visual input from the periphery of the receptive field gives rise to an occlusive interaction, which prevents the two depolarising potentials from summating. But summation seems to be possible at the level of the ganglion cell, between the centrifugal input, mediated by amacrine cells and the visual input arising from the centre of the receptive field. This hypothesis may also explain the centrifugal effects on ganglion cell photoresponses observed in the chick[11].

It can be concluded that when a ganglion cell photoresponse coincides with the graded synaptic response to optic nerve stimulation an increased sensitivity to illumination of the central with respect to the peripheral areas is observed. This results in a redistribution of excitability over the ganglion cell receptive field. This effect may be of special functional significance for the detection of light stimuli of low intensity.

Coupling between rod photoreceptors in a vertebrate retina

The exquisite sensitivity of the scotopic visual system is well known to result, in large part, from a 'pooling' of the signals generated by the rod photoreceptors. It was once assumed that spatial integration of rod signals occurs at cellular sites proximal to the photoreceptors but recent evidence indicates that, in turtle and toad retinae, there is a marked spatial summation of the receptor potential recorded in a single rod[1–3]. In the snapping turtle, *Chelydra serpentina*, we have estimated an individual rod to interact summatively with as many as 200 other rods[3]. Such pooling of signals at the input to the visual system will influence not only the sensitivity of the system but also spatial resolution of visual stimuli.

In the work reported here we demonstrate, by impaling pairs of cells, that the pathway of rod–rod interaction is not through the extracellular medium, nor is the horizontal cell an interneurone in the pathway. The interaction seems to be mediated by specific and direct pathways between rods that involve electrical and/or chemical synapses. The coupling in this pathway is summative and reciprocal. Furthermore, hyperpolarising currents are shown to be more effective than depolarising currents in eliciting responses in neighbouring rods.

We impaled and made simultaneous intracellular recordings from 27 pairs of neighbouring rods. We used an eyecup preparation of the snapping turtle retina[3], into which two micropipette electrodes were advanced independently. This method is similar to that used by Baylor *et al.*[4] on turtle cones. Rods were identified by their response characteristics, verified by intracellular injection of Procion yellow[3]. The separation between the rods of each pair was first determined by finding, for each rod, the positions at which brief flashes of a well focused light spot, 25 μm in diameter, elicited maximal responses. Extrinsic currents were then injected into each rod in turn, and were monitored directly by a current-sensing amplifier; the potential of the neighbouring rod was recorded simultaneously.

The results shown in Fig. 1 are from a typical experiment in which the rods were separated by 75 μm. In Fig. 1*a* the depolarising current (1.8 nA) evoked a depolarisation of about 2 mV in rod 2, whereas the hyperpolarising current (1.5 nA) evoked a hyperpolarisation of almost 9.5 mV. As a monitor of the cell integrity, a light stimulus was presented after each current injection. The slow hyperpolarisation on the right of each voltage record is the normal light response of the rod.

Essentially identical results were obtained when current was injected into rod 2 while monitoring the potential in rod 1. Figure 1*b* shows that depolarising and hyperpolarising current pulses of 1.8 nA, injected into rod 2, elicited in rod 1 a depolarisation of 1.2 mV and a hyperpolarisation of 8.3 mV, respectively.

The control records of Fig. 1*c* were obtained when the electrode was withdrawn from rod 1 to a position nearby in the extracellular medium. They show the resulting intracellular potentials in rod 2 when current pulses of ± 1.6 nA were injected into the extracellular medium near rod 1. In all cases these potentials were less than 1 mV, much smaller than those recorded when both electrodes were intracellular. Similar results were obtained when the current-passing electrode was intracellular and the voltage-recording electrode was just outside the other cell. The small potentials that were still recorded in these conditions must have resulted from current flow in ground loops within the recording system, because they could be recorded even when the current-passing electrode was withdrawn completely from the eye.

Our results confirm that in the snapping turtle, the rod photoreceptors are functionally coupled to one another. More important, several additional points are demonstrated. First, the polarity of the coupled potential in one rod is the same as the potential induced by injecting current into the other rod. This is consistent with previous recordings from single rods, which indicate that the rod–rod interaction is summative. Second, the coupling between rods is reciprocal. Third, the magnitude of the coupled potential depends on the direction of extrinsic current; inward hyperpolarising currents evoked larger coupled potentials than outward depolarising currents of the same strength. Fourth, since the effects of intracellularly injected currents could not be mimicked by injecting similar currents into the extracellular medium, we conclude that summative interactions between rods must be mediated by specific intercellular pathways.

Of the 27 pairs of rods from which recordings were made, 14 pairs were found to be coupled, and in all cases

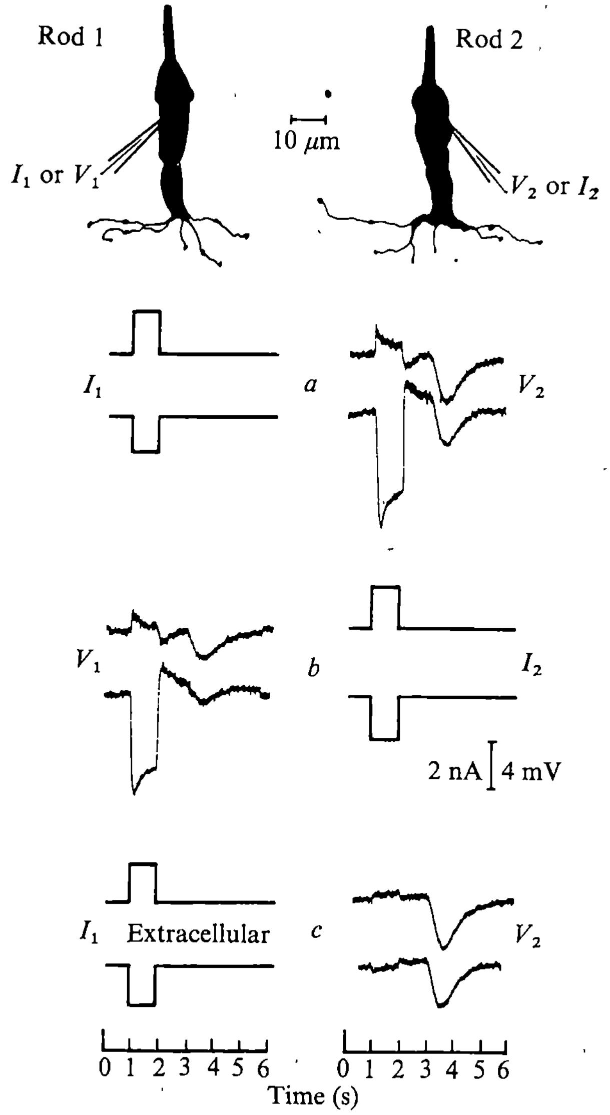

Fig. 1 Simultaneous intracellular recordings from two rods separated by 75 μm. Our recording situation is depicted schematically at the top, using camera lucida drawings of two snapping turtle rods that were delineated by injection of Procion yellow[3]. The current records, I_1 and I_2, show the respective time courses of extrinsic current through rod 1 and rod 2. The potential records, V_2 and V_1, show the respective responses of rod 2 and rod 1, first to a current pulse passed through the other impaled rod and then to a light flash. *a*, Depolarising (outward) current pulse of 1.8 nA and a hyperpolarising (inward) current pulse of 1.5 nA were passed into rod 1. The resulting potential changes are shown in the right column. The top records show the depolarising current in rod 1 and the associated potential change in rod 2; the hyperpolarising current and its effects are shown in the lower records. This convention is also followed in *b* and *c*. *b*, Two 1.8-nA current pulses of opposite direction were passed into rod 2. On the left are shown the potential deflections in rod 1. *c*, As a control, the electrode was withdrawn from rod 1 and current pulses of ±1.6 nA were passed through its tip, while still recording in rod 2. The magnitude and direction of the potentials in all these recordings are given with respect to the resting membrane potential of the rod in darkness.

the coupling characteristics were as described. The maximum separation of coupled rods was about 110 μm. This compares with an upper limit of 150 μm which we found by determining the retinal area over which light responses summate in a single rod[3]. Of the 13 pairs of rods that were not coupled, the rods of 12 pairs were separated by more than 120 μm. For one pair, however, the separation was only 50 μm. In that case the injection of currents into either rod failed to evoke a potential in the other rod, although each rod was clearly influenced by the light responses of rods up to about 150 μm away. Baylor *et al.*[4] showed that the cones of the red-eared turtle, *Pseudemys scripta elegans*, are summatively and reciprocally coupled over distances up to 50 μm. Rods of the snapping turtle exhibit a similar coupling over more than twice that distance.

The only interneurone known to be involved in receptor interactions is the horizontal cell, which has been shown by double impalement recordings to mediate antagonistic interaction between rather widely separated cones in the red-eared turtle[4]. It seems unlikely, therefore, that the horizontal cell would be involved in summative interactions between rods. In addition, the area over which rod signals are summative is much smaller than the receptive field of horizontal cells[3]. In this work we made many simultaneous recordings from a rod and a nearby L-type horizontal cell. When extrinsic currents up to ± 6 nA were injected into the horizontal cell, there was consistently no significant potential evoked in the rod. It thus seems likely that summative rod interaction is mediated by direct pathways between rods.

An interesting feature of snapping turtle rods is that numerous teleodendria, up to 40 μm long, extend laterally across the retina from their broad synaptic terminals. These have been demonstrated by both Golgi staining (Leeper and Stell, personal communication) and Procion yellow injections[3], and are depicted at the top of Fig. 1. The teleodendria may constitute the pathways by which rods can interact selectively with each other.

The teleodendria exhibit both *en passage* and terminal swellings not unlike the presynaptic structures found at chemical synapses in other parts of the nervous system[5]. In our work we could not detect the delay of a chemical synapse, because our electrode resistance of 300–400 MΩ resulted in a recording time constant of 10 ms. Thus the involvement of chemical synapses cannot yet be ruled out.

The greater effectiveness of hyperpolarising currents in evoking potentials in neighbouring rods may not result from the nature of the coupling itself, but from a nonlinear current–voltage relationship in each rod. This is suggested by one experiment in which we impaled a single rod with two electrodes and noted that a hyperpolarising current produced a larger change of membrane potential than a depolarising current of equal strength. Thus further work must be done to elucidate the mechanism underlying the special efficiency of hyperpolarising responses in eliciting responses in neighbouring rods Regardless of its basis, it seems likely that this effect is functionally significant, since the rod's normal light response is a hyperpolarisation.

We thank Dr K. T. Brown for advice and assistance. This work was funded by a postdoctoral fellowship (D R.C.) and a research grant (K.T.B.) from the National Eye Institute.

Diurnal rhythm in rat pineal cyclic nucleotide phosphodiesterase activity

MANY substances in the rat pineal organ exhibit marked diurnal variations, some of these fluctuations are circadian, that is, cued but not driven by environmental lighting. The content of the pineal hormone melatonin[1] for example, is seven- to tenfold higher during the dark phase of the diurnal cycle than during the light phase[2] Similarly, the activities of the melatonin-synthesising enzymes 5-hydroxytryptamine-*N*-acetyl transferase (NAT) and hydroxyindole-*O*-methyl transferase (HIOMT) are also higher in the dark (by factors of 15–70-fold and threefold, respectively[3,4]). The immediate precursor of melatonin, *N*-acetyl 5-HT is 10–30-fold higher in the dark than in the light[5]. In contrast the pineal content of the precursor of *N*-acetyl 5-HT, 5-HT is twofold higher in the light than in the dark phase of the diurnal cycle[6], suggesting that changes in NAT activity regulate changes in melatonin biosynthesis. These changes have been shown to be controlled by environmental light acting through the retina by way of central nervous pathways to the superior cervical ganglion, and thence through postganglionic sympathetic fibres to the pineal body[7]. Noradrenaline released from these fibres acts on β adrenoceptors on the parenchymal pineal cells to stimulate adenylate cyclase, causing an increase in intracellular cyclic AMP which is followed by increased NAT activity and melatonin biosynthesis[8,9] Decentralisation, superior cervical ganglionectomy, administration of β-adrenoceptor blocking drugs or protein synthesis inhibitors can all block the light–dark changes observed in NAT activity in this organ[10,11].

We have recently shown that stimulation of adenylate cyclase by cholera toxin is also an effective stimulus for the induction of NAT in rat pineal organ cultures. The increases in adenylate cyclase activity caused by choleragen also lead to increases in the cyclic AMP hydrolysing enzyme, cyclic nucleotide phosphodiesterase (PDE), so that the increases in cellular cyclic AMP content caused by choleragen are only transient[12].

In view of the importance of PDE in modifying intracellular cyclic AMP levels, and thereby cellular responsiveness to β-adrenoceptor stimulation, we have studied the physiological regulation of this enzyme in a diurnal lighting situation. We report here that PDE activity in the rat

Table 1 Effect of superior cervical ganglionectomy and (–) -propranolol on dark-induced increase in pineal PDE activity

Treatment	Time of death	Cyclic AMP hydrolysis	Cyclic GMP hydrolysis
Sham	1200 light	0.9 ± 0.15	1.9 ± 0.24
Ganglionectomy	1200 light	1.0 ± 0.13	1.9 ± 0.31
Sham	2400 dark	1.6 ± 0.11*	2.9 ± 0.25*
Ganglionectomy	2400 dark	1.0 ± 0.22	2.1 ± 0.43
Saline	1200 light	0.87 ± 0.09	1.7 ± 0.24
(–)-Propranolol	1200 light	0.84 ± 0.05	1.6 ± 0.12
Saline	2400 dark	1.50 ± 0.13*	2.7 ± 0.22*
(–)-Propranolol	2400 dark	0.93 ± 0.10	1.8 ± 0.17

Rats were ganglionectomised bilaterally under Equithesin anaesthesia, or sham operated; allowed to recover for 1 week, and killed at noon and midnight of a 12 h light–12 h dark schedule. Pineals were quickly removed and frozen and PDE activity was determined (see legend to Fig. 1). Other animals were injected with (–)-propranolol (20 mg kg^{-1}) or 0.9% saline subcutaneously at 2000 or 0800 and killed at 2400 and 1200 respectively, the pineals removed and PDE determined Each point is the mean of 5 pineals ± s.e.m. Values are expressed as nmol hydrolysed per 10 min per pineal. *$P < 0.001$ as compared with noon control values.

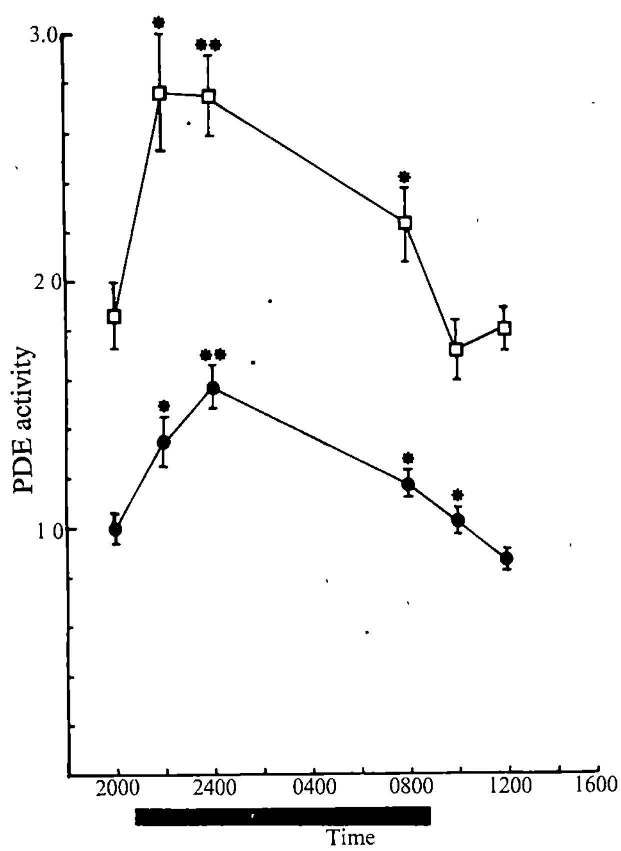

Fig. 1 Diurnal variation in cyclic nucleotide phosphodiesterase in rat pineal organ. Rats were maintained on a 12 h light–12 h dark schedule, with lights on from 0900 to 2100 and were killed at times indicated, and pineals removed and frozen. A single pineal was homogenised in distilled water (100 µl) and PDE activity determined in an aliquot by the method of Thompson and Appleman[13]. Values were corrected for recovery losses of adenosine and guanosine according to the method of Lynch and Cheung[14]. ●, Cyclic AMP hydrolysis at 10^{-6} M substrate concentration; □, cyclic GMP hydrolysis at 10^{-6} M substrate concentration. Each point is the mean of 5 animals. Vertical bars indicate ± s.e.m. Values are expressed as nmol hydrolysed per 10 min per pineal. $^{**}P < 0.001$; $^{*}P < 0.05$ compared with noon values.

pineal is significantly higher during the dark phase of a diurnal lighting regimen, and that this diurnal rhythm seems to be associated with increased β-adrenoceptor stimulation during the dark phase.

Male Sprague–Dawley rats (150–200 g) were housed in groups of 10 in a controlled lighting situation, with lights on from 0900 to 2100; the animals were given food and water *ad libitum* Light was provided by a 60-W incandescent bulb 60 cm from the cage, and temperature was constant at 23–24 °C In some animals, bilateral superior cervical ganglionectomy was performed under Equithesin anaesthesia. Rats were decapitated at various times during the light or dark periods, the heads were chilled on ice and the pineal body quickly removed and stored at −20 °C before assay Cyclic nucleotide phosphodiesterase (PDE) activity was determined by the method of Thompson and Appleman[13] and values were corrected by the method of Lynch and Cheung[14] (see legend to Fig 1).

Table 2 Effect of cycloheximide on dark-induced increase in pineal PDE activity

Treatment	Time of death	Cyclic AMP hydrolysis	Cyclic GMP hydrolysis
Saline	1200 light	0.72 ± 0.05	1.81 ± 0.14
Cycloheximide	1200 light	0.57 ± 0.10	1.6 ± 0.35
Saline	2400 dark	1.25 ± 0.1**	2.6 ± 0.13**
Cycloheximide	2400 dark	0.89 ± 0.04*	2.3 ± 0.06*

Rats were injected at 2000 and 0800 with 30 mg kg^{-1} cycloheximide or 0.9% saline subcutaneously, and killed 4 h later at 2400 and 1200 respectively; pineals removed, and PDE activity determined Each point is the mean of 5 animals ± s.e.m. Values are expressed as nmol hydrolysed per 10 min per pineal $^{**}P < 0.001$ $^{*}P < 0.05$ compared with saline-treated controls killed at noon.

PDE activity in the rat pineal organ exhibited a 24-h rhythm for the hydrolysis of both cyclic AMP and cyclic GMP (Fig. 1), with the highest values occurring in each case in the dark. At 1 µM substrate concentration maximal cyclic AMP hydrolysis in the dark at 2400 was 183% of that at 1200 in the light (Fig. 1), and cyclic GMP hydrolysis at 2400 was 162% of that measured in the light (Fig. 1). Since both cyclic AMP and cyclic GMP are hydrolysed with complex kinetic behaviour in the pineal body (K.P.M. and L.L.I., in preparation), phosphodiesterase activity was also measured at higher concentrations of each nucleotide (100 µM). Both cyclic AMP and cyclic GMP hydrolysis were again maximally increased by 200% in the dark compared to the light values at this substrate concentration.

To determine whether the diurnal rhythm in pineal cyclic nucleotide PDE was controlled by changes in sympathetic nerve activity in the postganglionic fibres innervating the pineal organ, bilateral superior cervical ganglionectomy was performed in some animals. These were killed a week after the operation at midnight and at noon, and pineal PDE measured (Table 1). Ganglionectomy completely blocked the dark-induced increase in pineal PDE, ganglionectomised animals having PDE levels not significantly different from sham-operated controls killed in the light. This suggests that increased sympathetic activity in the dark is responsible for the increased pineal PDE. To determine whether the changes in PDE activity were mediated by noradrenaline release, the β-adrenoceptor blocking agent (−)-propranolol was injected 1 h before the lights went off (2000), or 1 h before the lights went on (0800). PDE activity was again determined at noon and midnight (Table 1) (−)-Propranolol blocked the dark-induced increase in pineal PDE activity, propranolol-treated animals having PDE levels not significantly different from saline-injected controls killed in the light.

Treatment with the protein synthesis inhibitor cycloheximide 1 h before the lights went off (2000), or 1 h before the lights went on (0800) partially suppressed the dark-induced increase in pineal PDE (Table 2). At midnight, PDE levels in the cycloheximide-treated animals were still significantly increased over noon control values, being 125% of the latter for both cyclic AMP and cyclic GMP hydrolysis.

These results are consistent with the recent findings that administration of the β-adrenoceptor agonist isoprenaline *in vivo* can increase PDE activity in the rat pineal organ[16] The diurnal changes observed in PDE activity in the pineal may result from an increased synthesis of PDE enzyme protein in the dark, or possibly through changes in the content of an endogenous activator. In the rat adrenal medulla, an increased concentration of an endogenous activator for PDE has been shown to occur within 20 min after carbamylcholine injection *in vivo*[15], although there is as yet no evidence for the occurrence of such changes in the pineal organ.

Since changes in cyclic AMP seem to be sufficient for the induction of NAT activity in the pineal body[12], and since increases in PDE activity lead to decreases in cyclic AMP content[12], it is clear that alterations in PDE activity can lead to alterations in the sensitivity of pineal biosynthetic enzymes to β-adrenoceptor stimulation, by altering the half life of the intracellular mediator cyclic AMP. The fact that twofold changes in the activity of this enzyme occur in normal physiological conditions is interesting, since diurnal changes in the sensitivity of pineal biosynthetic enzymes to β-adrenoceptor stimulation also occur normally in controlled lighting regimens. Receptor sensitivity is highest during the light period, when PDE activity is lowest, and receptor sensitivity is lowest during the dark period, when PDE activity is increased[17]. Since it seems probable that PDE is induced by high levels of its substrate, cyclic AMP[12], its activity will, therefore, be high after periods of intense receptor stimulation and low after periods of receptor inactivity. The phenomena of sub- and supersensitivity could thus be at least partially explained by a shift in the dose–response curve of adenylate cyclase activation on intracellular cyclic AMP content, controlled by alterations in the rate of degradation of intracellular cyclic AMP. Alterations in ^{3}H-alprenolol binding have recently been observed in sub- and supersensitive pineals[18], suggesting that changes in the population of available receptors may also occur; such changes have also been shown to occur with a marked diurnal cycle[19]. Thus it is probable that several mechanisms contribute to changes in adrenoceptor sensitivity and therefore regulate tissue responses to catecholamine stimulation. For example, superior cervical ganglionectomy causes a striking supersensitivity in the accumulation of cyclic AMP and induction of NAT on β-adrenergic stimulation in daytime rats[20], as well as an increased adenylate cyclase response[21,8]; and our results demonstrate that these phenomena cannot be explained in terms of changes in PDE activity, as the PDE levels are not changed in ganglionectomised animals.

In vivo and *in vitro* activation of soluble tryptophan hydroxylase from rat brainstem

TRYPTOPHAN hydroxylation is the rate-limiting step in the biosynthesis of 5-hydroxytryptamine (5-HT) in central serotonergic neurones. In physiological states, tryptophan hydroxylase (EC 1.14.16.4), the key enzyme, is not saturated by its substrate[1]. Thus, three factors which modulate the concentration of tryptophan in brain—the levels of free tryptophan in plasma[2,3], the ratio of total tryptophan levels to those of other neutral amino acids[4], and the uptake process for tryptophan in brain tissues[5,6]—are important in the control of 5-HT synthesis. On the basis of indirect evidence[7,8], it was suggested that tryptophan hydroxylase could also play a regulatory role. Among the mechanisms possibly involved, rapid changes in the enzyme affinity for its substrate and/or its cofactor may take place. Indeed, such changes are responsible for the activation of tyrosine hydroxylase seen in dopaminergic terminals after blockade of dopaminergic receptors by neuroleptics[9]. We used methiothepin(1-[10,11-dihydro-8-(methylthio)-dibenzo(b,f)thiepin-10-yl]-4-methylpiperazine maleate), a potent blocker of central serotonergic receptors[10], to look for a similar activation of tryptophan hydroxylase. Our results indicate that the affinity of this enzyme for its substrate is markedly enhanced in methiothepin-treated tissue.

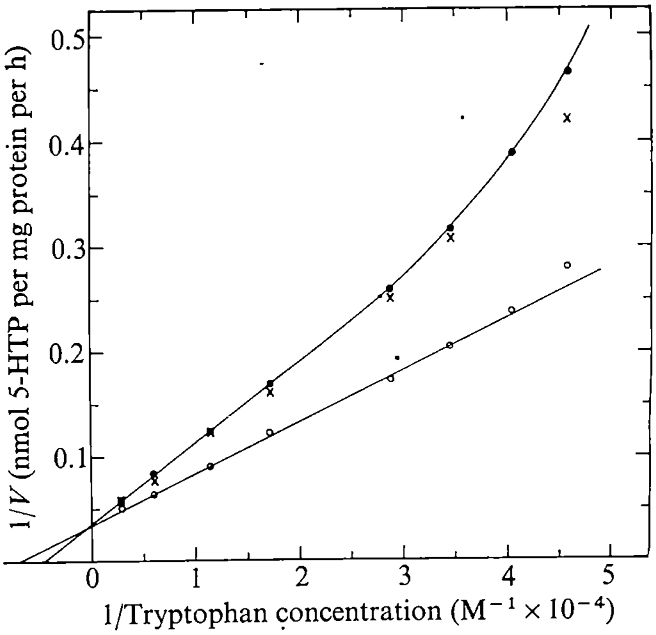

Fig. 1 Double reciprocal plots of tryptophan hydroxylase activity against tryptophan concentration. Effects of *in vivo* methiothepin (○) or methiothepin–LSD treatment (×); ●, control. Methiothepin and LSD were injected as described in Table 2. Soluble enzyme was prepared from the brainstem of rats. Tissues were homogenised (20 s) with a Polytron PT10,OD apparatus in 3 volumes 0.05 M Tris acetate, *p*H 7.6, containing 1 mM β-mercaptoethanol. Homogenates were centrifuged at 30,000*g* for 30 min at 4 °C and the supernatant was used as the final enzyme solution. Tryptophan hydroxylase activity was assayed in the presence of 0.32 mM 6-MPH$_4$ and various concentrations of tryptophan as described previously[12] except that the incubation period was shortened to 15 min. In these conditions, the formation of 5-hydroxytryptophan (5-HTP) was linear with respect to both time of incubation and protein concentration (0.5–1.2 mg ml^{-1}) in the assay mixture. The reaction was stopped by addition of 0.2 ml 4 N perchloric acid Precipitated proteins removed by centrifugation were estimated by the procedure of Lowry *et al.*[13] using bovine serum albumin as standard. 5-HTP was determined in aliquots (0.5 ml) of supernatant by the OPT spectrofluorimetric method[12] or by its native fluorescence in 3 N HCl (ref 1) or 4 N HClO$_4$. Blanks were made by adding 6-MPH$_4$ at the end of the incubation. For the calculations, standards were made by adding known amounts of 5-HTP (1–2 μg) to some samples just before incubation. Statistical calculations were done according to Snedecor and Cochran[14]. Apparent K_m and V_{max} were determined by double reciprocal plotting Each point is the mean of three determinations carried out with tryptophan hydroxylase extracted from groups of 8 rats.

In preliminary experiments, male Sprague–Dawley rats (250–300 g) kept in a controlled environment for 10 d, were injected intraperitoneally with methiothepin (20 mg kg^{-1}) and killed 90 min later by decapitation. Slices of the brainstem were prepared and incubated for 30 min at 37 °C in the presence of ^{3}H-tryptophan. In these conditions (described in detail elsewhere[11]) the rates of formation of ^{3}H-5-HT and ^{3}H-5-hydroxyindole acetic acid (^{3}H-5-HIAA) were markedly stimulated when compared with those in control tissues (+61%). This effect was related partly to an enhanced accumulation of ^{3}H-tryptophan in slices (+30%); however, it was also due to an activation of the rate of tryptophan hydroxylation, as the conversion index

Saline	3.14±0.18
Methiothepin	4.21±0.22*
LSD	3.20±0.12
LSD–methiothepin	2.98±0.24
Apomorphine	3.49±0.15
Apomorphine–methiothepin	4.54±0.28†

Methiothepin (20 mg kg^{-1} intraperitoneally) was injected 140 min before death. LSD (1 mg kg^{-1} intraperitoneally) was injected twice, 160 and 120 min before death. The same schedule was used for apomorphine administration (each 5 mg kg^{-1} intraperitoneally). Tryptophan hydroxylase was assayed as described previously[12] with 0.16 mM 6-MPH$_4$ and 0 24 mM tryptophan. The enzymatic activity is expressed in nmol 5-HTP formed per mg protein and per h. Each value is the mean ± s.e.m. of determinations made on groups of 8 rats.

*$P < 0.05$ compared with saline-treated rats.

†$P < 0.05$ compared with saline- or apomorphine-treated rats.

of tryptophan into 5-hydroxyindoles (^{3}H-5-hydroxyindoles/tryptophan specific activity) was 33% higher in slices of treated rats. A similar, but less pronounced stimulatory effect (+24%) of methiothepin on *in vitro* 5-HT synthesis was observed when the drug (30 μM) was added directly to the incubating medium. This could be prevented when slices were incubated in the presence of both methiothepin (30 μM) and LSD (10 μM, D-lysergic acid diethylamide bitartrate, Sandoz) a well known agonist of 5-HT receptors.

When estimated in the presence of subsaturating concentrations of tryptophan (0.24 mM) and cofactor (0.16 mM) the activity of tryptophan hydroxylase isolated from tissues of methiothepin-pretreated rats (20 mg kg^{-1} intraperitoneally) was increased by 30–40% (Table 1). This stimulation was observed from 90 min to 5 h after administration of the 5-HT blocking agent, whereas methiothepin incubated directly with the control enzyme was ineffective and inhibited the enzyme activity at high concentrations (−27% at 50 μM). LSD injected twice (each 1 mg kg^{-1} intraperitoneally) 20 min before and 20 min after methiothepin (20 mg kg^{-1} intraperitoneally) prevented the stimulation of tryptophan hydroxylase estimated 140 min after the 5-HT antagonist injection (Table 1). The potent agonist of dopaminergic receptors, apomorphine (5 mg kg^{-1} intraperitoneally, Hoffmann–La Roche) injected 20 min before and 20 min after methiothepin did not alter the activation of tryptophan hydroxylase induced by the 5-HT blocking agent (Table 1). In the presence of a high concentration of tryptophan (0.5 mM), control tryptophan hydroxylase exhibited an apparent K_m for the pteridine cofactor, 2-amino-4-hydroxy-6-methyl-5,6,7,8-tetrahydropteridine. (6-MPH$_4$ Calbiochem), equal to 183 μM. The enzyme isolated from the brainstem of methiothepin-treated rats exhibited the same affinity for the cofactor and its V_{max} was slightly but not significantly increased (Table 2). Conversely, methiothepin treatment increased significantly the affinity of the enzyme for tryptophan (Table 2) without changing its V_{max}. The determination of these kinetic parameters was carried out with a subsaturating concentration of 6-MPH$_4$ (0.32 mM) as the reduced pteridinic cofactor inhibited tryptophan hydroxylase activity when its concentration reached 0.4 mM (M.H. and S.B., unpublished). After double reciprocal plotting, the curve obtained with the enzyme extracted from control tissues was parabolic with an upward concavity suggesting a cooperative effect (Fig. 1); (Hill plot gave an n value close to 2). In contrast, the curve became linear for the enzyme of methiothepin-treated rats. As shown in Fig. 1, when rats were treated as in the previous experiment both with methiothepin and LSD, the affinity of the enzyme for tryptophan returned to the control value.

The change in affinity of the enzyme for its substrate in methiothepin-treated rats as well as the parabolic curve observed for the enzyme of control tissues (Fig. 1) suggest that tryptophan hydroxylase shares allosteric properties with other polymeric enzymes. Such enzymes can be activated by mild trypsinisation or exposure to small concentrations of detergents. Therefore, the effects of trypsin (1 : 250, Difco) and sodium dodecyl sulphate (SDS, Sigma) on the kinetic characteristics of the enzyme were examined. A tryptophan hydroxylase solution was incubated at 30 °C for 30 min in the presence of trypsin (6.5 μg proteolytic enzyme per mg protein in the brainstem supernatant). The reaction was stopped with 500 μg soybean inhibitor (Worthington) and the enzyme activity assayed as in Fig. 1. In these conditions, the affinity of tryptophan hydroxylase for tryptophan was markedly increased (Table 2). The V_{max} was reduced but a similar change occurred when the enzyme was preincubated for 30 min at 30 °C in the absence of trypsin, indicating that this alteration was simply related to the instability of tryptophan hydroxylase. When the enzyme assay was carried out in the presence of 0.01% detergent, a significant change in the enyzme affinity for its substrate was also seen. Both with trypsin and SDS, the affinity of tryptophan hydroxylase for the cofactor as well as its V_{max} (in the presence of 0.5 mM tryptophan) were significantly increased (Table 2).

The changes in 5-HT synthesis induced by the 5-HT antagonist, methiothepin, may be related to an increased transport of tryptophan in tissues, but also to an activation of tryptophan hydroxylase. At it could be directly observed *in vitro*, the affinity of the enzyme for its substrate amino acid was selectively

Table 2 Effects of various treatments on kinetic parameters of soluble tryptophan hydroxylase from rat brainstem

	Tryptophan		6-MPH$_4$	
	K_m(μM)	V_{max}	K_m(μM)	V_{max}
Control	234±17 (11)	22.1±1.4	183±15 (8)	23.7±1.6

SDS	110± 5* (5)	27.0±3.0	102±11* (5)	46.4±5.2*
Preincubated control	213±22 (6)	11.2±0.8	166±14 (5)	12.2±0.9
Trypsin	106± 6* (6)	12.3±1.1	104±12* (4)	19.1±1.5*

Determinations of apparent K_m and V_{max} of tryptophan hydroxylase with tryptophan concentrations in the range 20 μM–0 5 mM were carried out in the presence of 0.32 mM 6-MPH$_4$. When the concentration of 6-MPH$_4$ was the variable, tryptophan concentration was maintained at 0.5 mM. *In vivo* treatment with methiothepin (20 mg kg^{-1} intraperitoneally) occurred 120 min before death. SDS (0.01%) was added to the standard assay mixture without preincubation. The effect of trypsin was analysed after 30-min preincubation of tryptophan hydroxylase solution with the proteolytic enzyme (6.5 μg trypsin per mg protein of the brainstem supernatant) at 30 °C. 'Preincubated control' corresponds to tryptophan hydroxylase solution incubated for 30 min at 30 °C in the absence of trypsin. V_{max} is expressed in nmol 5-HTP formed per mg protein and per h. Each value is the mean ± s.e.m. of determinations made in 4–11 experiments (numbers of experiments indicated in parentheses).

*$P < 0.05$ compared with respective control values.

two proteins present in active enzyme prepared from human foetal and monkey livers. This protein was also demonstrated in livers obtained from the patients who died of unrelated diseases (whose livers were normal). Study of this protein, and of fragments of the native enzyme which seem to copurify, may be useful in the elucidation of the defect in PKU. The general approach may be useful in the study of other inborn errors of metabolism in which the enzyme involved is rapidly inactivated after death or when the mutant enzyme is inactive

Monkey liver phenylalanine hydroxylase was purified as already described[4]. The small modifications (Fig. 1) which were made for crude extracts of human livers did not alter the proteins isolated The specific activity of each preparation is shown in Fig. 1. The proteins thus purified were then studied by the Gradipore technique[6] modified by the use of sodium dodecyl sulphate (SDS) (Fig. 1).

Purified monkey liver enzyme yielded two proteins of similar molecular weight (Fig. 1*b* and *g*) which ran between the two marker proteins which were used (catalase molecular weight 57,500 and ovalbumin molecular weight 45,000) (Fig. 1*a*). This indicates molecular weights very similar to those found when enzyme purified from rat liver by traditional methods was analysed by SDS electrophoresis—two proteins with molecular weight of 50,000 and 49,000 respectively have been described[7].

The preparation from the 16-week foetus showed a similar pair of proteins (Fig. 1*c*). The preparation from the 34-week foetus (Fig. 1*f*) from the normal human liver (Fig. 1*e*) and from the PKU liver (Fig 1*d*) all showed only the protein of smaller molecular weight (protein 2). Additional bands corresponding to smaller protein species were also noted in the preparations from PKU liver, from normal livers, and from the 34-week foetal liver (Fig. 1*d–f*).

Phenylalanine hydroxylase should be the only protein in liver which can bind to the pteridine adsorbent at the high concentration of NaCl (0.8 M) used and specifically eluted by phenylalanine. Consequently there is good reason to believe that the protein purified by this technique represents phenylalanine hydroxylase in an active or inactive form. Material isolated from monkey liver and from the foetal livers showed substantial phenylalanine hydroxylase activity. One protein species (protein 2) purified from the normal human livers and from the PKU liver behaved in the same way as one of the proteins obtained from those livers with enzyme activity, and we believe that this protein represents a component of phenylalanine hydroxylase. This is supported by the close correspondence between the behaviour of the monkey liver enzyme purified by this method and that described for purified rat liver phenylalaline hydroxylase[7].

Kaufman[7] has produced smaller species which are still active, by proteolytic cleavage of purified rat liver phenylalanine hydroxylase. This type of molecule may be represented among the smaller species purified from human livers (Fig. 1*d–f*).

Protein 1 was found only in the active preparations from monkey liver and from the 16-week foetus. Rapid degradation after death may explain the absence of this protein from the 34-week foetal liver, and from livers obtained at autopsy from older patients which had low activity. The degradation of this protein species may explain the rapid loss in enzyme activity observed after death[3]. The same mechanism may explain the absence of this band from the PKU liver preparation It is also possible, however, that it represents the effect of the PKU mutation

The next step must be to study the strucure of the proteins isolated from this PKU liver. The preparations analysed in the experiment illustrated in Fig. 1 have been subjected to isoelectric focusing. But because of the considerable heterogeneity revealed, it was not possible to detect a simple charge-change mutation.

We thank Phillip Grattan and Ian Jennings for technical assistance and Drs K. Hayes, D Pitt and D. Sillence and M. A Winther and the Departments of Pathology of St Vincent's Hospital and the Royal Children's Hospital for liver samples. We thank Dr B. Davidson for criticism of the manuscript. This work was supported by an NH and MRC grant and R.G.H.C. was the recipient of a Queen Elizabeth II fellowship.

Inhibition of reverse transcriptases of primate type C viruses by 7S immunoglobulin from patients with leukaemia

WE have characterised[1] type C virions which are released spontaneously from a diploid strain of human embryonic fibroblasts. These 'HEL-12 virions' have structural and biochemical properties of known RNA tumour viruses and are antigenically related to subhuman primate type C viruses. Immunological analyses have so far excluded cross reactivity between HEL-12 virions and avian (ASV), murine MuSV, or feline RNA sarcoma or leukaemia viruses.

Several lines of evidence strongly suggest that HEL-12 virions originate in the human cell strain from which they were isolated[1]. Unambiguous proof of their human origin is, however, difficult to obtain, particularly in the absence of an undisputed human type C reference virus. We have approached this problem by asking if humans have humoral immunity to HEL-12 virion antigens. Because antibody to RNA-dependent DNA polymerase (reverse transcriptase[2]) is easily quantifiable and can be used to distinguish primate from non-primate type C viruses[3], purified immunoglobulin (Ig) from eight patients with various types of leukaemia was assayed for anti-reverse transcriptase antibody. We found that the 7S Ig from the plasma of two leukaemic patients significantly inhibited the incorporation of ^{3}H-dTTP by the reverse transcriptase of HEL-12 virions, woolly monkey fibrosarcoma (simian sarcoma) virus (SiSV)[4] and baboon endogenous virus (BEV)[5].

Ig was purified from the plasma of eight patients with leukaemia by differential fractionation with ammonium sulphate and rate zonal sedimentation of the precipitated Ig in 10–40% linear sucrose gradients[6]. The major protein peak migrated with a sedimentation coefficient of 7S (Fig. 1). The gradient profiles of Ig from leukaemic patients were not substantially different from those obtained with Ig from normal adult volunteers (Fig. 1). The pooled, purified 7S fraction from each patient was dialysed exhaustively, and antibody was quantitated by radial immunodiffusion in Agarose plates embedded with rabbit anti-human IgG, IgA or IgM (ref. 8). All precipitated protein was accounted for as either IgG (~90%) or IgA (~10%); no IgM was detected. Electrophoresis in sodium dodecyl sulphate (SDS)-polyacrylamide gels[9] revealed that

Ig was purified from plasma of each patient as described in Fig. 1 Growth and purification of HEL-12 virions, G-MuLV, and Kirsten murine sarcoma (leukaemia) virus (KiMuSV (KiMuLV)) described previously[1,9] BEV, gift of Dr R C Gallo, National Cancer Institute, Bethesda, Maryland. HL23V-1, type C particle originally isolated by Gallagher and Gallo[11] now grown in dog thymus cells[12] SiSV and Schmidt–Ruppin strain of Rous sarcoma virus (SR-RSV), (Electro-Nucleonics Laboratories, Bethesda, Maryland) were disrupted and frozen immediately on receipt[1]. To test for Ig inhibitory activity, all viruses were disrupted for 5 min at 37 °C in 0 1 % Nonidet P40 (NP40) detergent, 5 μl virus (~ 12,000–80,000 c.p.m. ^{3}H-dTMP rendered acid precipitable in 40 min using poly(A)·oligo(dT)$_{12-18}$ as template) were mixed with 5 μl 0 6 M KCl solution containing 50 mg ml^{-1} bovine serum albumin (KCl–BSA) To this was added 20 μl dilution of appropriate Ig. Entire mixture incubated for 2 h at 4 °C; 170 μl reverse transcriptase reagents (0.025 % NP40, 25 mM Tris-HCl, *p*H 8 1, 7m M 2-mercaptoethanol, 0 2 mM MnCl$_2$, 60 mM KCl, 1 μg poly(A)·oligo(dT)$_{12-18}$ (Collaborative Research, Waltham, Massachusetts) 5 μCi ^{3}H-dTTP (specific activity 55 Ci mmol^{-1}, Schwarz–Mann, Orangeburg, New York) and 0 0083 mM 'cold' dTTP (Sigma) were added; entire mixture incubated at 37 °C for 40 min. Reaction mixture chilled quickly in ice and precipitated by addition of 25 volumes ice-cold 5 % TCA–2 % sodium pyrophosphate Acid-precipitable radioactivity determined[9,13]. Inhibition expressed relative to reactions containing virus without Ig. This reference value determined from average of four identical reaction mixtures. Figures represent percentage inhibition of reverse transcriptase at highest Ig concentration used. In cases in which inhibition was observed, value given represents a plateau level, at which increasing the Ig concentration resulted in no further inhibition of enzymatic activity

ALL, Acute lymphocytic leukaemia; CML, chronic myelocytic leukaemia; AML, acute myelocytic leukaemia; ND, not determined

more than 95% of the purified protein migrated, as expected for heavy and light chains of IgG and IgA (ref 10).

The extent of inhibition of the reverse transcriptase from various type C viruses was compared using purified 7S Ig from each patient (Table 1). Ig from six of the patients did not inhibit significantly the reverse transcriptase of any of the viruses tested. 7S Ig from patients M.R. and R.M., however, reduced the incorporation of ^{3}H-dTTP by reverse transcriptase in the following order: BEV>HEL-12> SiSV>HL23V-1 (ASV7573), (Table 1 and Fig. 2). These findings were confirmed repeatedly for Ig fractions obtained at different times from each of the patients. The difference in inhibition between the enzymes from HEL-12 virions and SiSV is probably related to the antigenic heterogeneity of the former[14]. We have found[14] that the HEL-12 virion population contains at least two components, one with antigenic characteristics of SiSV, the other with properties of BEV. Interestingly enough, the reverse transcriptase of a type C virus isolated by Gallagher and Gallo[11,12] and referred to as HL23V-1, was not significantly inhibited by 7S Ig from patient M.R. The reasons for the lack of reverse transcriptase inhibition of this isolate are unclear, even though the HL23V-1 virus is known to be related to SiSV. The results may be attributable to qualitative differences between the 7S Ig fractions of patients M.R and R M., as well as antigenic differences between the reverse transcriptases of HEL-12, HL23V-1 and primate viruses such as SiSV. We have also examined for inhibitory activity the 7S Ig fraction of six normal volunteers. The viruses used as sources of reverse transcriptase included HEL-12, SiSV,

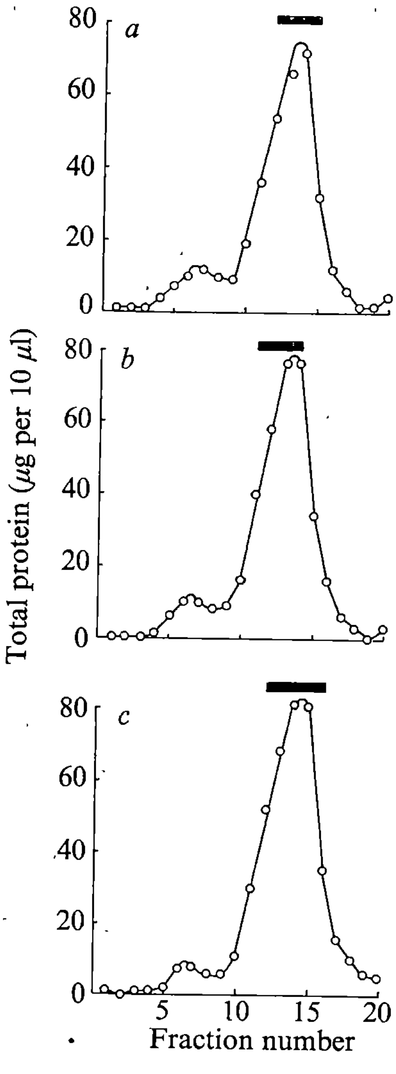

Fig. 1 Representative zonal sedimentation profiles of Ig from patients M.R. (*a*) and R.M. (*b*), and a normal volunteer (*c*). Blood from patients drawn into sterile, heparinised tubes, allowed to stand at 4 °C for 3–8 h and centrifuged at 1,100 r.p m for 10 min. Plasma stored at −20 °C. For Ig purification, 1.0 ml plasma from each patient was diluted with an equal volume of TNE buffer and slowly mixed with 2.0 ml saturated solution ammonium sulphate at 4 °C. After stirring for 30 min, precipitate centrifuged for 30 min at 2,000*g*. Supernatant fluid discarded, pellet resuspended in 2.0 ml TNE buffer, and precipitation by ammonium sulphate repeated. After centrifugation at 2,000*g*, pellet resuspended in 300 μl TNE buffer and dialysed exhaustively at 4 °C against 0.04 M phosphate buffer, *p*H 6.9 300 μl dialysate layered on 5 ml linear 10–40 % sucrose gradient in TNE buffer and centrifuged at 4 °C in a SW50.1 rotor at 35,000 r p.m. for 16.25 h 20 equal-volume fractions collected from bottom of tube, and 10 μl aliquots assayed for protein according to method of Lowry *et al.*[7]. IgG purified on Sephadex G-200, included in a parallel gradient, sedimented at fraction 14. Fractions indicated by bars were pooled, dialysed exhaustively against 0.1 M Tris-HCl, *p*H 8.0, and stored at −20 °C. Direction of sedimentation from right to left

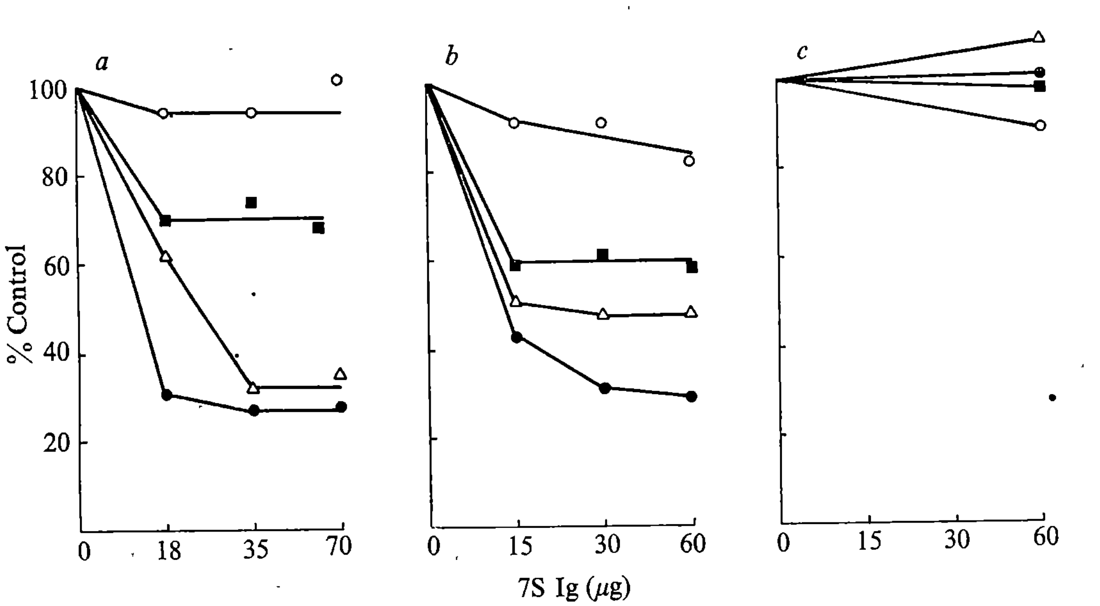

Fig. 2 Inhibition of type C virus reverse transcriptases by purified 7S Ig. 20 μl dialysed 7S Ig fraction from patient M R (*a*) or R.M. (*b*) or from a normal volunteer (*c*) incubated for 2 h at 4 °C with 5 μl KCl–BSA and 5 μl appropriate NP40-disrupted type C virus (12,000–80,000 c.p m ^{3}H-dTTP incorporated in 40 min). Reverse transcriptase reagents added (170 μl). Acid-precipitable ^{3}H-radioactivity measured after 40 min incubation at 37 °C All values expressed relative to average of quadruplicate reactions for each virus run in absence of 7S Ig. Each point represents average of duplicate samples. ○, G-MuLV; ■, SiSV; △, HEL-12 virions; ●, BEV

and Gross murine leukaemia virus (G-MuLV). In none of the cases was a greater than 10% inhibition observed at comparable 7S Ig concentrations (not shown).

The above observations with the 7S Ig of patients M R. and R.M. were extended to the purified reverse transcriptases of avian myeloblastosis virus (AMV) and SiSV. At the concentrations tested, 7S Ig from patients M.R. and R.M did not significantly inhibit the activity of AMV reverse transcriptase (Fig. 3). Substantial inhibition of the SiSV enzyme was, however, observed in the case of both Igs.

Since destruction of the RNA template or of the enzymatic poly(dT) product by plasma nucleases could account for the observed inhibition, 7S Igs were incubated with ^{3}H-poly(A) or with poly(A)·^{3}H-poly(dT) (Table 2). As determined by hydrolysis of the labelled polynucleotides, Ig from leukaemic patients did not contain poly(A) nuclease activity nor was ^{3}H-poly(dT) hydrolysed to a significant degree by any of the Igs tested.

The inhibition might also have been due to the presence of anti-nucleic acid antibodies in the Ig fraction. Aliquots of Ig were therefore incubated with ^{3}H-poly(A) or with poly(A)·^{3}H-poly(dT). The Igs were precipitated with half saturated ammonium sulphate which precipitates only nucleic acid molecules complexed with antibody[17]. As shown in Table 2, anti-nucleic acid antibodies were not detected by this assay method in any of the samples tested.

Why do patients with leukaemia develop a humoral antibody against an internal virion component such as reverse transcriptase? Three explanations can be offered: leukaemic leukocytes may produce type C viruses which are degraded and release antigenic reverse transcriptase[11,18,19] related to the reverse transcriptase of HEL-12 virions; lysis of leukaemic leukocytes may release "particle-associated reverse transcriptase[20–22]" (note that both patients with inhibitory antibody had undergone long term chemotherapy and had survived for approximately one year from the time of initial diagnosis; however, the patients were never in haematological remission); reverse transcriptase may be exposed at the surface of leukaemic leukocytes, as are other internal virion proteins in infected animal cells[23–25].

Irrespective of the mechanism by which reverse transcriptase exerts its antigenic effect, the antibody response observed in the two patients seems highly specific for the reverse transcriptases from viruses of primate origin. The specificity of reverse transcriptase inhibition was substantiated using purified enzyme preparations derived from stocks of AMV and SiSV. Thus, it cannot be argued that

^{3}H-poly(A), Miles Laboratories, Elkhart, Indiana. Poly(A)·^{3}H-poly(dT), synthesised in a standard reverse transcriptase reaction[1,9,13] using purified reverse transcriptase from AMV as enzyme source (Schwarz–Mann). Reaction mixture diluted tenfold in TNE buffer (0.1 M NaCl, 10 mM Tris-HCl, *p*H 7.3, 1 mM EDTA) and extracted once with TNE-saturated recrystallised phenol and once with chloroform–isoamyl alcohol (24:1). Product precipitated at −20 °C for 48 h by addition of 2 volumes 100% ethanol. After centrifugation at 10,000*g* for 60 min, pellet resuspended in a minimal volume 0.1 M Tris-HCl, *p*H 8.0, and stored at −20 °C. After isopycnic centrifugation in neutral CsCl gradients, > 95% ^{3}H-radioactivity found associated with RNA.

*Hydrolysis by 7S Ig measured after incubation of 10 μl Ig and 5 μl ^{3}H-poly(A) (~ 1,500 c.p.m. per 5 μl) or poly(A)·^{3}H-poly(dT) (~ 1,000 c.p.m. per 5 μl) for 2 h at 4 °C and for 40 min at 37 °C. Mixture precipitated by addition of excess ice-cold 10% TCA. Acid-insoluble material collected on a 0.45-μm membrane filter (Millipore) and dried thoroughly. Unhydrolysed radioactivity measured in toluene-based scintillation fluid.

†10 μl Ig in 0.1 M Tris-HCl, *p*H 8.0, incubated with 5 μl ^{3}H-poly(A) or poly(A)·^{3}H-poly(dT) for 2 h at 0 °C and for 40 min at 37 °C. Ig precipitated by addition of 5 ml half-saturated ammonium sulphate solution. Precipitate centrifuged, washed with additional 5 ml half-saturated ammonium sulphate solution and centrifuged Amount of ^{3}H-label in precipitate determined and expressed as percentage total acid-precipitable input c.p.m.

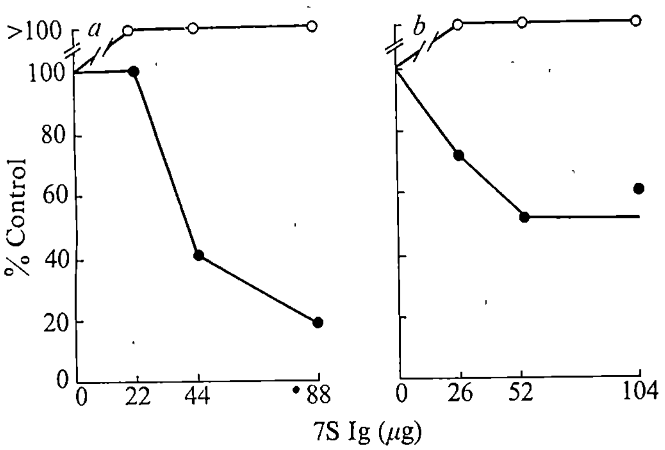

Fig. 3 Inhibition of purified reverse transcriptases by 7S Ig from patients M.R. (*a*) and R.M. (*b*). AMV (○) and SiSV (●) reverse transcriptases purified as described previously[15,16]. AMV enzyme, purchased from Schwarz-Mann; SiSV enzyme, gift of Drs R. E Gallagher and R. C. Gallo. Both enzymes stored at −20 °C in 0.26 M KCl, 30 mM Tris-HCl, *p*H 7.9, 0.6 mM dithiothreitol, 0.06% Sterox SL, and 50% glycerol. 40 μl 7S Ig in 0.1 M Tris-HCl, *p*H 8 0, incubated with 10 μl enzyme for 2 h at 4 °C with constant mild agitation. Reverse transcriptase reagents (150 μl) were added (see Table 1) and mixture incubated for 40 min at 37 °C. Each point determined from average of triplicate samples and expressed relative to average of six identical control samples containing enzyme in absence of 7S Ig.

the selective inhibition was the result of differential accessibility of the reverse transcriptases of primate viruses or of a nonspecific inhibition. The results indicate that some adult patients with leukaemia mount a humoral immune response against two antigenically distinct reverse transcriptase or against an enzyme which shares determinants with both SiSV and BEV enzymes. Although our observations are consistent with findings of SiSV- and BEV-related polypeptides in certain human tissues[20,22,26-28], our patient population is obviously too small to conclude that the humoral response to reverse transcriptase is confined strictly to patients with leukaemia.

We thank Drs D. Gillespie, R. Gallagher, R. Gallo, S. Panem, R. Rothberg and C. Rieger for discussions. Supported by the Renee Shaffer Gettleman Memorial Foundation Auxiliary and the US Public Health Service (National Cancer Institute). Increasing haemoglobin β-chain synthesis in foetal development is associated with a declining γ- to α-mRNA ratio

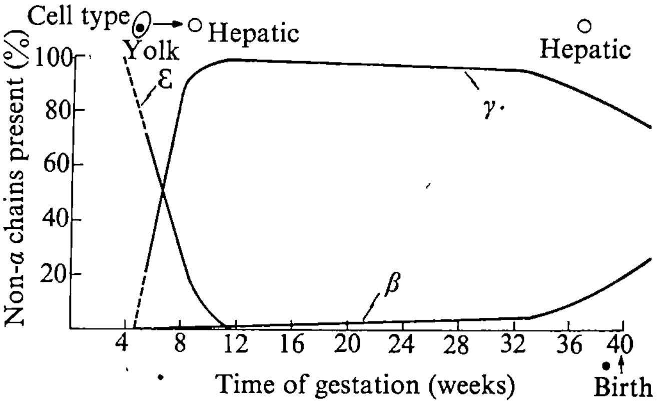
DURING human foetal development, the predominant haemoglobin in erythrocytes switches twice (Fig. 1). First, ε chains of embryonic haemoglobins in erythroblasts of yolk sac origin are replaced by γ chains of foetal haemoglobin and traces of β chains of adult haemoglobin. This switch occurs very early in foetal development, coincident with the appearance of a new type of peripheral erythrocyte of hepatic origin. Second, at about 32 weeks of gestation, predominantly γ-chain production gives way to increased β-chain synthesis within a constant cell type[1]. This double haemoglobin switch also occurs in other animals, including sheep[2]. Not only is very little known about the biological basis for the switch from γ- to β-chain production, but the basic changes in gene activity involved in the switching process are obscure. An understanding of the γ to β switch has clinical importance, for if one could block the switch and increase γ-chain production, sickle cell anaemia and β-thalassaemia could be treated effectively. We present here data concerning changes in globin gene activity, as assessed by globin mRNA levels, which are temporally related to the turning up of β-chain synthesis. These observations were originally made in erythroid cells of aborted human foetuses and were extended to cells from foetal sheep.

Globin mRNA of human sheep reticulocytes was isolated by oligo(dT)-cellulose chromatography of polyribosomal RNA[3,4]. Gould and Hamlyn demonstrated that the mRNA region of rabbit reticulocyte RNA contained two bands after acrylamide gel electrophoresis in formamide[5], and subsequent work in many laboratories demonstrated that the faster migrating of these RNAs is α mRNA and the slower is β mRNA[6-10]. This electrophoretic procedure separates the

Fig. 1 Percentage of non-α chains in foetal development plotted against time of gestation. The erythroid cell type, yolk sac or hepatic, is shown above.



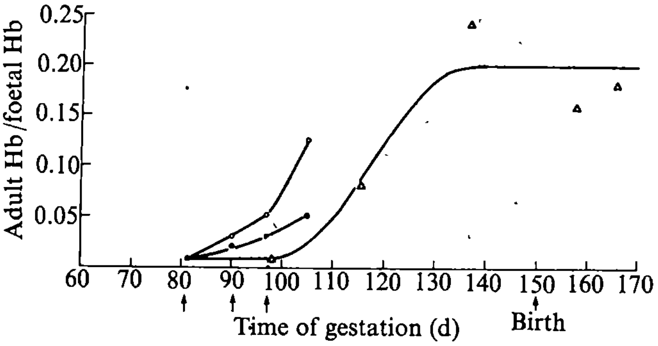


Fig. 2 Synthesis of adult haemoglobin (Hb) compared with that of foetal haemoglobin plotted against age of sheep from conception. The normal curve (△) is shown in addition to data obtained on two foetal sheep bled at times indicated by the arrows. ○, Sheep 5,283; ●, sheep 5,216. Erythroid cells of foetal sheep were washed and incubated with ^{35}S-methionine for 3 h (ref. 15). The haemoglobins were separated by Bio-Rex 70 chromatography as described for separation of human foetal and adult haemoglobins[15] except that the starting buffer was 0 019 M in sodium phosphate. Sheep haemoglobins A and B elute close to one another with starting buffer at 25 °C, and haemoglobin C elutes when the sodium phosphate concentration is increased to 0.058 M at 25 °C. Haemoglobin C synthesis was questionable except in sheep 5283 at 105 d when it accounted for nearly 5% of total haemoglobin synthesis.

α and β mRNAs in several species, including man[10,11], mouse[7], rabbit[6], sheep and goat (unpublished results of H.H.K. and P.G.S.). The same technique has shown that β mRNA is deficient in reticulocyte RNA preparations from human foetuses[11], and that in man, γ mRNA has an intermediate mobility between the β and α mRNAs[10–11].

In globin mRNA preparations from human adult reticulocytes, the ratio of β mRNA to α mRNA was determined by gel electrophoresis to be near 1 (ref. 11). Unfortunately, we have been unable to separate the γ and α mRNAs sufficiently to allow accurate estimation of the ratio of their concentrations in foetal cells

Therefore, we assayed foetal mRNA preparations in an ascites cell-free system[12] and compared the γ- to α-chain synthesis ratios with the β to α ratios obtained with mRNA from adult cells (Table 1). Although the cell-free system does not facilitate quantitation of the absolute ratios of chains synthesised, it makes possible the comparison of chain synthesis ratios directed by different mRNA preparations when mRNA is present in limiting concentrations. In this system the RNA from sickle cell patients and a 32-week premature infant gave β/α or γ/α ratios near unity. In contrast, assays of mRNA from mid-trimester foetuses resulted in γ/α-chain ratios much greater than 1. Thus, cell-free assays suggested that γ/α-mRNA ratios were greater than 1 at mid-trimester and near 1 at 32 weeks of gestation in man.

Table 1 Cell-free globin synthesis ratios

Human mRNA source	Chain synthesis ratio
	(β/α)
Adults (SS disease)	1.1
	1.0
	(γ/α)
32-week premature infant	1.4
Mid-trimester foetuses	4.0
	4.5

The source of globin mRNA for these assays was reticulocyte polyribosomal RNA. Assay conditions were those previously described[12] and mRNA concentrations were less than 1 µg per 60 µl, well below the concentration of 4–6 µg mRNA per 60 µl, which is non-limiting in our laboratory. Product was analysed by chain separation on Cellogel electrophoresis[16]. In addition, a γ/α-synthetic ratio of 2.1 was obtained in a mid-trimester foetal sample analysed by peptide mapping which is twice the β/α ratio observed in assays of adult mRNA preparations analysed in this manner.

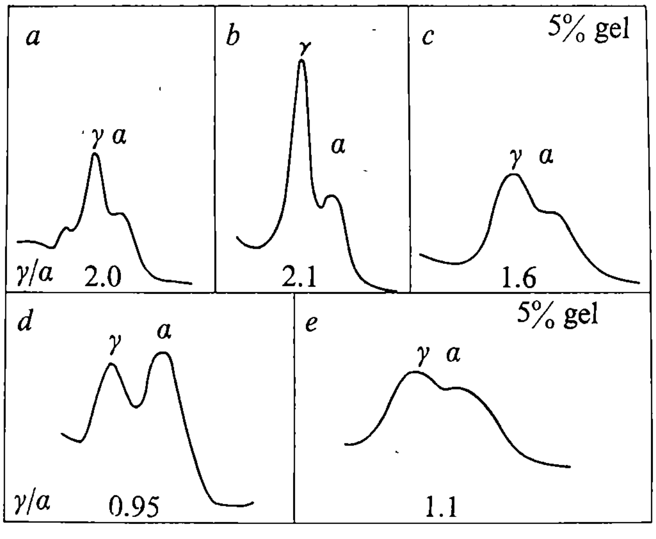

Fig. 3 Gel scans of globin mRNAs of foetal sheep at: *a*, 74 d; *b*, 81 d; *c*, 95 d; *d*, 98 d; *e*, 115 d of gestation. Reticulocytes were washed and lysed, and polyribosomes were obtained by ultracentrifugation[3]. The RNA solution was extracted, chromatographed on oligo(dT)-cellulose[4], and the mRNA fraction was subjected to electrophoresis in formamide on 7% polyacrylamide gels[6]. Scans of the gels after treatment with Stains-All were performed at 600 nm. Results shown in (*c*) and (*e*) were obtained with 5% polyacrylamide gels.

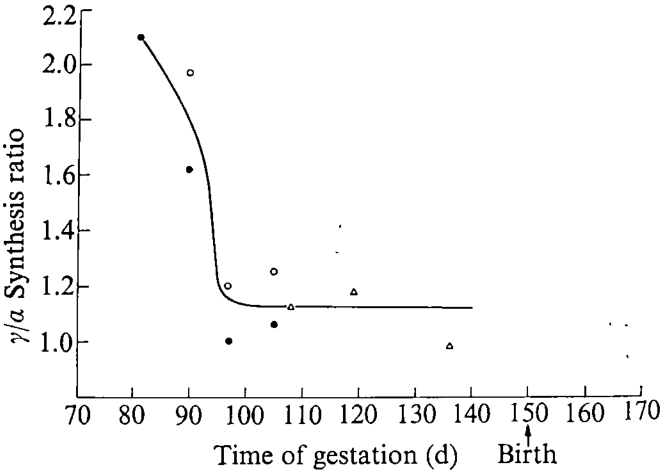
To provide further evidence for a declining γ/α-mRNA ratio in late foetal development, we used cells from foetal sheep. This animal has the following advantages. (1) Haemoglobin switching during development is very similar to that in man. At birth, adult haemoglobin accounts for 5–10% of total haemoglobin[2]. (2) Foetal sheep can be obtained at known gestational ages. (3) The foetus can be removed surgically from the uterus, manipulated and returned to the uterus without significant mortality.

Fig. 4 The γ/α synthesis ratio of foetal sheep reticulocytes plotted against time of gestation. Reticulocytes were incubated with ^{3}H-leucine and the radioactive chains were separated by Cellogel electrophoresis in urea and mercaptoethanol[16]. The relative amounts of γ and α chains recovered after electrophoresis and staining were determined by the absorbancy of dissolved Cellogel strips and the data were used to correct the d.p.m. associated with the γ and α chains for the yield of each chain. Results obtained with sheep foetuses that were not chronically bled are indicated by triangles. Bled foetuses were: ●, 5,283; ○, 5,216.



Blood samples were obtained from foetal sheep at various times during gestation, and haemoglobin synthesis, together with globin mRNA quantities, was studied in the cells. The ratio of adult haemoglobin synthesis to foetal haemoglobin synthesis was determined at various times of gestation (Fig. 2). The synthesis of adult haemoglobin is about 1% that of foetal haemoglobin until about 100 d of foetal life, which is two-thirds of the way through gestation. It then rises to 20% that of foetal haemoglobin by 130–140 d of gestation.

When globin mRNA of foetal sheep is subjected to formamide gel electrophoresis, unlike the situation in man, the non-α mRNA (the presumed γ mRNA) separates quite well from α mRNA (Fig. 3). When these two RNAs were eluted separately from gels in which the RNA separation was suboptimal, the slower migrating band directed the synthesis of 1.6 times as many γ chains as α chains in the cell-free system, while the faster migrating band directed the synthesis of a twofold excess of α chains. Sheep β mRNA has an electrophoretic mobility similar to that of γ mRNA by this technique But β-chain synthesis accounts for less than 10% of non-α chain synthesis up to 115 d of gestation, indicating that γ mRNA should be free of significant β-mRNA contamination until late in gestation. The ratio of γ mRNA to α mRNA was about 2 in reticulocytes at 70–80 d and then declined to near 1 at 98–100 d of gestation. Although it remained in this general range, a sample obtained at 145 d had a (γ mRNA+β mRNA) to α mRNA ratio of 1.3.

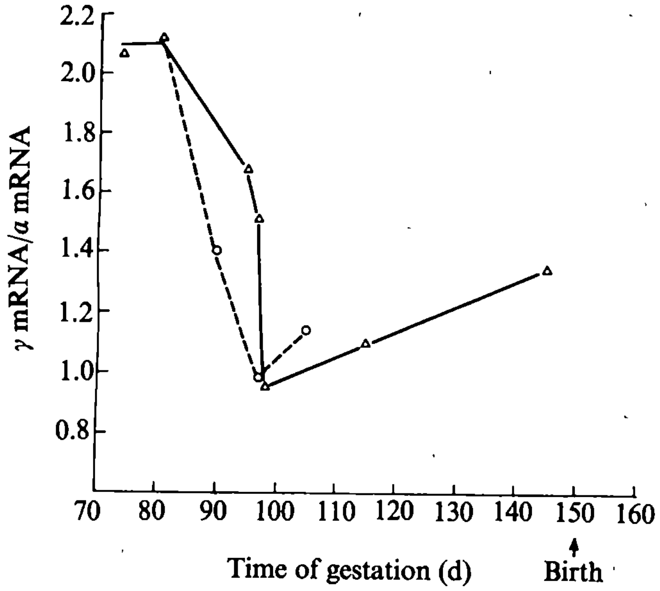


Fig. 5 The γ/α-mRNA ratio plotted against the time of gestation. Results from normal (△) and chronically bled foetuses (○) are shown. Blood from the two foetuses undergoing bleeding was pooled at each point to ensure sufficient mRNA for analysis.

To determine whether the decline in γ/α-mRNA ratio is important for the subsequent turning up of β-chain synthesis, we attempted to alter the timing of increased β-chain synthesis by chronic bleeding of foetal sheep. Two foetuses were bled of approximately one-fifth of their blood volume (40 ml) at 81, 90 and 97 d, and then bled and killed at 105 d of gestation. Haemoglobin and globin chain synthesis by reticulocytes, and globin mRNA levels were studied at these times. In one bled foetal sheep, the synthesis of adult haemoglobin increased prematurely, reaching 12.5% that of foetal haemoglobin at 105 d of gestation (Fig. 2). Adult haemoglobin synthesis in untreated foetuses at that gestational age is about 3% of foetal haemoglobin synthesis. In the second sheep, adult haemoglobin synthesis was also increased, but the moderate rise observed may not be significantly different from normal.

We then asked whether the premature increase in β-chain synthesis was associated with premature changes in γ/α mRNA and γ/α-chain synthesis ratios. In Fig. 4 the reticulocyte γ/α-chain synthesis ratio is plotted against the time of gestation in the bled foetuses. This ratio was about 2 at 80 d of gestation, suggesting that in the sheep translational controls do not operate to balance the synthesis of α and γ chains in the early foetus. In contrast, synthesis of α and γ chains during early foetal life in man is balanced[13]. Moreover, the γ/α-chain synthesis ratio dropped to 1 at about 90–100 d of gestation Just as the ratio of γ/α-chain synthesis declined at 90 d of gestation, so the γ/α-mRNA ratio also declined precipitously between 90 and 100 d of foetal age in both normal foetuses and bled foetal sheep (Fig. 5).

These studies of the turning up of β-chain synthesis suggest the following conclusions. First, β-chain switching in the sheep may be hastened by continued bleeding of the foetus. Whether this premature turning up of β-chain synthesis is a response to stress, hypoxia or other factors is not clear. Erythroprotein was not detectable in the blood of the bled foetuses until the day of death when it was 0.2 U ml^{-1} in one sheep (denoted 5,283, data of J. L. Spivak). Second, the γ/α-mRNA ratio is greater than 1 early in foetal development and decreases to unity around the time of increased β-chain production.

These data and the fact that the number of γ genes in man is at least twice that of β genes[1,14], suggest the following hypotheses. (1) Active γ-chain genes lead to a γ/α-mRNA ratio of 2 in the foetus, in contrast to the β/α-mRNA ratio of 1 in the adult. (2) This ratio is maintained until about 30 weeks of gestation in man and 90 d of gestation in sheep when transcription of γ-chain genes declines, leading finally to a partial deficiency of γ chains within precursor erythroid cells, which is followed by an increased production of β chains in these cells. The data presented here indicate that a relative decline in γ mRNA occurs in reticulocytes at about the time of increased β-chain synthesis, but they do not demonstrate that this decline is a necessary precedent to the turning up of β-chain production. In these experiments a premature increase of β-chain synthesis was produced in two bled foetal sheep, but a premature decline in the γ/α-mRNA ratio and the parallel γ/α-chain synthesis ratio, which the data suggest, requires further investigation.

This work was supported in part by a contract and grants from the National Institutes of Health, and by an Independent Order of Odd Fellows Research Professorship (A.M.S.). We thank Shirley L. Johnson for technical assistance.

Half life of yeast messenger RNA

WE have determined the half life of *Saccharomyces cerevisiae* messenger RNA (mRNA) and its associated poly(A) sequences, from the kinetics of their labelling with ^{14}C-adenine. Corrections have been made for changes in the ATP pool specific activity during the labelling period. This method of determining the mRNA half life is preferred to observing the decay of mRNA in the presence of inhibitors because changes in the cell metabolism caused by an inhibitor may also change the mRNA half life[1]. One of our purposes in determining these half lives is for their use in the characterisation of temperature-sensitive mutants which are defective in macromolecular synthesis[2]. For this reason we have determined the half lives of mRNA and poly(A) in two different conditions, at 23 and 36 °C.

The incorporation of ^{14}C-adenine into mRNA has been followed in total mRNA and in the poly(A) portion of mRNA. The total mRNA was obtained from polysomes isolated on sucrose gradients. To separate rRNA and mRNA, the polysome fractions were collected and rerun on 10–30% sucrose gradients in low magnesium buffer, in which the polysomes dissociate into 40S and 60S subunits and mRNA. Figure 1 shows a typical subunit gradient, in this case from polysomes labelled for 30 min at 36 °C with ^{14}C-adenine. The rRNA in the 60S and 40S subunits is clearly resolved. The mRNA forms a broad peak that, for the most part, sediments more slowly than the 40S subunit. The division between counts in mRNA and subunits is estimated by assuming that the specific activity of the subunit RNA is constant across the peak. (The tRNA accounts for < 3% of the radioactivity in the ribosomal subunits.) The radioactivity in mRNA is determined from these gradients and normalised to the absorption in total ribosomal RNA on the gradients, to correct for variations in the extent of cell lysis in the sample. These data are plotted in Fig. 2. The curve drawn through the points is a computer fit of equation (3), as is discussed below.

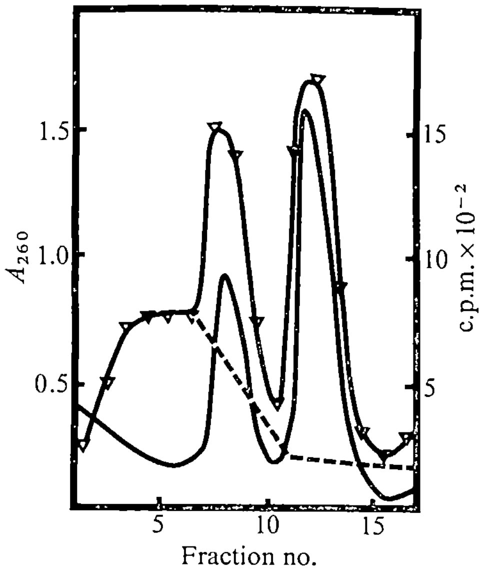

Fig. 1 Dissociation of polysomes into ribosomal subunits and mRNA. Cells were converted to spheroplasts[12], which were labelled with ^{14}C-adenine for the indicated time, lysed, and layered on sucrose gradients containing 0.03 Mg^{2+} (ref. 12) The polysome region (as determined by an ultraviolet scan) from these gradients was pooled and centrifuged at 160,000*g* for 3 h and the pellet resuspended in S buffer (0.01 M Tris, 0.1 M NaCl, 10^{-5} M $MgCl_2$, *p*H 7.4) to dissociate the polyribosomes This was layered on a 15–30% sucrose gradient in S buffer and centrifuged at 90,000*g* for 17 h. The gradient shown is representative, and is from a culture labelled for 30 min at 36 °C. ▽, c p.m. in ^{14}C-adenine. The theoretical curves for mRNA (- - -) and rRNA (——) are also shown

Table 1 Ratio of ^{3}H/^{14}C in intercellular pools*

	ATP			
	23 °C		36 °C	
Time labelled with ^{3}H-adenine (min)	Average value	Mean deviation	Average value	Mean deviation
5	0.41	0.01	0.38	0.04
15	0.83	0.12	0.88	0.01
30	1.00		1.00	

*Spheroplasts were prepared as in Fig. 2 and allowed to grow for 3 h in media labelled with 0.5 µCi ml^{-1} ^{14}C-adenine (specific activity 45 mCi mmol^{-1}). 30 µCi ml^{-1} ^{3}H-adenine (10 Ci mmol^{-1}) was added, and 1-ml samples were collected in equal volumes of 10% TCA. The TCA samples were filtered, and the filtrate was charcoal absorbed and washed as described in ref. 9, except that the mixture used to elute the nucleotides from the charcoal was ethanol–28% NH_4OH–H_2O (65:2:32 v/v). The samples were dissolved in water with carrier ATP, GTP, UTP, and CTP, and were spotted on thin-layer PEI cellulose plates (Brinkman, CEL 300 PEI, 20×20 cm). The solvent system used to separate the trinucleotides was developed by Neuhard *et al.*[10] and modified by Mowbray[11]. Plates were developed 3 cm in 2 M LiCl–2 M acetic acid (1:1 v/v) and then to 15 cm in 2.5 M LiCl–2 M acetic acid (1:1 v/v) in the first dimension. They were dried, washed in methanol, and developed in the second dimension first to 5 cm in 3 M ammonium acetate, 3.6% boric acid *p*H 7.0 and then to 15 cm in 4 M ammonium acetate, 5% boric acid *p*H 7.0. The plates were dried and the ATP and GTP spots identified by autoradiography and the ultraviolet absorption of the markers. These spots were cut out and counted to determine the ^{3}H/^{14}C ratio.

The half life of poly(A) in polysomes was determined by following the incorporation of ^{14}C-adenine into nuclease-resistant material, isolated from polysomes, which binds to poly(dT)– cellulose columns[4]. These data were fitted in the same way as total mRNA (Fig. 3).

Table 2 Decay constants of yeast RNA*

	mRNA			Poly(A)		
	µ	*k*	Half life	µ	*k*	Half life
23°C	0.0416	0.115	16.6	0.0601	0.115	11.5
36°C	0.0421	0.128	16.4	0.0547	0.128	12 6

*Values have been obtained from the computer fit of the data shown in Figs 2 and 3 and are corrected for the labelling of the ATP precursor. The values for the half lives of mRNA and the associated poly(A) sequences, uncorrected for the labelling kinetics of the ATP pool, were ~ 9 min longer in each case.

The radioactivity in mRNA as a function of time depends on the specific activity of the ATP precursor pools as well as the rate of synthesis and destruction of mRNA. If the change in specific activity of the ATP pools was neglected, the amount of mRNA after short times would be underestimated relative to the amount made after longer periods of labelling. We measured the specific activity of the ATP pool in cultures labelled identically to those used for the determinations of half life using two-dimensional thin-layer chromatography to isolate cellular nucleoside triphosphates (Table 1). Since the conversion of adenine to guanine is restricted by the presence of non-radioactive guanine in the medium, the labelling of GTP was ~ 10% of that of ATP. This yielded, given the relative sizes of the ATP and GTP pools[3], a specific activity of the GTP of < 30% of that of the ATP at the longest labelling times. The evolution of this rise in specific activity, in so far as could be measured (data not shown), followed that of the ATP. For these reasons a correction for the kinetics of labelling of the GTP was not necessary.

We have fitted our data for the labelling of mRNA (Figs 2 and 3) to an equation which takes into account changes in ATP specific activity. We assume that the specific activity of the mRNA is a function of the specific activity of the ATP pool and of the rate of synthesis and degradation of mRNA

$$\frac{dM}{dt} = \mu(P-M) \qquad (1)$$

where M is the specific activity of the messenger pool, μ is the rate of synthesis of mRNA per unit of mRNA in the cell, and P is the specific activity of the ATP pool The assumptions involved in this equation are that the amount of mRNA per unit cell mass is constant, and that the decay of mRNA is random. To obtain values for P we have fitted the data for the specific activity of the ATP pools to a curve of the form

$$P = 1-\exp(-kt) \qquad (2)$$

where k is the time constant of labelling of the ATP pool and the final specific activity of the ATP pool is defined as 1.0. Using equations (1) and (2) and solving for M

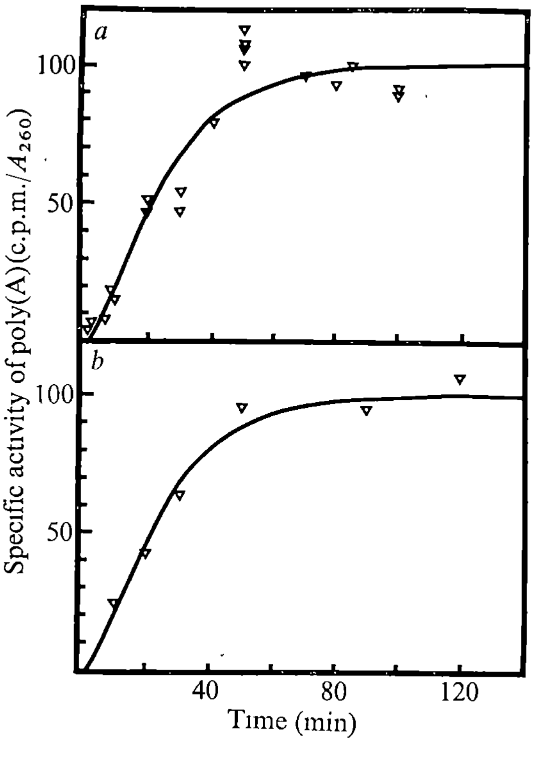
$$M = 1+\left[\frac{k\exp(-\mu t)-\mu\exp(-kt)}{\mu-k}\right] \qquad (3)$$

When the specific activity of the pool is constant, the solution to equation (1) is

$$M = 1-\exp(-\mu t) \qquad (4)$$

Table 2 gives the values of k and μ for each of the curves in Figs 2 and 3 as well as the half lives of the RNA. The half life of total mRNA is ~ 16 min at both 23 and 36 °C whereas that of poly(A) is ~ 12 min at both 23 and 36 °C. This difference of ~ 4 min in the half lives of mRNA and poly(A) could arise from: first, differences in the labelling of internal precursor pools from which poly(A) and mRNA are made; second, clipping of poly(A) during the lifetime of the messenger so that an older message would have shorter poly(A) sequences or third, the presence of a longer lived fraction of mRNA that contains no poly(A).

Fig. 2 The kinetics of ^{14}C-adenine incorporation into mRNA. The curve is a least squares computer fit of the data points to equation (3) with k determined from the data in Table 1 The specific activity of mRNA is normalised to 100 for maximum labelling a, mRNA labelled at 23 °C; b, mRNA labelled at 36 °C.



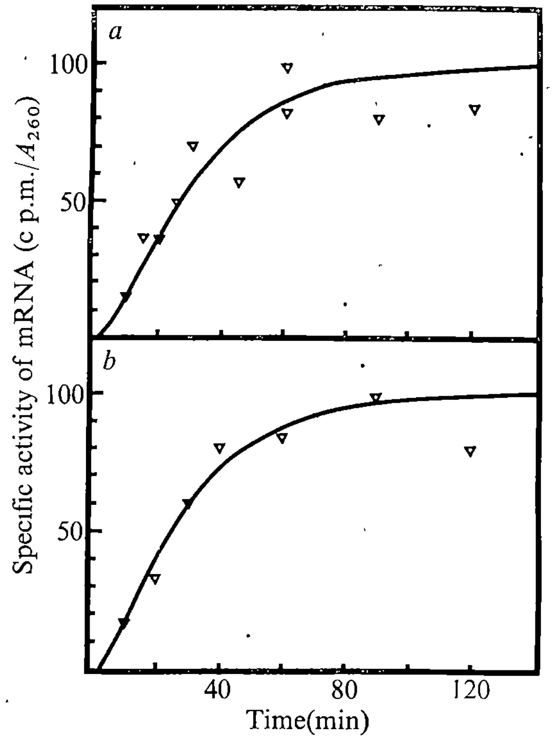


Fig. 3 The kinetics of ^{14}C-adenine incorporation into messenger-associated poly(A). The curve is a least squares computer fit of the data points to equation (3), with k determined from the data in Table 1. a, Poly(A) labelled at 23 °C; b, poly(A) labelled at 36 °C.

There have been several previous determinations of yeast mRNA half life. Hartwell *et al.* have measured the kinetics of incorporation of ^{14}C-adenine into polysomes in the presence of cyclohexamide and the decay of polysomes in the mutant *rna 1* which is defective in cytoplasmic RNA production[5]. Also, Tønneson and Friesen have followed the decay of protein synthesis in the presence of daunomycin or ethidium bromide[6]. The value obtained for the half life of mRNA in these experiments was ~ 22 min.

The value we obtained for the half life of the mRNA in yeast is 10–15% of the cell doubling time. This is intermediate between the values obtained for *E. coli* of ~ 3–6% of the doubling time, and values obtained for HeLa cells and mouse C cells of 70% or more of the cell doubling time[7,8].

We thank Joy Barnitz, Robert Petersen and Pamela Sutherland for help. This investigation was supported by Public Health Service grants from the National Institute of General Medical Sciences and a grant from the National Cancer Institute.

Aminoacylation and nucleoside modification of *in vitro* synthesised transfer RNA

TRANSCRIPTION of transfer RNA (tRNA) genes *in vitro* by purified RNA polymerase has the advantage of producing completely unmodified tRNA precursors which provide a substrate for the study of the processes and modifications leading to the formation of mature tRNA molecules. We have shown[1] that the tRNA genes, *tRNA$_1^{Tyr}$* (*su$_3^+$* and *su$_3^-$*), *tRNA$_2^{Gly}$ su$^+$A36*, *tRNA$_3^{Thr}$* and *tRNA$_2^{Tyr}$* (carried by the respective φ80psu$_3^{+,-}$ and λh80T phage DNA[2,3]), were transcribed *in vitro* by *Escherichia coli* RNA polymerase into polycistronic tRNA precursors. These precursors were cleaved on incubation with a supernatant fraction from *E. coli*, yielding mature size tRNA molecules[1]. The transcription *in vitro* of an active *tRNA$_1^{Tyr}$ su$_3^+$* by crude S-30 *E. coli* extracts or a combination of partially purified fractions has been described[4–6]. The formation of the primary transcription products of the *tRNA^{Tyr}* gene was not, however, clearly demonstrated and it was concluded that an additional *E. coli* extract fraction would be required to enable purified RNA polymerase to function in tRNA synthesis[5,6]. We report here evidence indicating that the *in vitro* transcription of φ80psu$_3^{+,-}$ or λh80T DNA by purified *E. coli* RNA polymerase alone produces tRNA precursor molecules which are not only processed to form mature-size tRNA[1] but are also recognised by specific modifying enzymes. In addition the tRNA molecules (tRNA$_1^{Tyr}$, tRNA$_2^{Tyr}$, tRNA$_3^{Thr}$ and tRNA$_2^{Gly}$) synthesised and processed *in vitro*, possess amino acid acceptance activity.

For the study of the formation of modified nucleosides in *in vitro* synthesised tRNA, φ80psu$_3^{+,-}$ and λh80T DNA were transcribed by *E. coli* RNA polymerase in reaction mixtures containing α-^{32}P-CTP, α-^{32}P-UTP or α-^{32}P-ATP. After 30 min incubation at 37 °C RNA synthesis was terminated by addition of actinomycin D and DNase I. Synthesised RNA was processed by incubation for 90 min at 37 °C with a dialysed *E. coli* S-100 extract. RNA was extracted with phenol, precipitated using ethanol and fractionated by electrophoresis on a 5% polyacrylamide–7 M urea gel, as described previously[1]. tRNAs were located by autoradiography, extracted from the gel and digested by T$_1$ or T$_2$ RNase. Modified nucleosides, obtained as a result of the enzymatic activities present in S-100 extracts, were identified by two-dimensional thin-layer chromatography of the 3′ mononucleotides from T$_2$ RNase hydrolysates. Alternatively, oligonucleotides were isolated from two-dimensional fingerprints of T$_1$ RNase digestion fragments, hydrolysed by alkali or T$_2$ RNase, and the modified nucleotides identified by paper chromatography[7].

Table 1 Levels of nucleotide modifications in *in vitro* synthesised tRNA

Modified nucleotide	Molar yield Expected	Molar yield Formed*
	For tRNA$_1^{Tyr}$ or tRNA$_2^{Tyr}$

U*p	1	—

*Molar yields of modified nucleotides determined by paper chromatography of T$_2$ RNase hydrolysates of the respective T$_1$ oligonucleotides extracted from fingerprints.

†In tRNA$_1^{Tyr}$ synthesised *in vitro* in presence of α-^{32}P-UTP, only one of the two s^{4}Up residues (U$_9$) is expected to be labelled by nearest-neighbour α-^{32}P-UMP distribution.

‡s^{4}U was measured in tRNA$_1^{Tyr}$ only.

§Molar yield of t^{6}A was determined from two-dimensional thin-layer chromatography as described in Fig. 3, assuming two residues in the 1:1 mixture of tRNA^{Thr} tRNA^{Gly}.

To study the formation of pseudouridine (ψ), the *in vitro* synthesised tRNAs were labelled by incorporation of α-^{32}P-CMP. tRNA$_1^{Tyr}$ and tRNA$_2^{Tyr}$ contain two ψ residues: one in the T$_1$ fragment TψCG and a second near the anticodon in the oligonucleotides ACUCUAAAψCUG or UAAAψCUG (Fig. 1). tRNA^{Thr} and tRNA^{Gly} contain one ψ each in the TψCG fragments. Digestion of the α-^{32}P-CMP-labelled oligonucleotides by alkali generated ^{32}P-labelled ψMP which was then identified by paper chromatography (Fig. 2). Results show that incubation of the primary transcription products with dialysed *E. coli* S-100 extracts, a complete modification of U to ψ occurs in the TψCG fragments derived from tRNA$_1^{Tyr}$ (Fig. 2*a*, strip 2), tRNA$_2^{Tyr}$, tRNA^{Thr} and tRNA^{Gly} (Fig. 2*b*, strips 1 and 3). Formation of ψ in the anticodon region of tRNA^{Tyr} was also quantitative

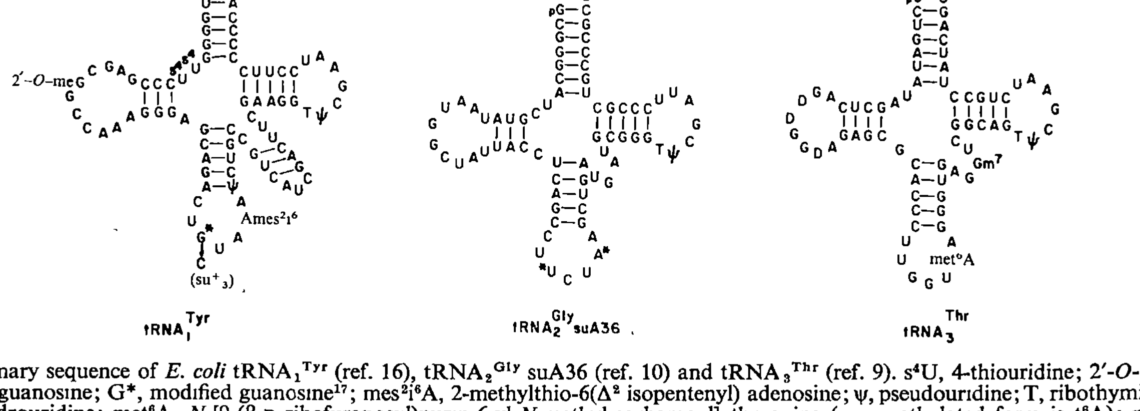

Fig. 1 Primary sequence of *E. coli* tRNA$_1^{Tyr}$ (ref. 16), tRNA$_2^{Gly}$ suA36 (ref. 10) and tRNA$_3^{Thr}$ (ref. 9). s^{4}U, 4-thiouridine; 2′-*O*-meG, 2′-*O*-methylguanosine; G*, modified guanosine[17]; mes^{2}i^{6}A, 2-methylthio-6(Δ^2 isopentenyl) adenosine; ψ, pseudouridine; T, ribothymidine; D, 5,6-dihydrouridine; met^{6}A, *N*-[9-(β-D-ribofuranosyl)purin-6-yl-*N*-methyl-carbamoyl] threonine (non-methylated form is t^{6}A); me^{7}G, 7-methylguanosine; U*, unidentified derivative of uridine; A*, derivative of t^{6}A.

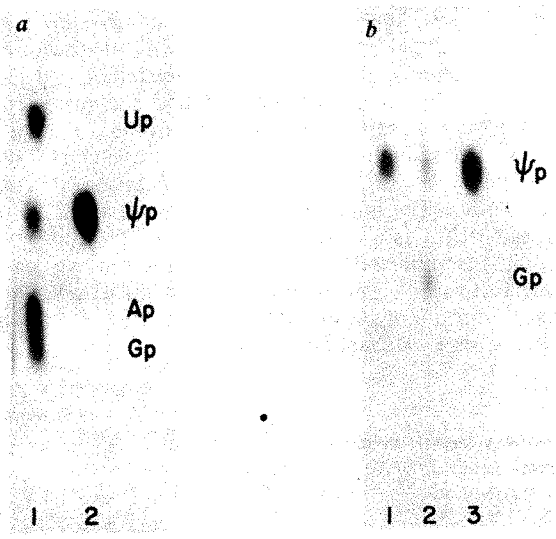

Fig. 2 Paper chromatography of hydrolysates of ψp-containing T$_1$ oligonucleotides from *in vitro* synthesised tRNAs. tRNA$_1^{Tyr}$, tRNA$_2^{Tyr}$, tRNA^{Gly} and tRNA^{Thr} were synthesised *in vitro* by transcribing 20 μg φ80psu$_3^{+,-}$ or λh80T DNA in 200 μl reaction mixtures containing 0.05 M Tris-HCl (*p*H 7.9), 0.01 M MgCl$_2$, 0.05 M KCl, 1 mM dithiothreitol, 0.4 mM each of ATP, GTP and UTP, 60 μM α-^{32}P-CTP (10.3 Ci mmol^{-1}; Amersham, England), 12 μg ρ termination factor and 160 U RNA polymerase (1,600 U mg^{-1}). Synthesis was initiated after 5 min preincubation at 38 °C by addition of nucleoside triphosphates. After 30 min incubation at 38 °C the reaction was stopped by addition of actinomycin D (20 μg) and DNase 1 (2 μg). The mixture was incubated with 400 μg dialysed S-100 extract for 90 min at 38 °C. Synthesised tRNAs were phenol extracted, purified by acrylamide gel electrophoresis, digested by T$_1$ RNase and the resulting oligonucleotides fractionated by two-dimensional electrophoresis as described previously[1]. ψp-containing oligonucleotides from fingerprints were extracted, alkali digested and analysed for nearest-neighbour distribution of α-^{32}P-CMP by paper chromatography in an isopropanol–HCl–H$_2$O (680 : 176 : 144 v/v) system[7]. *a*, Hydrolysates of (1) ACUCUAAAψCUG(C) and (2) TψCG derived from tRNA$_1^{Tyr}$ su$_3^+$; *b*, hydrolysates of (1) TψCG, (2) UAAAψCUG(C) derived from tRNA$_2^{Tyr}$, and (3) TψCG from tRNA^{Tyr} and tRNA^{Gly}. DNA-dependent RNA polymerase was prepared from *E. coli* MRE-600 cells[20] and further purified by low salt glycerol centrifugation[21]. Termination factor ρ (ref. 14) and S-100 extract[1] were prepared from *E. coli* MRE-600.

and the nearest-neighbour distribution of CMP was as expected —1 (ψp):1 (Up):1 (Ap): 1 (Gp) for ACUCUAAAψCUG(C) of tRNA$_1^{Tyr}$ su$_3^+$ and 1(ψp):1(Gp) for UAAAψCUG(C) of tRNA$_2^{Tyr}$ (Fig. 2*a*, strip 1 and Fig. 2*b*, strip 2).

From these results it may be concluded that the *in vitro* synthesised tRNA can serve as a substrate for the two enzymatic activities[8] responsible for the formation of ψ in the TψCG and in the anticodon regions of the tRNA. Formation of ψ is the only modification observed in the *in vitro* synthesised tRNAs as a result of incubation with dialysed S-100 extracts. To study the methylations leading to the formation of T and me^{7}G or the thiolation leading to the formation of s^{4}U, tRNA molecules were synthesised *in vitro* with α-^{32}P-UTP and incubated with dialysed S-100 extract in the presence of S-adenosyl-L-methionine or L-cysteine, respectively. Figure 3*a* shows the two-dimensional thin-layer chromatography of a T$_2$ RNase digest of tRNA^{Thr}, tRNA^{Gly} (1:1 tRNA mixture migrating as a single band on acrylamide gel[1]) in which the methylated nucleotides Tp and me^{7}Gp can be identified. Tp was also determined in the TψCG fragments isolated from two-dimensional fingerprints of T$_1$ RNase digests. Yield of Tp was found to increase with S-adenosyl-L-methionine concentration, reaching 100% at 1.15×10^{-4} M. Formation of me^{7}G was inferred also from the presence of the olignucleotide me^{7}GUCG in a two-dimensional fingerprint of the T$_1$ digest of α-^{32}P-UMP-labelled tRNA^{Thr} (data not shown). me^{7}G was identified by paper chromatography of a T$_2$ digest of the oligonucloetide, and an efficiency of 75% measured for me^{7}G synthesis.

Figure 3*b* shows the modification of U$_9$ of tRNA$_1^{Tyr}$ to s^{4}U (yield 74%). The synthesis of the hypermodified bases mes^{2}i^{6}A (in tRNA$_1^{Tyr}$ and tRNA$_2^{Tyr}$) and t^{6}A (in tRNA^{Thr}, tRNA^{Gly}) is illustrated in Fig. 3*c* and *d*. tRNAs were synthesised with α-^{32}P-ATP and incubated with S-100. extracts in the presence of specific cofactors as described in Fig. 3*c* and *d*. A yield of 62–75% was observed for mes^{2}i^{6}A and 64% for t^{6}A modifications of the specific A residues. Note, however, that A$_{37}$ in tRNA^{Thr} was modified only to t^{6}A and was not further methylated to met^{6}A as expected from the studies of Clarke and Carbon[9]. In addition it was observed that the molar yield of t^{6}A in the *in vitro* synthesised tRNA^{Thr} tRNA^{Gly} mixture exceeded the expected value for a single t^{6}A residue present in tRNA^{Thr}, thus supporting data of Roberts and Carbon[10] showing the presence of a t^{6}A derivative at A$_{37}$ in tRNA^{Gly} *su$^+$A36*. The molar yields of the nucleotide modifications obtained in *in vitro* synthesised tRNA molecules are summarised in Table 1.

To test the amino acid accepting ability of the *in vitro* synthesised tRNA molecules, φ80psu$_3^{+,-}$ and λh80T DNAs were transcribed by purified RNA polymerase in the presence or absence of termination factor ρ and the synthesised tRNA precursors were processed by a tRNA-free dialysed *E. coli* extract. The resulting tRNAs were extracted with phenol, precipitated using ethanol and assayed for acceptance of ^{3}H-tyrosine, ^{3}H-threonine and ^{3}H-glycine. Figure 4 shows the linearity of aminoacyl-tRNA formation as a function of *in vitro* synthesised tRNA. Note the enhancing effect of ρ, when present

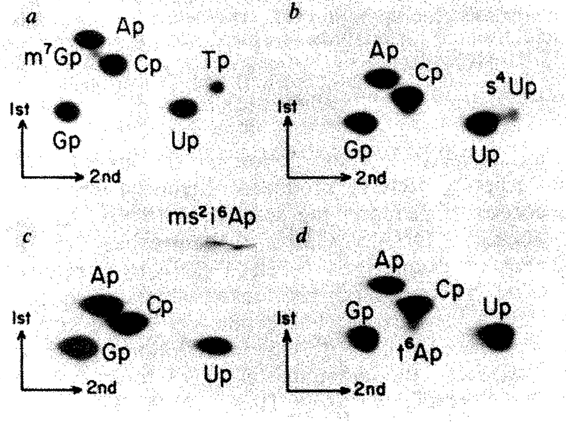

Fig. 3 Autoradiography of two-dimensional thin-layer chromatography of T$_2$ digests of *in vitro* synthesised and modified tRNAs. *a*, α-^{32}P-UMP-labelled tRNA^{Thr} tRNA^{Gly} mixture (1:1) was synthesised *in vitro* by transcription of λh80T DNA, followed by 90-min incubation with 2.2 mg ml^{-1} dialysed *E. coli* S-100 extract, 0.12 mM S-adenosyl-L-methionine and 0.6 mM EDTA. *b*, α-^{32}P-UMP-labelled tRNA$_1^{Tyr}$ was synthesised by transcription of φ80psu$_3^{+,-}$ DNA followed by 90-min incubation with 2.2 mg ml^{-1}dialysed *E. coli* S-100 extract, 1 mM L-cysteine, 5 mM ATP, 0.05 mM pyridoxal phosphate and 10 mM β-mercaptoethanol. α-^{32}P-ATP-labelled tRNA$_2^{Tyr}$ (c) and α-^{32}P-ATP-labelled tRNA^{Thr}/tRNA^{Gly} (*d*) were synthesised by transcription of λh80T DNA followed by 90 min incubation with 4.4 mg ml^{-1} non-dialysed *E. coli* S-100 extract, (0.2 mM) Δ^3-isopentenyl pyrophosphate (Fox chemicals), 4 mM ATP, 1 mM L-cysteine, 0.12 mM S-adenosyl-L-methionine, 10 mM β-mercaptoethanol, 450 μg ml^{-1} isopentenylpyrophosphate isomerase[18], 0.4 mM L-threonine and 25 μg ml^{-1} folinic acid. tRNAs were extracted with phenol, precipitated using ethanol, separated by acrylamide gel electrophoresis and extracted as described previously[1]. T$_2$ RNase hydrolysis was as described by Barrell[7] and the two-dimensional chromatography followed the method of Nishimura[19]. Molar yields of modified nucleotides were determined by summing radioactivity found in all the spots from the respective plate. This number was normalised to the expected number of moles of nucleotides in a nearest-neighbour position to the incorporated α-^{32}P-UMP, -AMP or -CMP as determined from the primary sequence of the respective tRNA (Fig. 1). The fraction of radioactivity in the modified nucleotide spot related to the calculated radioactivity for a single nucleotide gives the molar yield of modification.

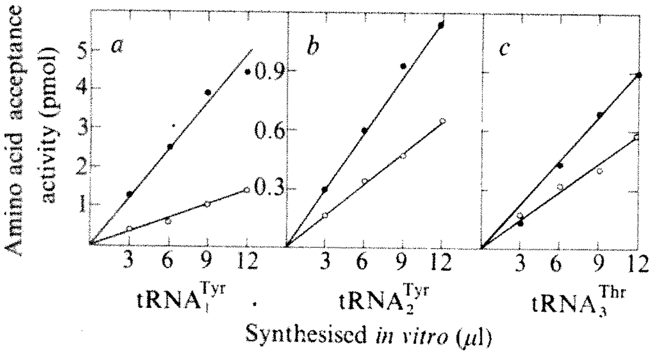

Fig 4. Amino acid acceptance of *in vitro* synthesised tRNAs. $tRNA_1^{Tyr}$ (*a*), $tRNA_2^{Tyr}$ (*b*) and $tRNA^{Thr}$ (*c*) were synthesised *in vitro* in the presence (●) or absence (○) of 12 μg ρ factor in 200 μl reaction mixtures containing 0.05 M Tris-HCl (*p*H 7.9), 0.01 M $MgCl_2$, 0,05 M KCl, 1 mM dithiothreitol, 0.4 mM each of ATP, CTP, UTP and GTP, 20 μg $\varphi 80psu_3^{+,-}$ DNA or 30 μg λh80T DNA, and 160 U RNA polymerase (1,600 U mg^{-1}). Synthesis was initiated after 5 min preincubation at 38 °C by addition of nucleoside triphosphates. After 30 min incubation at 38 °C the reaction was stopped by addition of 20 μg actinomycin D and 2 μg DNase I. tRNA-free S-100 extract (320 μg) was added and the incubation continued for 90 min. Synthesised tRNA was extracted with phenol, precipitated using ethanol and dissolved in 45 μl water. Aliquots of 3, 6, 9 and 12 μl were assayed for amino acid acceptance in 50 μl reaction mixtures containing 0.04 M Tris-HCl (*p*H 7.5), 0.01 M $MgCl_2$, 2 mM ATP, 3 mM glutathion, 1.5 μM L-3.5-^3H-tyrosine (41 Ci $mmol^{-1}$, Amersham UK) or 11 μM L-^3H-threonine 1.8 Ci $mmol^{-1}$ (New England Nuclear), 19 unlabelled amino acids (except tyrosine or except threonine respectively) and purified tyrosyl-tRNA synthetase[22] or 16 μg tRNA-free S-100 extract containing threonyl-tRNA synthetase. Incorporation of ^3H-labelled amino acids into acid-insoluble material was measured after 10 min incubation at 37 °C. tRNA-free S-100 extract was prepared by passing an *E. coli* S-100 extract adjusted to 0.4 M KCl through a DEAE–cellulose column.

during tRNA gene transcription on the amounts of amino acid-accepting tRNAs produced. Figure 4 shows that the presence of ρ increases the amount of $tRNA_1^{Tyr}$ transcribed on $\varphi 80psu_3^{+,-}$ DNA by a factor of 3–4 and that of the $tRNA_2^{Tyr}$ and $tRNA^{Thr}$ transcribed on λh80T DNA by a factor of 1.5–2. These results confirm our previous observations concerning the effect of ρ factor on tRNA synthesis[11,12]. We have shown[13] that the presence of ρ during transcription of the $tRNA_1^{Tyr}$ gene increases the amounts of tRNA precursor produced without affecting its size. Thus, although it is generally assumed that ρ factor affects only the termination of an RNA molecule[14] our results do not indicate a termination effect for ρ in tRNA gene transcription. Note that transcription of tRNA genes by purified RNA polymerase also takes place in the absence of ρ and does not require any additional factor as suggested by Bikoff and Gefter[5,6].

The efficiency of production of amino acid chargeable tRNA molecules in the *in vitro* system is remarkable. From the data reported in the legend to Fig. 4 it can be calculated that the transcription of approximately 1.4 pmol $tRNA_1^{Tyr}$ gene DNA (20 μg $\varphi 80psu_3^{+,-}$ DNA of molecular weight 30×10^6, containing 2 $tRNA_1^{Tyr}$ genes) resulted in the formation of 5.6 and 19.5 pmol $tRNA_1^{Tyr}$ when synthesised in the absence or presence of ρ respectively. Transcription *in vitro* of λh80T DNA was found to produce $tRNA_2^{Tyr}$ and $tRNA^{Thr}$ in equivalent amounts as determined by their amino acid acceptor activities (Fig. 4*b* and *c*). The glycine-accepting capacity of synthesised $tRNA^{Gly}$ was only 50% of that measured for $tRNA_2^{Tyr}$ or $tRNA^{Thr}$ (data not shown). This is probably due to the lower affinity of glycyl-tRNA synthetase for the $tRNA_2^{Gly}su^+A36$ species[15].

From the present *in vitro* studies we conclude that purified RNA polymerase alone can efficiently transcribe tRNA genes to produce primary tRNA percursors. The high fidelity of the transcription is illustrated by the fact that the synthesised RNA molecules are recognised as substrates by processing nucleases, by nucleoside modifying enzymes and by the aminoacyl-tRNA synthetases. Note that tRNAs synthesised *in vitro*, when processed by dialysed S-100 extracts, are (with the exception of ψ formation) completely unmodified. The unmodified tRNA precursors can be correctly processed and the resulting unmodified tRNAs are capable of charging with the corresponding amino acid. These findings argue against a possible role of the modified bases in tRNA precursor processing or tRNA aminoacylation. The present study shows that the *in vitro* synthesised tRNA is a suitable substrate for the study of the enzymes involved in nucleoside modifications and may serve to elucidate further the role of the modified nucleosides in the biological functions of mature tRNA.

We thank Mr Y. Tichauer for assistance.

Evolutionary origin of 5.8S ribosomal RNA

IN prokaryotes, the genes for 5S, 16S and 23S ribosomal RNA are linked in a polycistronic transcriptional unit[1,2]. In eukaryotes, on the other hand, the analogous unit contains the genes for 5.8S, 18S and 28S rRNAs, whereas the 5S RNA genes are found elsewhere in the genome. The analogous positions occupied by prokaryotic 5S RNA genes and eukaryotic 5.8S RNA in their respective genomes prompted Doolittle and Pace to speculate that these two RNA classes, both of which are components of the large ribosomal subunit, might have a common evolutionary origin[3]. If these RNAs are in fact homologous, one would expect their sequences to bear some relationship to each other. We report here our evaluation of possible structural relationships between known sequences of 5.8S and 5S rRNA, and conclude that they have no common evolutionary origin.

The comparison of RNA sequences is extremely difficult when insertions and deletions have to be considered. Recently, however, we have developed a test of similarity which can be applied to RNA sequences and which involves the establishment of the best alignment (most identities) of two sequences allowing a fixed number of insertions/deletions[4]. The number of positions in the alignment which are occupied by identical bases in the two sequences is counted. The process is repeated, increasing the allowed number of insertions/deletions by one. The number of identities are then compared with like values computed

Table 1 Comparison of 5S and 5.8S RNA sequences

Experiment	RNA	Insertions or deletions	Identities	Identities in random sequences
1	5.8S yeast 5.8S hepatoma	2	112	61
2	5.8S yeast 5S *E. coli*	8	67	66
3	5.8S yeast 5S KB cells	8	66	65
4	5.8S yeast 5S protoprokaryote	8	62	60
5	5.8S yeast 5S protoeukaryote	8	58	61
6	5.8S hepatoma 5S *E. coli*	8	67	69
7	5.8S hepatoma 5S KB cells	8	63	66
8	5.8S hepatoma 5S protoprokaryote	8	61	61
9	5.8S hepatoma 5S protoeukaryote	8	59	64

*The number of identities between random sequences is an average of five different experiments. Random sequences have the same composition and length as the two real sequences being compared in each experiment. We have chosen to give the number of identities found permitting eight insertions or deletions, since these are representative of values obtained permitting either more or less.

from random sequences. Related sequences show statistically significant increases in the number of identities found for each increase in the number of insertions/deletions permitted, up to a certain limit.

Previously, we have shown that 5S RNAs of eukaryotes and prokaryotes are homologous using this test. When applied to the comparison of the two known sequences of 5.8S RNA[5,6], an unequivocal relationship is apparent (see Table 1). It would seem, given the relatively large difference between the 5S sequences from yeast and humans[7,8], that 5.8S RNAs are more conservative to evolutionary change than eukaryotic 5S RNA. Such resistance to the fixation of natural mutations usually indicates an important structural and functional role. In fact, the sequences of all mammalian 5S RNA are apparently identical[9] and the same holds for 5.8S RNA[6]. The fact that both molecules are evolutionarily conservative increases the probability of finding a common origin, if in fact one exists

As shown in Table 1, the test when applied to the comparison of either the eukaryotic or prokaryotic 5S RNA sequence with either 5.8S RNA sequence (yeast and hepatoma) shows them to be no more related than random sequences.

One might argue that in spite of the conservative evolution of these molecules, all similarities of sequences have been wiped out during their independant evolution from a hypothetical ancestor. We have, however, developed methods to infer hypothetical ancestral sequences using known 5S RNA sequences[10]. With a corpus of 15 known sequences we have estimated ancestral prokaryote and eukaryote sequences: no 5S RNA ancestral sequences show any relationship to known 5.8S RNA sequences.

These results indicate that 5.8S RNA does not share a common ancestor with 5S RNA and therefore did not arise by duplication of the 5S RNA gene followed by divergence. One interesting possibility is that the 5.8S RNA evolved from the intercistronic region of the bacterial ribosomal genome.

Bean halo-blight toxin

Pseudomonas phaseolicola causes a disease of beans commonly called halo blight. The halo is a chlorotic zone which appears in the leaf round each infection site. It has been interpreted as the effect of a toxin produced at, and diffusing away from, the infection site. The zone characteristically contains a relatively large amount of the amino acid ornithine[1]. When *Ps. phaseolicola* was grown in a defined liquid culture medium at 18 °C the filter-sterilised medium, when applied to bean leaves, caused the chlorosis symptom of the disease[2]. From such media I have isolated a substance, 80–90% pure, which, when introduced to the leaf at a level of 100 ng per g fresh weight, causes both chlorosis and accumulation of ornithine. I report here the highly unusual structure of this compound. Its extreme lability in the presence of weak acids has made its isolation difficult, but has helped in the resolution of its structure.

The pure substance is water soluble, and hydrolysis with 6 M HCl (100 °C, 18 h) liberates three amino acids (ornithine, alanine and homoarginine). In spite of the presence of two basic amino acids (ornithine and homoarginine) the toxin itself behaves during electrophoresis at *p*H 2 like the acidic amino acids, suggesting that it also contains strong acid groups. More gentle hydrolysis of the toxin with dilute HCl (0.01 M, 40 °C, 2 h) yields a new compound which contains the same amino acids as the toxin but which shows no toxic properties. This new compound has, at *p*H 2, an electrophoretic mobility a little greater than that of ornithine, and now consistent with its content of basic amino acids. Sequential cleavage with carboxypeptidase and gas chromatography–mass spectrometry showed it to be the tripeptide ornithylalanylhomoarginine (structure 1, Fig. 1).

Because ornithine is the N-terminal amino acid of the tripeptide, both ornithine amino groups are unbonded. When, however, the intact toxin was reacted with 1-fluoro-2,4-dinitrobenzene and the product was hydrolysed, N^α-dinitrophenylornithine was the only amino acid derivative produced. The tripeptide, in contrast, gave N^α,N^δ-di-dinitrophenylornithine. This shows that the δ-NH_2 of the toxin is bonded. There are two possible interpretations: either the toxin structure is cyclic (for example, cyclic-N^δ-ornithylalanylhomoarginyl) incorporating the ornithyl side chain in the ring (in which case dilute acid must open the ring at the ornithyl-N^δ-peptide bond), or the toxin structure is linear with a non-peptide group bonded to the ornithyl-N^δ (in which case dilute acid would yield peptide and non-peptide products; structure 2, Fig. 1).

The former was excluded when the action of carboxypeptidase enzymes on the toxin was studied. Homoarginine, then alanine, were sequentially cleaved, yielding a product which contained only one amino acid, ornithine. Because carboxypeptidase requires the presence of a free terminal carboxylic acid group to be able to act on the adjacent peptide bond (hence its sequential action), the cyclic structure would not have been attacked by it. I therefore conclude that the toxin is represented by structure 2, and that there is a further group present that is liberated from the toxin by the action of dilute acid.

The product of the carboxypeptidase reaction, which is ornithine with some unknown group still attached, behaves as a toxin on bean leaves, and has unusual properties. At *p*H 2 ornithine alone migrates electrophoretically as a strong cation. The unknown compound, however, which contains ornithine, migrates as an anion, indicating that there must be a compensating strongly negative charge. Carboxylic acid groups are not sufficiently anionic at *p*H 2 to satisfy this structural requirement; biologically, the most likely groups to have the required properties are phosphate or sulphate. Specific detection procedures for phosphate[3] showed that the toxin and the carboxypeptidase products all contained phosphate. When the bacteria were grown in medium containing ^{32}P-phosphate, ^{32}P was incorporated into the toxin. One of the products of acid hydrolysis of the ^{32}P-toxin did not contain ^{32}P, and had the electrophoretic properties of inorganic sulphate. When the bacteria were grown in medium containing ^{35}S-sulphate, ^{35}S was also incorporated into the toxin. On acid hydrolysis of the toxin, ^{32}P and ^{35}S were released in PO_4^{3-} (P_i) and SO_4^{2-}, respectively.

Fig. 1 Proposed structures.

The time course of hydrolysis by dilute acid gave further information (Fig. 2). The toxin was broken down rapidly, yielding the tripeptide and an intermediate (I) which contained both P and S. This intermediate hydrolysed rather more slowly, yielding free P_i (P_i estimation showed that there was 1 mol per mol of toxin) and another compound (which contained no P) which I call intermediate II. Free inorganic sulphate was liberated from intermediate II under more vigorous conditions (0.6 M HCl, 60 °C).

I then investigated the identity of intermediate II. Yield estimates based on ^{35}S measurements indicated a molecular weight (as its ammonium salt) of about 120. Initial chromatographic studies indicated that it was similar to synthetic sulphate esters of low molecular weight hydroxyacids, for example glycolic acid-*O*-sulphate and lactic acid-*O*-sulphate. These compounds had characteristic proton magnetic resonance (PMR) spectra. Therefore, 40 mg of purified ^{35}S-toxin was hydrolysed gently to yield 6 mg of purified intermediate II for PMR study. After proton exchange in D_2O, the sample was thoroughly dried, and the PMR spectrum in 99.8% D_2O was examined. Unlike a similar quantity of lactic acid-*O*-sulphate, the sulphate compound from the toxin showed no proton signals (apart from HOD). The only likely compound to satisfy the requirement of low molecular weight and no non-exchangeable protons is sulphamic acid (molecular weight, ammonium sulphamate 114). Authentic sulphamic acid was indistinguishable chromatographically and electrophoretically from intermediate II; also both reacted with cold dilute nitrous acid to yield free inorganic sulphate.

The structural components of the toxin are now apparent and its final structure depends on establishing the way sulphamic acid, P_i and the tripeptide are linked together. Intermediate I, which contains both P and S (but not the peptide), reacted with cold dilute nitrous acid in the same way as sulphamic acid, yielding a new product still containing both phosphate and sulphate. This indicates that, like sulphamic acid, intermediate I contains a terminal NH_2. Thus, the phosphate group of intermediate I is connected to sulphamic acid through S, not N, and the structure of intermediate I is established as 4 in Fig. 1. The structure of the toxin is thus 5 in Fig. 1. As far as I can determine, this peptide-ornithyl-N^δ-phosphosulphamyl type of structure has no direct parallel in the chemistry of natural products.

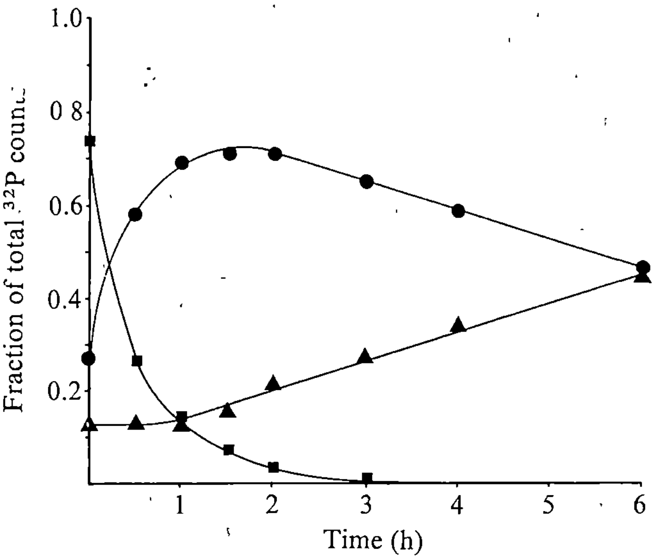

Fig. 2 Time course of hydrolysis of ^{32}P-toxin with 0.025 M HCl (40 °C). ●, Intermediate I; ▲, PO_4^{3-}; ■, toxin.

The action of the toxin in pathogenesis remains to be determined but it may be possible to account for accumulation of ornithine in the tissues of the diseased plant. An important biochemical reaction involving ornithine is its condensation with carbamyl phosphate to form citrulline. Two structural features of the toxin may be significant: the effective part of the toxin is a N^δ-substituted ornithine; and, the substituent group is an analogue of carbamyl phosphate, in which the >CO group is replaced by $>SO_2$. The toxin may therefore be useful in the study of the mechanism of action of ornithine transcarbamylase.

I thank Miss Beth Parsons for technical assistance, and Dr R. L. Bieleski for helpful discussions.

matters arising

Niche breadth in Bryozoans

O'Connor *et al.*[1] consider a resource gradient with an optimum point for a particular species. Other factors being equal, individuals migrating to a new environment will tend to select the optimum, or near optimum. As population density increases, the advantages of being near the optimum may be offset by intraspecific competition[2]. Migrants may therefore choose a suboptimal point on the resource gradient. As population density increases so will the range of resource gradient used.

O'Connor *et al.*[1] use the phenomenon of an increase in range with population density as a test for intraspecific competition. This is not a suitable test because range will increase with population density even in the absence of intraspecific competition. If intraspecific competition was not occurring and individuals chose the resource optimum with an associated variance from a normal distribution (say, mean of zero and variance of unity), then the expected range would increase with population density (going from five to fifty individuals the expected range would increase from 2.32 to 4.50 (ref 3)). It is not necessary to postulate a normal distribution or even a resource optimum for an expected increase of range with population density.

Using the epiphytic bryozoan *Alcyonidium hirsutum* settling on the serrated wrack *Fucus serratus*, it is probably permissible to replace the percentage cover used by O'Connor *et al*[1] by the numbers of individuals over a wide range of settlement density, provided that settled individuals are of the same age[4]. The optimum on the particular resource gradient used has been investigated previously[5].

O'Connor et al. reply—We accept the point raised by Harvey *et al*[1] but it does not alter our earlier conclusion that *Alcyonidium hirsutum* shows increased niche breadth in the presence of intraspecific competition and decreased niche breadth in the presence of interspecific competition. Range on the resource gradient is indeed correlated statistically with the number of bryozoan settlements on each *Fucus serratus* frond, but because these fronds vary in age along their length, it is less reasonable to assume that the resulting colonies should be of equal age. In practice the partial correlation coefficient between *Alcyonidium* abundance (percentage cover) and its range, controlling for the number of faces colonised on each plant (and thus for the effect suggested by Harvey *et al.*) was 0.506 ($P<0.05$) That is, *Alcyonidium* shows increased range in resource utilisation as its own population levels rise, and does so independently of the statistical artefact suggested.

For the other three bryozoan species whose distribution we analysed, we reported small positive correlations between range and abundance, in small samples containing some unmeasured interspecific competition Correcting for the possible statistical effect by partial correlation left us with positive correlations in the case of *Flustrellidra hispida* ($r_p=0.419$, $P<0.2$) and *Electra pilosa* ($r_p=0.215$, $P<0.3$), but with a negative value in the case of *Membranipora membranacea* ($r_p=-0.463$, $P<0.2$). Thus only for this species might our first results have originated in a sample-size effect, though as we pointed out previously, we have available to us only samples which are subject to some degree of interspecific competition which tends to reduce niche breadth anyway In summary, therefore, our results still indicate that intraspecific and interspecific competition lead respectively to increase and decrease in niche breadth in *A. hirsutum* and possibly in other bryozoan species as well

We thank Alec Vardy for reviewing our statistical argument.

[1] Harvey, P. H., Ryland, J S., and Hayward, P J, *Nature*, 260, 77 (1976).

The claim of O'Connor *et al.*[1] that distributional and density data for the bryozoan *Alcyonidium hirsutum* growing on *Fucus* fronds demonstrate the effects of both intra- and interspecific competition on niche width is unsound for both methodological and theoretical reasons. A positive correlation would be expected between the number of bryozoan colonies and the 'population level' as measured by percentage cover, and therefore the positive relationship found between the range of segments utilised and the population level is explicable without recourse to competition theory. On fronds which are more suitable overall, some of the less favoured segments would become acceptable, so that the frond is colonised more heavily and over a wider range of segments Other models will also produce this result. If darts are thrown at a linear target the range between darts should increase with the dart 'population size'.

Regarding interspecific competition we note that in the no-, one-, and two-competitor cases, decreasing sample sizes are used. A narrower niche width would thus be expected in the cases with competitors irrespective of interspecific effects. The utilisation curves for the first two cases, however, do not differ significantly (Kolmogorov–Smirnov two-sample test[2]), negating conclusions based on supposed differences between them. The two-competitor curve is based on too few colonised segments (18) for much confidence to be placed in supposed trends; furthermore, when allowance is made for the modal shift there is no significant difference between this and the non-competitor curve. Finally, B.

$$(\ln B = -\Sigma p_i \ln p_i)$$

is an accepted measure of niche width[3,4]. The value for the one-competitor case is higher than for the no-competitor curve, contrary to the prediction of O'Connor *et al.*[1].

R. H. Crozier
School of Zoology,
University of New South Wales,

[3] Cody, M L , *Competition and the Structure of Bird Communities* (Princeton University Press, Princeton, 1974).
[4] Levins, R , *Evolution in Changing Environments* (Princeton University Press, Princeton, 1968)

O'CONNOR ET AL REPLY—Crozier and Day[1] offer four distinct criticisms of our analysis[2] of niche breadth in Bryozoa. They suggest, first, that on fronds which are more suitable overall some of the less favoured segments would become acceptable, yielding a competition-free correlation between range and population level. As we pointed out explicitly in our paper, however, the available space at the optimum height is not physically filled at the higher population levels, so that animals settling elsewhere are behaving maladaptively if intraspecific competition is absent. Competition theory readily explains such suboptimal settlement in terms of a balance between the disadvantages of being away from the competition-free optimum of the resource gradient and the advantages of the reduced intraspecific competition found away from the optimum[3,4]; the model suggested by Crozier and Day[1] leaves us, on the other hand, with unexplained maladaptive behaviour on the part of the bryozoans.

The linear dart target criticism advanced is essentially that of Harvey *et al.*[5], to which we have responded with a partial correlation analysis[6] demonstrating that increase in resource range with increasing *Alcyonidium* population size was independent of the number of observations or 'darts'. We note in addition here that the dart effect is in any case too small to account for our results. Thus, if the change in *Alcyonidium* numbers between 2% and 4% cover (the latter being our median value) involved an increase of as few as 2 individuals at settlement, the dart effect predicts[7] only an increase in range of 84%, whereas we empirically observed an increase of 178%; for a slightly more realistic change of from 10 to 20 individuals, the dart effect is even less (21.4%), increasing the shortfall from the observed change even further. Similar calculations over other ranges of population size confirm our original conclusion, since the observed range increases are always substantially larger than any possible effect of sample size.

The third criticism by Crozier and Day[1], that the effect of sample size could explain our interspecific results, is incorrect on two grounds. First, for our interspecific analysis we used not the range of the resource utilisation function but rather its width at half height. This measure more closely resembles a standard deviation than a range in its statistical behaviour, that is, it is largely insensitive to changes in sample size. Second, even if this measure had been subject to the effect of sample size, the resulting increase would have been too small to account for the observed changes in niche breadth. Thus, for *Alcyonidium* our sample size effectively doubled (from 69 to 149) between the one-competitor and no-competitor situations: Fisher and Yates' table[7] shows that the effect of such a doubling of sample size would have been less than 14%, whereas the observed increase was of 34%, substantially larger. Similar calculations for the other seven comparisons show that in six cases the dart effect is too small by even bigger factors to account for the observed increases: only for the change in *Membranipora* niche breadth between the one- and two-competitor situations could an effect of sample size have accounted for the observed change. Therefore, even after assuming we had used range, and not the more stable width at half height, as our measure of niche breadth, the effects of the differences in sample sizes are so small that after making full allowance for them, seven of the eight comparisons are still indicative of competitive effects (Sign test[8], $P<0.05$), that is, the data still demonstrate that the presence of interspecific competitors on fronds reduces bryozoan niche breadths on those fronds We thus disregard this criticism of Crozier and Day[1].

Their final criticism is that the analyses chosen by them failed to support our conclusions. We note first that they overstate their case with respect to the Kolmogorov–Smirnov test: Siegel[8] explicitly states (p. 129) that the failure of this test to reject a null hypothesis (here that the one-competitor and no-competitor curves do not differ) does not mean that the hypothesis should then be accepted, contrary to the assertion of Crozier and Day. Second, we note that the formula

$$\ln B = -\Sigma p_i \ln p_i$$

requires that niche breadth be related to the Shannon–Wiener index of species diversity, H, by $B=\exp(H)$. Niche breadth and species diversity are thus mathematically related Since we know from empirical evidence[9] that different diversity indices lead to different biological conclusions, even when applied to the same data, we are unable to accept any one of the related niche breadth formulae as definitive The widespread acceptance of any particular formula may merely reflect uncritical acceptance of its hidden assumptions The measure of niche breadth we used has the merit of being distribution free and has an even more widespread acceptance in measuring distribution widths[10] than the information theory measure tested by Crozier and Day. We would naturally like to see all niche breadth measures tested with our data supporting our conclusions, but when simple measures support biologically sensible conclusions and complex measures fail to do so, we feel it appropriate to suggest that maybe the mathematics, rather than the biology, is at fault.

In summary, therefore, the criticisms offered by Crozier and Day[1] are only partially valid, and have too small an effect to invalidate our conclusions.

We thank Jim Gilliam for helpful discussion.

Enteropancreatic circulation of digestive enzyme

WE are studying highly specific intracellular proteinases and have read with interest yet alarm the two recent reports[1,2] by Rothman *et al* proposing an enteropancreatic circulation for digestive enzymes. This seems unlikely for the following reasons (accepting the premise that protein molecules can be transported across intestinal and pancreatic acinar cells).

If the proteins are absorbed into the bloodstream in the active enzyme forms (chymotrypsin and trypsin, for example) they would be inactivated very rapidly by the plasma inhibitors such as α_1-antitrypsin, α_1-antichymotrypsin and α_2-macroglobulin before they could hydrolyse physiological substrates like prothrombin, fibrinogen, plasminogen and kininogen. If any active molecules were lucky enough to escape this bombardment by circulating inhibitors and be reabsorbed by the pancreas, what a cruel fate to be inactivated at the last hurdle by the pancreatic inhibitors.

If the proteins are absorbed in the non-activated forms of chymotrypsinogen and trypsinogen, they might just escape the attention of the inhibitors and be reabsorbed by the pancreas but to what avail? If an excess of "protein" is secreted into the intestine, Rothman *et al* seem to be proposing that a large percentage of this can be conserved by recycling. The activation processes for zymogens such as chymotrypsinogen and trypsinogen would, however, seem to be too rapid and complete to allow any significant level of zymogen to remain. The digestive capacity is controlled, not by the degree of zymogen activation in the intestine, but by the absolute amount of zymogens released on hormonal stimulus of the pancreas.

Space will not permit critical evaluation or alternative explanation for Rothman *et al.'s* observations Their experiments have been conducted by following "insensitive" parameters such as protein output by the pancreas and chasing a few radioactive counts around the bloodstream. It would be illuminating to see the experiment done wherein (potential) enzymic activity is followed. Only then would we have to consider the feasibility of an enteropancreatic circulation.

R. J. BEYNON
J. KAY

University College,
Cardiff CF1 1XL, UK

[1] Gotze, H, and Rothman, S S., *Nature*, 257, 607 (1975)
[2] Liebow, C., and Rothman, S. S, *Science*, 189, 472 (1975)

ROTHMAN, GÖTZE AND LIEBOW REPLY—We are sorry that our observations and ideas have alarmed Kay and Beynon[1]; however, new scientific findings, are appropriately met with interest, not fear They feel that our observations must be explained in other, although unspecified, ways because in their view the circulation of digestive enzyme is quite impossible. If we understand their position correctly, they argue that all active proteolytic enzyme would be irreversibly bound in blood and that proenzyme entering the intestine would be immediately and completely activated in all circumstances and thus be unavailable for circulation. Since these postulates refer only to proteolytic enzyme and since a large percentage of the pancreatic digestive enzymes are not proteolytic, Kay and Beynon are apparently not questioning the existence of a circulation of digestive enzyme, but more narrowly the circulation of proteolytic digestive enzymes We have directed our response to this question.

Matters arising

Matters Arising is meant as a vehicle for comment and discussion about papers that appear in *Nature*. The originator of a Matters Arising contribution should initially send his manuscript to the author of the original paper and both parties should, wherever possible, agree on what is to be submitted. Neither contribution nor reply (if one is necessary) should be longer than 300 words and the briefest of replies, to the effect that a point is taken, should be considered.

Although the workings and physiological functions of plasma protein inhibitors are not completely understood. certainly the mere presence of various inhibitors in the blood (or acinar cell) does not mean that all enzyme is irreversibly bound by these molecules and taken out of circulation. On the contrary, it is the presence of these inhibitors in blood that makes it reasonable to conceive of active proteolytic enzyme being circulated. The point is that to prove whether or not active proteolytic digestive enzyme is circulated is a matter for further investigation, not presupposition. Relative to the potential for proenzyme circulation, Kay and Beynon do not cite the evidence on which they base their contention—that the activation of enzyme in the intestine is "too rapid and complete to allow any significant level of zymogen to remain." We are unaware of such evidence. They should remember that maximal activation does not mean that all the enzyme molecules have been activated, and that the activation kinetics of a few defined components in a test tube does not necessarily reflect what goes on in the intestine in various physiological situations. Kay and Beynon apparently insist on restricting the potential meaning of a biological phenomenon to their view of present knowledge of the chemistry and function of certain molecules. They thereby assume that they understand the chemistry and function of these molecules fully and that there are no unknown elements in the piece. On what basis do they make these assumptions?

Finally, in spite of their preconceived notions, the enteropancreatic circulation of digestive enzyme is a fact documented, not by "chasing a few counts around the bloodstream" as they egregiously suggest, but by demonstrating, with tracer kinetics, that labelled chymotrypsinogen instilled in the intestine reappears in pancreatic secretion collected directly from the duct and exclusively in the chymotrypsinogen band of secreted proteins separated by electrophoresis.

In the recent paper[2] which prompted Kay and Beynon's letter[1], we described experiments which suggest that this circulation may account for the movement of substantial amounts of protein. Two corollary observations further reinforce the interpretation that enzyme circulation is involved: (1) output (the increase in protein secretion) correlates strongly with input (digestive enzyme added to the intestinal lumen or injected into the bloodstream) with a slope of 0.92, or in other words, enhanced protein secretion by the pancreas accounted for 92% of protein input; and (2) these two variables fit the same regression line whether the collected secretion was injected into the bloodstream or instilled into the intestine. While these observations are subject to other interpretations (which were carefully pointed out in our article and which Kay and Beynon do not acknowledge in their letter), the circulation of substantial amounts of digestive enzyme is the most direct, and thus, the best interpretation of the results. It is on this basis that we feel it should be the hypothesis for the moment. If Kay and Beynon really have a more convincing interpretation of these experiments, then why do they hesitate to present it? We would greet it with interest, not alarm.

Doubts about the role of the locus coeruleus in learning and the phosphorylation mechanism engaged in the cerebellum

GILBERT[1] has proposed a model of how the cerebellum, with the assistance of the locus coeruleus, could memorise movements. We have been studying the anatomy and chemistry of these and related systems, and have evidence that bears directly on that hypothesis.

The first point concerns the crucial role of the locus coeruleus in the memory consolidation of "motor signals stored in the cerebellum"[1]. The evidence to support that view comes from one study[2] which observed the effects of locus coeruleus lesions on learning. The results have, however, been brought into question[3]. Using a different approach, our laboratory has been studying the effects of localised brain stimulation on learning and retention performances (see ref. 4). Quite remarkable localisations have been obtained in the medial nucleus of the amygdala[5], substantia nigra, pars compacta[6], medial and sulcal portions of frontal cortex[7] and the lateral portions of the medial forebrain bundle[8]. In these specific regions, but not in surrounding locations, brain stimulation during learning disrupted retention. Using the same paradigm we have found no effect of locus coeruleus stimulation[7]. The results cast doubts on the essentiality of the locus coeruleus to the learning and memory of movements.

Related to the issue of the involvement of the locus coeruleus in learning is the point made by Gilbert[1] that "the locus coeruleus... will support intracranial self-stimulation". Though it is not to be denied that intracranial self-stimulation (ICSS) can be obtained when electrodes are in the region of the locus coeruleus[9], it is by no means proven that the locus coeruleus or its axonal system is responsible for that behaviour. Our evidence argues against a role for the locus coeruleus in intracranial self-stimulation Intracranial self-stimulation in the region of the dorsal bundle, the efferent ascending pathway of the locus coeruleus, is unaffected by the bilateral destruction of the locus coeruleus[10]: and intracranial self-stimulation has not always been obtained when electrodes are in the locus coeruleus[11,12] Given the uncertainty of the locus coeruleus involvement in brain stimulation reward it seems premature to invoke a role for it in memorising learned movements.

The second point concerns the mechanism of storage proposed by Gilbert[1]: the phosphorylation of membrane protein. We have studied the endogenous phosphorylation of four protein components of brain membranes[13], and have found that one component, which we term band F, is altered by a training experience[14]. This effect is most noticeable in the caudate nucleus, but alterations (admittedly of a less dramatic nature) have also been observed in the cerebal cortex. An analysis of the vermis of the cerebellum, however, has yielded negative results; that is, there is no change in cerebellar membrane phosphorylation as a consequence of training such as was observed with membranes of the caudate nucleus Although this represents an initial finding in two replicated experiments, the results gathered to date lend no support to Gilbert's views[1] on the location of the mechanism of storage. Actually, the phosphorylation mechanism itself may be appropriate, but its location may be elsewhere, for example, in the caudate nucleus, rather than in the cerebellum.

Though I am in sympathy with the approach offered by Gilbert, I question the detailed mechanism proposed, both with respect to the involvement of the locus coeruleus in learning and reinforcement and with respect to alterations in phosphorylation within the cerebellum. Our data, though negative on both specific points, point to particular brain locations potentially involved in memory, and to related regions where chemical storage mechanisms could be engaged following a learning experience.

I thank J. U. D. Sonratliff for technical assistance and David Morgan for helpful discussion. This work was supported by grants from the Alfred P. Sloane Foundation, NIH and NSF.

DR GILBERT REPLIES—To support my proposal about motor learning in the cerebellum[1], I cited a study[2] which showed that locus coeruleus lesions markedly impaired, or abolished, the ability to learn to run with increased speed in an L-shaped runway for a food reward. Routtenberg questions the result of my study (see refs 1 and 2) because there seems to be no learning deficit in a T-maze discrimination task for animals with locus ceoruleus lesions[3]. The types of learning being tested in those studies are, however, quite different; and the results are not necessarily contradictory. I have described[1,4] how the cerebellum could store information required for the production of coordinated muscular activity in a learned movement. I have not suggested that the cerebellum is involved in other types of learning such as T-maze discrimination, and the fact that there is no learning deficit for this task with locus coeruleus lesions is irrelevant to my proposal.

Stimulation of the locus coeruleus probably leads to an increased release of noradrenaline at Purkyne cells[5] and could therefore lead to enhanced retention. The enhancement of retention by central administration of noradrenaline only occurs after depletion of central noradrenaline stores[6], however, and the stimulation of the locus coeruleus could be expected to enhance retention only in similar conditions. Therefore, the negative results of locus coeruleus stimulation[7] do not conflict with its proposed role[1] in long term memory consolidation.

Two independent studies[8,9] have shown that the locus coeruleus will support intracranial self-stimulation (ICSS), though with different experimental conditions no ICSS is obtained[10,11]. There seems to be no doubt that the locus coeruleus is closely involved with the positive reinforcement system of the brain, although I agree that the details of this involvement have not been determined. My theory does not require that the locus coeruleus cells directly contracting Purkyne cells support ICSS, but only that the locus coeruleus cells receive an input from the positive reinforcement system.

My suggestions about learning in the cerebellum were made on the basis of the large amount known about cerebellar anatomy and physiology. I would expect a similar memory mechanism to operate in other parts of the brain, however, especially in view of the widespread distribution of noradrenaline nerve terminals[12]. It is therefore very encouraging that a change in membrane phosphorylation as a consequence of training has been demonstrated[13] for certain regions of the brain. The possibility that this mechanism operates in the cerebellum has certainly not been excluded by preliminary experiments on a small number of protein components of membranes from a restricted region of the cerebellum.

In conclusion I am pleased that experiments are being carried out which test my proposed memory mechanism. I would add that there is increasing support[14,15] for the idea that the cerebellum is involved in motor learning.

reviews

Renaissance and revolution

John Watling

The Nature of Scientific Discovery. (A Symposium Commemorating the 500th Anniversary of the Birth of Nicolaus Copernicus.) Edited by Owen Gingerich. Pp. 616. (Smithsonian Institution: Washington, DC, 1975.) $15.

Painting of Copernicus by Jean-Leon Huens

THIS misleadingly titled book is a record of a symposium held in 1973 by the Smithsonian Institute of the United States to commemorate the 500th anniversary of the birth of Copernicus. Besides the papers read at the symposium, the book includes a description of the proceedings, a large number of introductory speeches, photographs from a commemorative film made by Charles Eames, a black and white reproduction of a painting of Copernicus by Leonard Baskin and a verbatim report of the discussions which followed some of the papers. The proceedings included a performance of a musical work entitled "Copernicus—Narrative and Credo" by Leo Smit to a text written, and, in that performance, spoken, by Fred Hoyle. Neither text nor score are provided, but the text seems to have been an account of Copernicus's life and times. One of the speeches relates that Edward Rosen, who has translated some of Copernicus's major works, summed up the curiosity of Copernicus in the question "What is night, and how is it produced?". Such absurd exaggerations of the ignorance of Copernicus's contemporaries can only hinder an appreciation of his achievement. Aristotle, the prevailing authority of the time, argues for the spherical shape of the Earth from the curved edge of its shadow on the Moon during a lunar eclipse (*De Caelo*, Book II, Chapter 14).

The declared object of the symposium was to investigate the nature of scientific discovery, taking Copernicus's work as an outstanding example, rather than to clarify and evaluate that work. In fact, the papers divide into three groups, those on aspects of the history of Copernicus's times, those on the nature of scientific discovery and those providing brief expositions of questions in present-day cosmology. The first group forms the bulk of the book and contains the only papers of serious interest. The four papers on scientific discovery throw little light on it. Toulmin expresses his opinion that science is losing its vigour in fragmentation and technology; it should turn back to its traditional allies, cosmology and theology. Gerald Holton expounds Einstein's thoughts on scientific discovery without contributing much to the wide development and criticism which such views have received, for example from Karl Popper. Heisenberg finds the influence of tradition in research in the fact that, once one man has discovered a problem, others are attracted to the task of solving it.

Surely studies of Copernicus's own work would have provided a worthier commemoration? There is no lack of problems concerning it. Copernicus demonstrated the possibility of a radical change of viewpoint, a change which brought into prominence exactly those relationships (the relationships to the sun) which, according to Newton's gravitational theory, were of the greatest importance in explaining planetary movements. Why did Copernicus propose a change whose advantages, it seems, he could not guess at? A number of points, however, are made which illuminate Copernicus's work and its importance. Bronowski finds the inspiration for the change of viewpoint in Renaissance studies of perspective, for those studies seek rules for determining how objects in space appear to observers situated at different vantage points. Gingerich points out the importance of Copernicus's change of viewpoint for Newton's theory. Rupert Hall stresses the mechanical problems posed by the need to reconcile the behaviour of bodies at the surface of the Earth with the Earth's motion: "If Galileo converted mechanics into a branch of natural philosophy, it was Copernicus who demanded that this be done."

The contributors are scarcely in accord over the significance of Copernicus's thought. Hall, as we have just seen, finds its value in the stimulus it gave to the investigation of real problems in dynamics. Toulmin, on the other hand, finds it in "the claim that the human mind does have the capacity to develop consistent and comprehensive theories about the world in which we live, and can do so on a scale that goes far beyond the reach of our experience." Again, whereas Bronowski finds Copernicus to have been "a humanist gentleman", inspired by the Renaissance enthusiasm for classical philosophy and literature, Toulmin finds him to be the re-incarnation of the greek scientific spirit, that of accosting the most profound questions about the natural world. Bronowski and Toulmin differ, too, about the scientific value of humanism.

(continued from previous page)

Bronowski claims that the Renaissance study of ancient texts established standards of accuracy and exactness of inference which revealed new possibilities to science. Toulmin holds that humanism favoured a scepticism concerning human knowledge inimical to confident theorising about nature. The most fundamental disagreement, however, is that between Bronowski and Heiko Obermann. Bronowski writes, "Copernicus's attitude implies that the single truth exists in nature and as nature, and cannot be established or overturned by any authority other than the study of nature herself." Obermann does not deny that that was Copernicus's attitude; what he does deny is that it is right. "Astronomy," he asserts, "cannot reveal the 'true causes' of astral phenomena insofar as final causality lies beyond its purview." Again, "the goal of the natural sciences is validity in the sense of accuracy, whereas that of the humanities, particularly of philosophy and theology, is validity in the sense of truth." How philosophy and theology are to reveal the true causes of astral phenomena, Obermann does not proceed to explain.

The historical papers I have mentioned are interesting, as are some that I have not found room for; unfortunately they are outweighed by a mass of material which is of very limited interest. □

Perceptive handbook

Handbook of Perception. Volume 5: Seeing. Edited by Edward C. Carterette and Morton P. Friedman. Pp. xxii+527. (Academic: New York and London, September 1975.) $28.50; £13.70.

THIS volume, the fourth to be published in a set of ten, could readily stand alone as an advanced textbook of visual perception. The contributors are well known, the text is uniformly clear and intelligent, and the level of presentation is more even than in earlier volumes. The organisation is conventional. Le Grand opens, with an informed history of visual science and an introduction to radiometry and photometry. In a distinguished chapter on receptive fields, J. Robson surveys the neurophysiology of the visual system and offers a shrewd discussion of the widely-canvassed idea that the visual cortex acts as an analyser of spatial frequencies. Colour vision is covered by R. and K. De Valois and by R. Boynton; temporal factors by L. Ganz; spatial resolution and interaction by J. Thomas; the perception of patterns and objects by Dodwell; depth perception by W. Richards; and the perception of movement by R. Sekuler. In a final chapter on Vision and Art, M. Pirenne discusses the difference between viewing a painting and viewing a *trompe l'oeil*. Although the chapter headings are classical the fresh concepts of the seventies have a firm place in the text. If there are no traces of the grand schools that once dominated textbooks of perception and if most of the debates are now at a technical level, then that may be wholesome enough. Dodwell indeed argues here that the need for all-embracing theory of visual perception has passed and that the many different processes necessary for perception must be considered individually and in detail.

What the book lacks is an Editor and its weakness lies in the same absence of coordination that marked earlier volumes: there is clear internal evidence that the contributors have not read each other's chapters and indeed there is grave doubt as to whether anyone with editorial authority has read the entire text. Thus the concepts of Fourier Analysis are independently introduced by Robson, by Ganz and by Thomas, when what was needed was one separate account written by a single hand. It is extraordinary, even outrageous, that Boynton and De Valois have not been invited, or have not been pressed, to read each other's excellent chapters on colour vision. Both chapters, for example, discuss the colour-naming work of Boynton and the attempt by De Valois to relate Boynton's results to the electrophysiology of the primate; each refers to earlier papers by the other but there are no cross-references between the two chapters. When cross-references do occur they are often blind: thus Le Grand writes "Chemical structure of rhodopsin and of other visual pigments will be discussed by Robson, in Chapter 4 of this volume", but the reader will turn to Chapter 4 in vain. **J. D. Mollon**

Subunit interactions in enzymes

Subunit Enzymes: Biochemistry and Functions. (Enzymology: A Series of Textbooks and Monographs.) Edited by Kurt E. Ebner. Pp. x+332. (Dekker: New York, August 1975.) $24.50.

THE aim of this book is to examine by means of representative examples the different types of subunit interactions that may exist in proteins. The proteins chosen for detailed consideration are glutamine synthetase of *Escherichia coli*, UDP-galactose-4-epimerase, lactose synthetase, acetyl coenzyme A carboxylases, tryptophan synthetase, and the steroid carrier protein. Each is the subject of a chapter written by research workers who have made major contributions to the field. An introductory chapter, on the general structure and thermodynamics of multisubunit proteins and molecular models for cooperativity, also contains sections on haemoglobin, CTP synthetase and glyceraldehyde-3-phosphate dehydrogenases, but these are not sufficiently detailed nor up-to-date to be of value. Most of the other chapters are clear and comprehensive accounts of the relationship between structure and function, with emphasis on the significance of the multisubunit structures; some include unpublished work and addenda containing recently published findings.

The acetyl coenzyme A carboxylases of *E. coli* and avian liver are described in an excellent article by Lane, Polakis and Moss. These are examples of protomers composed of several different polypeptide chains which catalyse distinct partial reactions or, in the case of the animal enzyme, combine with the allosteric activator citrate and induce association of the protomer to form the active linear polymer. Tryptophan synthetase (Crawford) has an $\alpha_2\beta_2$ structure, and the two types of polypeptide chain again catalyse separate partial reactions; in the protomer their catalytic efficiency is increased and dissociation of the indole intermediate is prevented. Glutamine synthetase is subject to covalent modification by an elaborate enzyme cascade system, regulated by metabolites, and in the article by Ginsberg and Stadtman the interactions between adenylylation, essential divalent cations and allosteric effectors are discussed in detail. Less is known about interactions between the two subunits in the UDP galactose epimerase molecule, which contains a single NAD^+ molecule acting unusually as a prosthetic group rather than a coenzyme (Gabriel, Kalckar and Darrow). The function of α lactalbumin as a modifier protein that decreases the K_m of galactosyl transferase for glucose as acceptor, and its possible role in the control of lactose synthesis in the mammary gland, is discussed by Ebner and Magee. The squalene and sterol carrier protein is needed for maximal activity of several enzymes involved in cholesterol and bile acid and synthesis, and its probable function as a lipid-carrier in these pathways is described by Dempsey.

This book serves a useful purpose in bringing together diverse examples of subunit interactions in enzymes. The omission of aspartate transcarbamylase is surprising. **K. Dalziel**

CALCUTTA

Cell membranes

Pathobiology of Cell Membranes. Vol. 1. Edited by Benjamin F. Trump and A. U. Arstila. Pp. xv+497. (Academic: New York and London, August 1975.) $36.50; £17.50.

THIS volume is the first of a projected "multivolume treatise designed for pathologists and cell biologists interested in the role of membrane alterations in disease processes". Each of eleven chapters was written by one or more experts, and each is followed by an editors' summary. The subject matter ranges from broad topics such as "Cell Membranes and Disease Processes" (B. F. Trump and A. U. Arstila) and "Alterations in Lysosomal Membranes as Related to Disease Processes" to more technical ones, such as "The Use of Circular Dichroism in the Study of the Structure of Cell Membranes" (R. W. Henkens). In large measure, the book deals with the pathogenesis of subcellular lesions with special emphasis on the possible or probable roles of various cell membranes. Consideration is thus given to "The Cellular Mechanisms of Hormonally Induced Tissue Atrophy" (H. J. Helminen), "Thyroid Lysosomes in Health and Disease" (R. Seljelid), "Toxic Changes in Mitochondrial Membranes and Mitochondrial Function" (R. A. Goyer and B. C. Rhyne) and "Human Intestinal Epithelium as a Biological Membrane" (W. O. Dobbins III). These chapters contain much information of a correlational nature, particularly on the ultrastructural level. Other chapters give overviews of some key properties of cell membranes from physicochemical, biochemical, physiological and pathophysiological perspectives and include, in addition to the chapter on circular dichroism, the following topics: "Lipid Peroxidation and Fluorescent Molecular Damage to Membranes" (A. L. Tappel), "Colloid Osmotic Pressure as a Cause of Pathological Swelling of Cells" (J. R. Robinson), "Photopathology of the Erythrocyte Membrane" (J. S. Cook), "The Endocytic Uptake of Macromolecules" (P. J. Jacques).

All of the authors have made it clear that there are gaps between more or less defined phenomena in model membrane systems and the pathophysiological behaviour of cell membranes *in vivo.* Nowhere in biology have models been more popular than in the study of cell membranes. The search for pathogenetic mechanisms has of necessity been either empirical or reduced to narrowly defined, idealised situations. Aware of this, the editors have taken a comprehensive stance in their preface, choice of topics and comments, thus reflecting the Hegelian dictum "*das Wahre ist das Ganze.*"

The book has been written and edited with care, is beautifully illustrated and well printed. It represents a major effort to relate data and ideas about cellular membranes derived from model systems to pathobiological phenomena. It should be read by students of disease, not only to obtain information or as a guide to primary sources, but as an aid to planning experiments. I look forward to the publication of the subsequent volumes.

G. W. Richter

Microprobe analysis

Electron Microprobe Analysis. (Cambridge Monograph on Physics.) By S. J. B. Reed. Pp. xvi+400. (Cambridge University: London and New York, 1975.) £12; $34.50.

THIS is a very useful monograph that fills a timely need for anyone who is considering the possibility of entering the field of microprobe analysis. It is but a short mental step from knowing that high energy electrons produce X rays when they strike solid objects to deciding that this would be a good method of analysing the composition of the object. The pitfalls, however, are numerous. Since the germinal work of Castaing in 1951 the field has developed at an astounding rate, and it is now known how to design suitable instruments and how to convert raw data into compositional details. Instruments are complicated and very expensive, and the investigator must often make the kinds of decisions as when he buys an automobile —which of the optional 'extras' do I really need? The analysis of raw data is equally, if not more, complex as numerous (and not small) corrections must be applied.

Clearly a readable text was badly needed to guide both neophyte and expert through this mass of detail, and this book serves that purpose well. An expert would surely conclude that each individual chapter is too short and glosses over the interesting details, but the essential facts are presented in each case even though some chapters are condensed almost to the point of reading like a telegram. To cover the fields of instrument design and the meaning of the data, the author was forced to summarise a vast literature, and he is to be commended for his efforts.

It would, however, have been valuable to provide the reader with a list of applicable texts and monographs at the end of each chapter for further reading and more detailed study. A carefully selected list would have been more valuable than chasing down the many references scattered throughout the text.

A. V. Crewe

NEW

The Nature of Seawater

Edward D. Goldberg, Editor
Scripps Institution of Oceanography

Report of the Dahlem Workshop on
The Nature of Seawater
Berlin 1975, March 10 to 15

From the Introduction by E. D. Goldberg: Herein are an unusual set of presentations. In the main they were written by some of the world's most distinguished chemists, who describe the areas of research that they are pursuing. These articles in pure chemistry were prepared for a group of marine chemists who assembled in March 1975 in Berlin, Germany to consider new approaches which might yield a better understanding of the compositions and reactions of oceanic systems. Now they are being presented to a wider audience of marine chemists with the same aim in mind.

obituary

Robert Stoneley sometimes remarked how much he regretted never having been a research student. The First World War took him away from University, and he returned to begin teaching straight away. Yet he made valuable contributions to theoretical geophysics during the years when he was heavily engaged in lecturing, first at Sheffield then at Leeds. His published papers were short and not frequent, averaging one a year, yet he made key contributions. His first paper, in 1924, investigated the possibility of waves channelled along the welded interface of two elastic media. These came to be called Stoneley waves, though he could never bring himself to use the name and spoke of 'interface waves of Rayleigh type'.

In 1925 another important paper showed that the observations of surface waves which had been used by seismologists to calculate phase velocities in fact gave group velocities. In 1926 he made a numerical study of the Earth's elastic yielding, using C. G. Knott's velocities of sound waves and shear waves throughout the Earth. This was one of the pioneer papers that led to the conclusion that the core of the Earth is liquid.

In 1931 Stoneley explored the significance of Jeffrey's remark that a deep earthquake should excite relatively small surface waves. This consequence of dynamical reciprocity was skilfully used by Stoneley to confirm that some earthquakes, suspect on account of anomalous travel times, had indeed originated at depths of several hundred kilometres.

During the 1920s and 1930s Stoneley worked both on theoretical problems of surface wave propagation in layered media, and on data analysis from seismograms or from tables in the International Seismological Summary. He showed how to separate double earthquakes, and how to distinguish in seismograms between Rayleigh and Love waves. Later he suggested to Michael Longuet-Higgins the work which led to an explanation of the origin of microseisms.

The Second World War, during which he carried very heavy teaching loads in Cambridge, interrupted his research for ten years. When he began to publish again it was in a valuable series of summaries or review articles on microseisms, waves in anisotropic media, surface waves, tsunami, oscillations of the Earth, deep structure of the Earth, and the history of modern seismology. He retained robust health and remarkable vigour for many years beyond retirement. During the period 1961–68 he served in Washington as consultant in the US Coast and Geodetic Survey and as Professor at the University of Pittsburgh.

A great formative influence in Robert Stoneley's career was his close friendship with Harold Jeffreys. Again and again in his papers there is reference to help or criticism from Jeffreys. Men of very different characters but similar in scientific interests—extending from differential equations to botany—their association was highly creative.

Robert Stoneley was a man of great personal kindness, responding eagerly to any request for help and going to any amount of trouble to provide it. He was patient and equitable, yet at the same time efficient, and the long list of organisations in which he served as secretary or chairman testifies to the confidence people placed in him. His advice and warm humanity were deeply appreciated everywhere.

E. R. Lapwood

George Hoyt Whipple, whose work in the 1920s led to the control of pernicious anaemia, died on February 1 at the age of 97.

After gaining his medical degree, at Johns Hopkins, Dr Whipple remained there until, at the age of 36, he became director of the Hooper foundation for medical research at the University of California. Whilst there he demonstrated that a diet containing raw liver was an effective way of treating experimental anaemia in dogs. That discovery led to clinical trials of raw liver for various anaemias culminating in 1926 when G. R. Minot and W. P. Murphy in Boston showed that pernicious anaemia, previously incurable, could be controlled by dietary liver. Dr Whipple's contribution to that success was recognised in his sharing the 1934 Nobel prize for medicine with Minot and Murphy. It was another fourteen years before teams at Merck and Glaxo simultaneously identified vitamin B_{12}, the active factor in the liver.

In 1921 Dr Whipple moved to Rochester University where he headed the newly founded medical school. During the next thirty years, first as professor of pathology and then as dean of the medical school, he continued to study the factors, particularly iron, that can reverse experimental anaemia. He also served as a trustee of the Rockefeller Foundation from 1927 to 1943 and as a scientific director from 1936 until 1953.

announcements

International meetings

April 15, Deadline for abstracts for **Nonspecific Immune Stimulation in Cancer and Autoimmune Disease** (to be held July 5–6 in Bucharest) (2nd International Symposium on Cancer Immunotherapy, Oncological Institute, P.O. Box 5916, Bucharest 12, Romania).

April 28–30, **Land as a Waste Management Alternative,** Rochester, N.Y. (Agricultural Waste Management Conference, 207 Riley-Robb Hall, Cornell University, Ithaca, New York 14583).

Person to Person

Going on sabattical with family to King's College, London, and would like to exchange a large 4-bedroom, furnished house in desirable area of Washington, D.C. and 20 min from NIH for comparable house or flat in interesting section of downtown London, with good schools. Seven months from June, but flexible. (Dr Mark Smulson, Department of Biochemistry, Georgetown University, Schools of Medicine and Dentistry, Washington, D.C. 20007.)

May 12–15, **Dictyostelium,** a workshop at Cold Spring Harbor, New York (Dr Harvey Lodish. Department of Biology, MIT, Cambridge, Mass, or Dr William Loomis, Department of Biology, University of California at San Diego, La Jolla, CA 92093).

May 30, Deadline for abstracts for the **27th Annual Session of the American Association for Laboratory Science** (to be held on November 7–12 at Houston) (Dr Charles W. McPherson, Animal Resources Branch, DRR, NIH, Bethesda MD20014).

Inequality of opportunity: questions but no answers

THE table shows admissions to UK universities in October 1975 for a selection of subjects. An attempt is made not only to show how many places are available as a percentage of the number of candidates, but also to indicate how some subjects are major exporters, others major importers of students. The medical sciences continue to export, notably to biology and biochemistry, even though the numbers of applicants for medicine was sharply down. The vigour of biology is remarkable. Even though it imported 40% of its students, applicants who named biology as their first preference grew by 20% from the previous year. Biomedically inclined schoolchildren are probably being increasingly advised to apply for biology rather than medicine. The physical sciences continue in the doldrums.

However much a popular subject, such as medicine or veterinary science, may export, it is abundantly clear that many students with quite good qualifications are being turned away who would have been accepted with open arms if they had possessed the same qualifications in less popular subjects. Can we afford to do this? How could it be stopped?

Subject	Candidates preferring this subject (a)	Places filled in this subject ($b+d$)	Percentage imported $100d/(b+d)$	Percentage exported $100c/b$	Percentage of candidates who get in somewhere $100(b+c)/a$	Places per candidate $(b+d)/a$

Controlling the new proliferation

Trade in nuclear technology is increasing. **John Stares** considers whether the nuclear Non-Proliferation Treaty, six years old last week, can still effectively control the spread of nuclear weapons.

DURING the six years since the Treaty on the Non-Proliferation of Nuclear Weapons (NPT) came into force, the peaceful uses of nuclear technology have become much more widespread. With this development has come the increased risk of the misuse of nuclear technology, for military rather than peaceful purposes. Through peaceful nuclear programmes, many countries (in addition to the five nuclear-weapon powers) have accumulated the technical expertise and knowledge, as well as the fissile materials, necessary to develop and manufacture nuclear weapons. In time the number of such countries will grow, and some disarmament experts have predicted that within a few years more countries will in fact "go nuclear". The Indian nuclear test in the spring of 1974 clearly demonstrated that, even for an underdeveloped country, the technological and economic constraints on producing nuclear explosives (whether for peaceful or military ends) that existed a few years have largely disappeared. Is it possible, then, to prevent nuclear-weapon proliferation? If so, is the NPT an effective means of doing so? Or must other means be found?

It is certain that the global demand for energy will continue to grow, and that the rate of growth will be highest in the underdeveloped countries. Development requires a plentiful supply of energy—cheap energy—and in the face of shortages and rising prices of other energy sources (oil, for example) the only viable alternative energy source at the moment for many, if not most, underdeveloped countries is nuclear energy. The capital outlays for constructing nuclear power stations may be higher than for oil- or coal-fired power stations, but nuclear fuelling costs are considerably lower than conventional ones, thus making nuclear electricity generation at least competitive in terms of cost with other methods. This is well illustrated by the fact that Iran plans to produce much of its future energy from nuclear power stations, even though it has enormous oil reserves: it is more economical for Iran to sell or conserve its oil than to burn it in power stations.

It is therefore right and proper that nuclear energy should be made available to the underdeveloped countries. This was recognised in the NPT: the Preamble declares that "the benefits of peaceful applications of nuclear technology should be made available for peaceful purposes to all Parties to the Treaty". But any country with its own nuclear power reactor has, on its territory, the raw materials for making nuclear weapons. (It is interesting to note that if a power reactor is operated to produce the cheapest electricity, the plutonium it produces will consist of a mixture of isotopes and will be suitable for making only crude nuclear weapons, not optimally efficient ones.) The number of countries with nuclear programmes is increasing. In 1970 when the NPT became effective, 15 countries were operating power reactors. By 1975 the number had risen to 19. And if present plans are fulfilled, nearly 30 countries will have their own nuclear power stations by 1980. The increase in the number of actual reactors is even more dramatic. In 1975 about 170 power reactors were in operation, about two-thirds of them in the nuclear-weapon countries. By 1980 it is estimated that the total will have increased to more than 400, and that more than half will be in countries that do not, now, have nuclear weapons.

In theory, the NPT seemed a reasonable system for ensuring that the spread of peaceful nuclear technology did not lead to the proliferation of nuclear weapons. Under the Treaty, all non-nuclear-weapon countries undertook not to manufacture or otherwise acquire nuclear weapons, or indeed any nuclear explosive device, and to permit the application of control procedures, called safeguards, on its nuclear activities "with a view to preventing the diversion of nuclear energy from peaceful purposes to nuclear weapons or other nuclear explosive devices". All parties to the Treaty undertook not to supply fissile material or equipment designed for processing, use or production of fissile material to a non-nuclear-weapon country without safeguards being applied. The Treaty certainly has its weaknesses, perhaps the major one being that it is imbalanced in favour of the nuclear-weapon countries. These were left free to develop and increase their own nuclear arsenals, and were not obliged to submit to safeguards on their nuclear activities.

The Treaty therefore does not ensure the non-proliferation of nuclear weapons, but only seeks to stop their spread to non-nuclear-weapon countries. However, if *all* countries had joined the NPT, the nuclear proliferation problem might now be much less serious than it is: an international system of safeguards covering all nuclear activities (except in the nuclear-weapon countries) would be in operation, and all but five countries would have given up the option of producing nuclear weapons. But several important countries are still not members. This group includes two nuclear-weapon powers, France and China; several other industrial countries, such as Japan (which signed the Treaty in February 1970 but has still not ratified it); and many underdeveloped countries, India being the classic example and others including Brazil, Egypt (which has signed, but not ratified), Israel, Pakistan and South Africa. Many of the countries, industrial and underdeveloped, that remain outside the Treaty are already sufficiently advanced technologically to be able to produce their own nuclear weapons very quickly if ever they decide to do so. It is even believed that some may secretly have done so.

Can anyone prevent this . . .

Photo: Col

The nuclear exporting countries are clearly worried by this situation and by the possibility that future exports of nuclear materials and equipment might be diverted to military uses. There have been protests at nuclear exports in a number of countries: for example, in the United States there were calls during recent hearings of the Senate Government Operations Committee for an embargo on nuclear exports, and in the

Canadian Parliament the Opposition has criticised the Government for allowing economic interests to take precedence over more serious concerns about proliferation. Despite these protests, it is unlikely, for economic reasons, that exports will stop. The nuclear-weapon countries have invested huge sums in developing nuclear technology, and they and other industrial countries such as Japan and West Germany look to exports to boost their economies. The United States is reported to earn about $1 billion per year from its nuclear shipments; the West German deal to supply Brazil with a complete fuel cycle is worth some $5 billion; and the recently announced deal between Canada and South Korea for the supply of a 600 MW reactor involves Canadian, British and US loans totalling $400 million.

Concern over misuse

But although the nuclear exporting countries may be unwilling to halt exports, they are concerned to prevent the misuse of exported technology. During 1975, seven of them—the so-called Nuclear Exporters Group consisting of Canada, France, West Germany, Japan, the USSR, the UK and the USA—held a series of secret meetings on this issue. In January this year they were reported to have reached agreement on new safeguards and control procedures. The exact details remain secret, but according to Dr Fred Ikle, Director of the US Arms Control and Disarmament Agency, in testimony to the Senate Foreign Relations Subcommittee on Arms Control, it is thought that in future, requirements for nuclear exports will involve: acceptance by recipient countries of internationally accepted safeguards drawn up by the International Atomic Energy Agency; assurances by recipient countries that they will not use nuclear exports to make nuclear explosives, for any purpose; provision by importers of adequate security measures to prevent theft or sabotage; and assurances by importers not to transfer materials or duplicates of equipment to third parties without setting similar conditions.

The effect of such measures is not likely to be striking. They may be seen as an attempt to strengthen the NPT, since they are, in essence, similar to the provisions contained in the Treaty itself. In the past, disarmament experts have suggested that membership of the NPT should be demanded as a requirement for receiving nuclear assistance. Apart from the fact that some countries may regard such a move as even more restrictive and discriminatory than the NPT itself, the Group could hardly adopt such a policy when two of its members have not themselves joined the Treaty. The measures could thus be regarded as a "second best" answer to this suggestion. On the other hand, it is even possible to envisage that these measures might weaken, rather than strengthen, the NPT: countries that have not already joined the Treaty may now perceive that there is no pressing need to do so, since they know that the exporting countries are willing to supply assistance under terms that are similar to those of the NPT—but with the important difference that recipient countries will only be required to make a "gentleman's agreement" not to make nuclear weapons, which is very different from undertaking a formal international treaty obligation not to do so.

What must be accepted sooner or later is that it is simply not possible to *prevent* a country from acquiring the *potential* to produce nuclear weapons. Applying stringent controls or conditions may slow the process, but any country with a peaceful nuclear programme will inevitably acquire a nuclear-weapon potential in the end. What may be possible—in fact what may be the only answer—is to *discourage* countries from realising this potential. The only barrier left to the acquisition of a nuclear force, now that the technological and economic constraints have lost their importance, is a political one. For countries that have joined the NPT, this Treaty represents the barrier: to produce nuclear weapons would be a violation of international commitments. Once countries that have not joined the Treaty acquire a nuclear-weapon potential, they will have the choice whether or not to realise it. This choice will be influenced by political, not technological, considerations, principally the countries' perceptions of their security needs.

The key here is the attitude and behaviour of the nuclear-weapon powers themselves. If they indicate that they do not regard nuclear weapons as essential to security by showing themselves willing to make meaningful reductions in their nuclear arsenals, other countries might well be encouraged to follow their example, and renounce the nuclear option. In Article VI of the NPT, all parties undertook "to pursue negotiations in good faith on effective measures relating to the cessation of the nuclear arms race at an early date and to nuclear disarmament, and on a treaty on general and complete disarmament under strict and effective international control". It can hardly be said that the nuclear weapon powers have lived up to this commitment: the United States and the Soviet Union have been engaged in the Strategic Arms Limitation Talks (SALT) for years, but they have reached no agreements of any significant disarmament value, and the build-up of their nuclear arsenals continues unabated; Britain has also continued to develop its nuclear force, as have France and China, which have not even joined the NPT. An act of faith on the part of these powers, a demonstration that they are serious in their intention to abide by their treaty obligations and in their attempts to achieve nuclear disarmament, would have vastly more impact on world peace and security than any number of secret meetings. □

. . . being developed from this?

SPACE

Bringing cooperation nearer

A joint move backing planned European involvement with a major NASA space science project of the 1980s has come from the European Science Foundation and the US National Academy of Sciences. Allan Piper reports

FOLLOWING a meeting between the European Science Foundation and the US National Academy of Sciences at Williamsburg in Virginia, it has become clear that the independent scientific community represented by the two organisations means to become involved in the new $350-millions Large Space Telescope project (LST) planned for the 1980s by NASA. Recommendations developed during the meeting particularly underline European interest in the telescope, already under consideration as a priority project in the European Space Agency's programme of cooperation with NASA.

The LST, planned as a 2-metre diffraction limited optical telescope, should be in orbit by the end of 1983 as part of NASA's forthcoming space shuttle programme. Essentially an advanced and updated version of the highly successful Copernicus telescope launched four years ago, it will be used in planetary, galactic and intergalactic studies. The planned payload includes instrumentation covering the entire optical spectrum from infrared to ultraviolet, providing astronomers with a first opportunity to obtain data which is not accessible from Earth-bound observatories.

Described at Williamsburg as the single most important next step that could be taken in astronomy, the project hogged the spotlight during the wider debate on international cooperation on space observatories.

Recommendations resulting from the meeting call among other things for an independent, international LST Science Institute. An ESF-USNAS advisory committee is also suggested to oversee the selection of instruments for the telescope's scientific payload.

But while the recommendations outwardly stress the importance of independent scientific involvement, it is the implicit backing for ESA-NASA cooperation on the project which is more significant. None of the Williamsburg scientists was directly involved with the LST, but their statements, both space agencies have indicated, will weigh in decisions on the next moves.

Under the circumstances that could prove crucial. The project is running through heavy weather in the US, where Congress has just declined to approve NASA funding for 1977 in the absence of outside backing. The congressional coyness is seen as nothing more than a firm come-on to ESA, known to be close to throwing in its lot for a share of the price tag, but there is a very real danger that it will serve only to turn away a possibly faint-hearted suitor.

The problem is that Congressional and ESA decision-making are almost exactly six months out of phase. So even though there is confidence that Congress will give NASA the nod for 1978 funds if ESA adopts the project in the meantime, ESA officials who were in any case sceptical of the project's running power in competition with the other five possible cooperative space ventures will now have to be convinced additionally that it is not a complete non-starter.

Before losing heart, however, ESA can reflect that Congress may view the project more favourably once the present heavy expenditure on the space shuttle begins to run down. Moreover, there is still a glimmer of hope that the decision not to programme 1977 funds for the LST may be reversed. In the US the Congressional snub has brought a deluge of angry protest letters from astronomers and other interested scientists. There is little chance at this stage of additional funds, but Congress is holding open an option on internal reallocation.

Although the European astronomy community is not as well organised at an informal level as its American counterpart, the need for a tightly orchestrated campaign before, and not after, an ESA decision is widely recognised. Already there is European concern that ESA's option on the project will go by the board because of misguided views that it will not serve any immediate needs in astronomy over and above those provided by projects already in the pipeline, such as the Northern Hemisphere Observatory. It is at that level that the ESF Space Science Committee, which shares observers with ESA, will be most effective in pointing out that the LST offers new and unique possibilities, and is not just a superfluous bonus. ☐

COMECON

THE new Five Year Plans of the Comecon member countries began this year, and according to the Comecon Committee on Scientific and Technical Cooperation, which met in Budapest in January, scientific cooperation will be largely devoted to research projects and problems "which cannot be solved by individual countries". These include power production, protection of metals against corrosion, increase of protein production, the comprehensive utilisation of timber, and the testing of new insecticides. Discussions will also take place on the establishment of an integrated system for the exchange of scientific and technical information which, if successfully implemented, could eliminate uneconomical duplication of research.

Special emphasis is to be placed on research into energy resources ranging from lignite to nuclear power. The production and consumption of energy by the Comecon bloc is still steadily expanding: according to Nikolai Faddeev (USSR), the Secretary of Comecon, the nuclear power stations in the USSR and those built with Soviet assistance in Bulgaria, the GDR and Czechoslovakia now have an aggregate capacity of 7,500 MW, and by 1980 this figure will have risen to some 30,000 MW.

A 2,750 km pipeline from Orenburg to the western frontier of the Soviet Union will carry some 15,000 million m^3 of gas per year from the Orenburg gas condensate deposit to Bulgaria, Hungary, the GDR, Romania and Czechoslovakia. The second string of the *Druzhba* oil pipeline from the Soviet Union has been completed, and in 1975 delivered some 50 million tons of oil. Joseph Zamparo, of the University of Genoa, addressing the Conference on Energy Alternatives sponsored by the American Nuclear Society, said that energy consumption of the Communist countries (including China) was increasing by an average of 6.5%, whereas all other countries were reducing their energy consumption by amounts ranging from 9% for Western Europe to 2% for Australia.

USA

A $20–million boost for earthquake prediction studies hangs in the balance at the moment, following reluctance on the part of the Office of Management and Budget to sanction the extra spending. Much of the initiative in seeking out the extra money has come from Vice-President Nelson Rockefeller, who has been particularly active in support of extra funds for earthquake research since the disaster in Guatemala.

All is not lost, however, as proponents of earthquake research were testifying before a Congressional committee last week and pointing out, in particular, implications of the recent finding that a small part of California has uplifted very recently, by as much as 25cm in 10 years.

If the increase of $20 million were to be given the go-ahead, it seems likely that it would be spent not on the employment of additional personnel by the US Geological Survey but on research in private industry and universities. The programme would include work on the socio-economic aspects of earthquakes and their prediction, on the effects of earthquakes and on an effort to develop within a decade the capability to predict earthquakes satisfactorily.

The scheme is, however, "comatose" at present, though with luck and some judicious Congressional lobbying it may yet get off the ground.

● More evidence of the "drug lag" in the United States—whereby the Food and Drug Administration now takes so long to give permission for clinical trials and ultimately for the sale of a drug that some key preparations are available in the USA long after they go on the market elsewhere in the world—is contained in a recent report showing how and where the US pharmaceutical industry spent its money on research and development.

Figures released by the Pharmaceutical Manufacturers Association (PMA) recently indicate that of the $859 million spent by US drug companies on research and development in 1974, $133 million was spent outside the USA. The latter amount is 22% higher than the figure for 1973, which in turn was 66% higher than for 1972. The amount spent within the United States was 12.8% higher in 1974, at $726 million. The increases for 1975, as budgeted, were more modest, 12% for spending outside the United States and 10% for spending within the country.

The PMA points out that, on average, it now costs $11.5 million to develop a drug inside the USA and $7.5 million outside, and that whereas US companies had accounted for some 70% of the new chemical agents put on the market between 1940 and 1970, that proportion divided to some 39% between 1971 and 1973.

The PMA emphasises that it does not want the drug regulations to be relaxed, but simply to see the FDA become more efficient and responsive to the need to get new drugs on to the market as quickly as possible. In 1972 it took between 5½ and 8 years to get a drug passed by the FDA, by contrast with the situation elsewhere in the world where the comparable period of time, the association maintains, was 6 to 24 months.

Photo : Cam & Pen Int

Perhaps Senator Edward Kennedy's proposal to split up the FDA into two separate agencies and streamline the procedures for drug approval would help matters.

● The Nuclear Regulatory Commission (NRC) has been served up with a critical but constructive report by the Special Review Group it set up to look into the celebrated fire at Browns Ferry nuclear power station, Alabama, last year. The fire was started by a candle being used to check for air leaks around cables passing from one of the two reactor buildings to a cable spreading room beneath the control room.

The report points out that the inflammable polyurethane foam used to block off air draughts was not in the original design for the plant, and, like the candle, should not have been used. The group recommends that the foam should either be replaced wherever it has been used in the Browns Ferry or other nuclear plants, or that special safety procedures should be set up if this is not possible. More generally, the group says that, better all-round fire prevention measures are needed in nuclear plants.

Fire fighting procedures at the Browns Ferry also come in for criticism. The report points out, in particular, that the part of the fire in the reactor building "was fought unsuccessfully for several hours with portable CO_2 and dry chemical extinguishers; however, once water was used, it was put out in a few minutes". The old maxim about not using water on electrical fires has to go quickly by the board in such cases if other means clearly fail, the report concludes after considering the views of fire experts.

The fact that several of the plant's control systems were damaged in the fire, including redundant systems that should have prevented complete loss of any function, also led the group to criticise other features of the Browns Ferry design (which, to be fair, was carried out in the mid-1960s). For example, wiring connected to some redundant devices was all located close together, with one set simply placed in a conduit. In spite of this, the fire damaged both sets of wires in several instances.

The group recommends that the NRC should sharpen up many of its procedures for developing standards, making inspections and so on, but points out that the very small probability of accidental release of radioactivity from such a fire is "about 20%" of that calculated from all other possible causes. Thus "urgent" action to reduce fire risks is not required, it says, and in particular there is no question of shutting down other plants while minor modification work is carried out.

The Browns Ferry reactors are expected to start generating electricity again in April.

● A paper released by the Washington-based Worldwatch Institute (*Abortion Liberalisation*: *A Worldwide Trend*) reports that 64% of the world's people live in countries where abortion is liberally available. Five years ago, in January 1971, the proportion was 38%, and writers Lestor R. Brown and Kathleen Newland say that "few social changes have ever swept the world so rapidly".

The worldwide movement, they argue, "reflects an increasing willingness by national legislatures to face the reality of abortion as a public health issue"—but the public health benefits of safe abortion depended on its availability in fact as well as in legal theory, which made cost and distribution important. Women would also continue to seek abortion, even when illicit and dangerous, while there was a lack of failure-proof and problem-free contraceptives. ●

FRANCE

The agreement reached at the recent Nice summit between the French and West German Technology ministers on cooperation in nuclear reactor technology, while vague, represents a pooling of risks, regarding both fast breeders and high temperature reactors, that both countries hope will work to their mutual advantage.

The indications are that Germany will benefit in the sphere of fast breeders. Her operation, conducted along with the Benelux countries, is racked by rising costs and due to bear fruit only in 1981, while France's 250 MW Phenix prototype sodium-cooled reactor has been working successfully for a year. In the field of high temperature reactors, on the other hand, Germany's project, although also behind schedule and increasingly costly, is one of the few of its type, and the Schmidt government appears prepared to take it further.

The money involved, of course, is enormous, and it is not clear whether financial backing will be divided equally between the two areas. It is expected that the two countries will contribute equally, but the agreement declares only that they should spend the amounts on the two areas taken together.

The conclusion came just a few weeks after the completion of a deal between France and the Westinghouse Electric Corporation which also reflected a trend to "Europeanise" the nuclear industry this side of the Atlantic. Westinghouse is to sell two-thirds of its 45% holding in Framatome, the French licensee of its pressurised light-water reactor, to the French Atomic Energy Commission (CEA) for $25 millions.

Westinghouse will transfer its remaining 15% Framatome interest to the Creusot-Loire Company, the heavy equipment suppliers with a 51% interest in Framatome, in 1982, when the licenses expire. Until then, Westinghouse will be able to buy up to 1,200 tonnes of uranium from the CEA. Westinghouse will also continue to receive royalties for Framatome's use of Westinghouse technology in fulfilling orders and options, which now extend to over 40 plants. Westinghouse will take part in a joint research and development programme as well.

This "partnership" through Framatome between the CEA and Creusot-Loire in respect of pressurised-water reactors could conceivably expand into the field of fast breeders with the Franco-German agreement. Cooperation between the two countries on fast breeders, it is understood, will take place through a joint company. On the German side will be Kraftwerke Union or a subsidiary; on the French side will be the CEA, or possibly Novatome, which is owned by the CEA and Framatome together with the Compagnie Generale d'Electricite (CGE). The CGE was involved in the ill-fated boiling-water reactors about which the government last year changed its mind; but, more importantly, it has a stake in a company working on the French fast breeder, GAAA, in which Creusot-Loire has been interested in order to widen its arena of nuclear activity. The size of the respective stakes appear to make it possible for CGE resistance to Creusot-Loire to be circumvented through Novatome.

Photo: Cam & Pen Int

● Another important deal which, like that involving Westinghouse, took months to finalise, was completed just before the New Year. An agreement between the American computer firm Honeywell Information Systems and the French government merges Honeywell's French subsidiary with the general-purpose business of the national computer company, CII, to form CII-HB, 20% owned by the government and, altogether, 53% owned by French interests.

The government is expected to give about $280 millions of subsidies over four years, and a government-sponsored finance company will purchase computers sold to the government and nationalised industries. Furthermore, the addition of the 1,300 employees of the CII Research and Development Engineering Department will enhance the research resources of the new company. The whole deal represents the third attempt in eight years to establish a French computer industry that can compete with IBM in the country. But it also represents a setback for attempts to forge an overall European solution.

● The 15-year period after 1955, an era of strong growth in research which coincided with considerable expansion of the French university system, has been followed by a recession which has left university research facing very serious problems.

Now, following the creation of an autonomous National Secretariat for Universities in 1974, ostensibly to oversee both CNRS and university-financed research, the government has belatedly laid some foundations for organising university research policy. A central role has been accorded to the Secretary of State for the Universities (Mme A. Saunier Seité, who replaced M J. P. Soisson in January's ministerial reshuffle) in overseeing co-ordination of university research—an objective that has been sought for a decade. Groups have been formed within the National Secretariat for this purpose, but the overall effort is being directed towards refining budgetary procedures that permit healthy growth as well as adjudicating between university research programmes.

The driving force behind all basic research is the National Scientific and Research Centre (CNRS), with a budget (in 1976) of about 21,000 million francs. It directly finances the major part of research in universities, with which its links are close; the universities' own budget for research last year amounted to an estimated 1,400 million francs, a figure which includes part of the salaries of professors and assistants.

University research which is independent of the CNRS faces typical problems. Laboratories unaided by the CNRS have seen the buying power of their finances eroded since 1969. Moreover, insufficient coordination at the national level has helped to diminish the credibility of an often vague (even non-existent) university research policy. Research teams in the smaller and medium-sized provincial universities have also faced difficulties attaining the necessary size, although all the universities are now feeling the crisis, including such large Parisian universities as the Pierre and Marie Curie University.

● At the end of January, just a fortnight after the court established by France and Britain began considering demarcation between their off-shore oil prospecting limits, on which a decision is expected in the summer, reports emerged of hydrocarbon finds at a depth of 5,840 feet off the Brittany coast, though not in a disputed area. Results of commercial tests are awaited, but drilling will continue to 9,850 feet.

IN BRIEF

Geothermal energy

Geothermal energy in the United Kingdom is not likely ever to be a major resource. This was the unsurprising conclusion to be drawn from evidence recently given to the Energy Sub-Committee of the Commons Select Committee on Science and Technology by Dr Bill Bullerwell, Deputy Director of the Institute of Geological Sciences. Even the few prospects worth pursuing, particularly in Cornwall and the West Hampshire Basin, did not warrant more than a proposed £800,000 research programme over the next three years. In the longer run Dr Bullerwell thought there were possibilities in disused North Sea wells, where temperatures up to 160 °C have been recorded; water might be circulated and the heat converted to hydrogen storage.

UK energy policy

The UK Department of Energy is aiming for a bigger Government say in shaping the country's future energy policy. The changes it proposes come in a 20-page report circulating among Government and trades union officials which was prepared by the political advisers to the Energy Secretary, Mr Anthony Wedgwood Benn. The report follows his call last week for a new approach to long-term planning, and suggests the introduction of new administrative set-ups within the nationalised fuel industries.

Telecommunications research

The UK telecommunications industry entered the telephone centenary week with a sharp reminder of its "competitive weaknesses". The Labour Research Department, an independent, union-backed organisation, has suggested that the fault lies in the comparatively low levels of telecommunications research spending in Britain, and sees one possible remedy in the extension of state control to the private supply industries.

Saving the wetlands

KENNETH MELLANBY

MAN has modified the natural landscape in all parts of the world, to make it more productive and to support a larger human population. He has felled the forests which originally covered most temperate areas, and he has drained marshes and fens to produce fertile farmland. In the past these activities were almost universally applauded. In the seventeenth century the Dutch engineer Vermuyden introduced scientific land drainage to East Anglia; he was hailed as a benefactor for turning the almost unproductive wasteland into some of the best arable in England. Others who extended his work, including the drainage of Whittlesea Mere, the largest lake in Southern England, were seldom criticised for their actions. Almost everyone thought that agricultural improvement should be encouraged.

The only objectors to drainage were the few "fen tigers", poor peasants who made their living catching eels and wildfowl, and cutting reed for thatch. Today, when most of Europe's marshes have been drained, and development is destroying (or improving) wetlands throughout the world, the ecological importance of such areas is being increasingly realised. We have the international "Convention on Wetlands of International Importance", and this year, 1976, the Council of Europe is sponsoring a European Wetlands Campaign. The intention is to try to preserve as many as possible of the remaining and unpolluted rivers, estuaries, lakes, ponds, marshes, bogs and fens as habitats for wildlife, particularly for waterfowl.

Agriculture is perhaps no longer the main cause of wetland destruction, though the unwise use of pesticides on crops near to rivers and marshes has taken its toll of fish and fish-eating birds. Industrial pollution has also had its effect on all forms of wildlife. Marshes near to human settlements, particularly in the tropics, are blamed for breeding mosquitoes which transmit malaria and other diseases, and may be saturated with DDT and other chemicals. Uncontrolled shooting has affected bird populations, and obtrusive sports like water skiing and speedboat racing have turned peaceful lakes into noisy infernos.

It would be absurd to pretend that the majority of the population of any developed country cared greatly for wetlands and their flora and fauna, and public concern in developing countries must be minimal. So the conservationists must be congratulated in obtaining such widespread international support, from scientists and politicians, for their preservation. However, though many of our governments pay lip service to this type of conservation, their actions have been incredibly dilatory and have not always accorded with their public protestations.

Although there have been international discussions on wetland and waterfowl conservation for decades, it was only in February 1971 that the text for a convention was formulated at Ramsar in Iran. It was then agreed that when seven different countries had ratified this convention, it would come into force. Bureaucracy has delayed this ratification for five years, during which period many valuable wetlands which might have been saved have been lost.

This delay has been particularly discouraging for the British ornithologists and conservationists who played a leading part in the whole campaign. They hoped that Britain would set an example by rapid action, so leading the world officially as well as scientifically. This was not to be. The convention was first ratified by Australia, then by Iran, Finland, Norway, Sweden and South Africa. This was the state of play in March 1975. One more signature was needed —surely this would be that of Britain. At a meeting in Germany months earlier the Foreign Office had assured our delegation that ratification was "imminent". However, Greece acceded in August 1975, bringing the convention into force. Bulgaria signed next, Britain came in ninth. Now Britain is used to seeing its representatives coming in far down the line at the Olympic Games, so perhaps we should not have been surprised to find our diplomats are as slow as our athletes.

However, let us be thankful for small mercies, in that, at long last, the Foreign Office has given its support to the efforts of our scientists. No doubt the official responsible will be suitably rewarded. As he has been concerned with fens and bogs, the most appropriate honour would be the prestigious Royal Victorian Chain; this rarer decoration would clearly be more suitable than the commoner Order of the Bath.

correspondence

Financial discrimination

SIR,—As is shown by a survey I made recently, reported on by May (February 12, page 446), many journals discriminate in various ways against the more or less impoverished. I publish a journal myself and have grounds for believing that such discrimination is unnecessary. It preserves showiness (at the expense of economies which leave the scientific content intact) and profit. Editors of journals are usually not impoverished, and the present system does have real advantages to those with money.

As with other socially irresponsible powers, a remedy requires joint action. I am therefore pursuing the following actions, and call on others to do likewise:

- To submit no paper to an irresponsible journal except when there is no reasonable alternative.
- To avoid citing papers published after the end of 1976 in irresponsible journals, when alternative citations are available.
- To refrain from refereeing papers for irresponsible journals.

Some journals are more irresponsible than others, and one can be more stringent with the worse ones.

Yours faithfully,
LEIGH VAN VALEN

Sex laws and inheritance

SIR,—The sexual discrimination laws now in force in the UK should not blind us to the existence of one social inequality which has a sound physiological basis I mean the nature of inheritance.

In general, any one of our chromosomes (or any part of one) may have come from any one of our grandparents: no fragment of genetic material can be identified with a particular grandparent, with the unique exception of the Y chromosome in men. A man's Y chromosome is certainly derived from his father and from his paternal grandfather and so on. No other chromosome has this singular property.

Consider in particular a woman's X chromosomes. They assuredly were derived one from her mother and one from her father. But the maternal one —is it in turn from her maternal grandmother or grandfather? It could be from either. Her paternal X chromosome is certainly derived from her paternal grandmother but its pedigree similarly stops short.

Quite generally, any of our forebears, from our grandparents back, may be completely unrepresented in our chromosomes (although crossing-over reduces the probability of any such omission).

Therefore, if a woman and her husband intend only their (genetic) descendants to receive their name, title or family silver, they had better ensure that it goes only to their sons and their sons' male descendants.

Yours faithfully,
J. R. JOHNSTONE

Nedlands, Western Australia

Journal guidelines

SIR,—As Professor Ziman remarks (January 29, page 264), evidence for or against the anonymity of referees is difficult to present. However, my claim that six years editorial experience confirmed the validity of the initial policy statement in the *Journal of Aerosol Science* can be enlarged on There were three reasons for identifying referees:

- The authoritarian age is over. Professor Ziman is in error in identifying this as a populist rejection of constraints imposed by the community. It refers, of course, to constraints imposed by a favoured section of the community.
- The standard of critique will be raised. By eliciting specific criticisms in place of diffuse; by 'curbing the vanity and pride of those who claim authority'; by disclosing a possibly partisan opinion in a debated field; by revealing a possible error in referee selection
- Encouragement and benefit will result to authors. The young scientist may be put in touch with a well-known figure; an argument between equals becomes definable; a senior worker should know the source of critical comment, especially when it comes from a younger person.

The opposing view of Professor Ziman rests largely upon emotional factors. I do not believe that they are exacerbated by disclosing a personal target—rather the reverse. One would expect a referee to excuse himself if asked to deal with the work of a friend or rival were the editor ineptly to place him in an embarrassing situation.

Yours faithfully,
C. N. DAVIES

University of Essex,
Colchester, UK

Fruit flies as security officers

SIR,—Trained dogs have an established role as aids to Customs Inspectors and Airport Security Guards because of their ability to "smell out" concealed drugs or explosives or other forms of contraband. What seems to have been overlooked is the possibility of using insects for the same purpose.

The simpler insects have genetically fixed responses to specific odours, usually resulting in a conspicuous clustering in the vicinity of the odour source which may be of an extremely low absolute intensity. Kikuchi (*Jap. J. Genet*, **48**(2), 105; 1973 and *Nature*, **243**, 36; 1973) isolated a mutant strain of *Drosophila melanogaster* that was strongly attracted to eighteen chemicals which were repellent to the parent strain. It seems likely, therefore, that a systematic search for other strains selectively responsive to various narcotic or explosive emanations can uncover specific "olfactory mutants" of a practically useful sort.

While there would be obvious objections to using such species as cockroaches, bees or houseflies, the relatively inconspicuous but not unfamiliar fruit flies would probably be an acceptable alternative to some of the existing security checks

Yours faithfully,
R. H. WRIGHT

The JPU in modern science

SIR,—In view of the current interest in citation-counting and other attempts to quantify scientific achievement, I wish to draw attention to a simple concept which may grow in importance in the future This is the JPU, or "Just Publishable Unit", which may be defined as the smallest amount of information which is normally accepted for publication as a separate item in a scientific journal. An example is the present communication.

Yours faithfully,
D FRASER

Ministry of Natural Resources,
Maple, Ontario, Canada

Molecular analysis of the oncogene

from Robin Weiss

GENETIC evidence that avian sarcoma viruses carry a specific gene for neoplastic transformation of the host cell has steadily accrued over the past five years. Martin (*Nature*, **227**, 1021; 1970) first isolated mutants of Rous sarcoma virus (RSV) which were temperature-sensitive for maintaining the transformed state of the cell, but which were not temperature-sensitive for viral replication. Then Vogt (*Virology*, **46**, 939; 1971) and Martin and Duesberg (*Virology*, **47**, 494; 1972) observed the spontaneous segregation of transformation-defective variants of RSV that were subsequently shown to be deletion mutants (Lai *et. al.*, *Proc natn. Acad. Sci. U.S.A.*, **70**, 2266; 1973) lacking 10–20% of the viral genome. Recent genetic analysis indicates that all temperature-sensitive transformation mutants represent a single gene (Wyke, Bell and Beamand, *Cold Spring Harbor Symp. quant. Biol*, **39**, 897; 1975) which map in the region deleted from the transformation-defective mutants (Martin and Bernstein, personal communication). Thus avian sarcoma viruses appear to carry a gene (called *sarc*) which is quite superfluous for viral replication, but which is essential for the maintenance of the malignant state of fibroblasts.

Stehelin, Guntaka, Varmus and Bishop (*J. molec. Biol*, **101**, 349; 1976) have prepared a specific cDNA$_{\text{sarc}}$ probe complementary to the sarc gene of the virus. This was accomplished by transcribing complementary DNA of non-defective RSV by its endogenous RNA-directed DNA polymerase activity, followed by molecular hybridisation to the RNA of a transformation-defective deletion mutant. The non-hybridised cDNA, which can be separated on a hydroxyapatite column, represents a uniform transcript of the deleted sequences. Nucleotide sequences homologous to avian cDNA$_{\text{sarc}}$ seem to be present in all avian sarcoma viruses, but are absent from avian leukosis viruses, and from sarcoma and leukaemia viruses of mammals. On page 170 of this issue of *Nature*, Stehelin, Varmus, Bishop and Vogt demonstrate that cDNA$_{\text{sarc}}$ hybridises with DNA from normal chicken cells

Previous studies by Neiman, *et al.* (*J Virol*, **13**, 837; 1974) indicated that the hybridisation of sarcoma virus RNA to normal chicken DNA was entirely blocked in the presence of excess RNA from transformation-defective viruses, suggesting that sarcoma-specific sequences were not present in the normal chicken genome. The discrepancy between their results and those of Stehelin *et al.* remain to be explained. Thermal denaturation experiments by Stehelin *et al*, however, show a 4 °C depression in melting temperature (Tm) of cDNA$_{\text{sarc}}$ duplexes with normal chicken DNA by comparison with the Tm of duplexes with the provirus of RSV. This indicates substantial mismatching between the viral sarc sequences and those endogenous in the chicken cell. Under Neiman's more stringent conditions of hybridisation, such partially homologous sequences might not be detected.

Hybridisation of cDNA$_{\text{sarc}}$ to DNA of other avian species reveals a widespread occurrence of sarc-like sequences in normal DNA, including that of a primitive ratite bird, the emu. The melting temperatures of the duplexes indicate a divergence of sarc sequences roughly in parallel with species divergence, in contrast to a much more rapid divergence of endogenous leukosis virus gene sequences. Stehelin *et al.* anticipate that the cellular DNA related to cDNA$_{\text{sarc}}$ serves some function which accounts for its conservation during avian speciation. The sequences are part of the unique fraction of cellular DNA and could represent either structural or regulatory genes. The sarc gene of the virus may have been acquired from a cellular genome, possibly (in view of the melting curves) from a species other than the chicken

It is not yet clear whether the sarc-like sequences in normal avian cells are specifically expressed in normal embryogenesis or following non-viral carcinogenesis, as suggested by Huebner and Todaro when they enunciated the viral oncogene concepts (*Proc natn. Acad. Sci. U.S A.*, **64**, 1087, 1969) Bishop and Varmus' laboratory is currently studying this question

The widespread occurrence of sequences related to cDNA$_{\text{sarc}}$ in avian species will doubtless stimulate more intensive studies of sarc sequences in mammalian sarcoma viruses. Scolnick, Parks and colleagues (*J. Virol.*, **12**, 458; 1973; **13**, 1211; 1974) have detected sarcoma-specific sequences in different strains of murine sarcoma virus (MSV). In the Kirsten and Harvey strains, the sarc sequences, plus other viral sequences, seem to be derived from a rat host, whereas Moloney strain MSV is related to the mouse only. It will be interesting to find out whether the 'sarc' sequences of feline and simian sarcoma viruses are related to those of MSV, and, by analogy with the wide phylogenetic representation of sarc sequences among avian species, whether any of these sarcoma viruses will be useful in probing sarc-specific expression in human tumours.

There is no genetic evidence so far of specific oncogenes in leukaemia viruses of any kind. Viruses that are typically leukaemogenic *in vivo* but can also transform fibroblasts *in vitro*, such as murine Abelson virus and avian MC29 virus, do not seem to carry sarc sequences (Scolnick *et al.*, *Proc. natn. Acad. Sci. U S.A.*, **72**, 4650; 1975; Graf and Stehelin, personal communication), and neither are sarc sequences detectable in the cellular RNA of Abelson-transformed fibroblasts. Thus these viruses may transform cells by a different mechanism or gene product.

If the viral sarc sequences do code for a specific protein, it may be possible to identify it by comparing *in vitro* translation products of sarcoma viruses with those of their transformation-defective deletion mutants. Such attempts by several laboratories have not, however, yielded an identifiable protein so far. Of course, the isolation of an 'oncoprotein' coded by the 1,600 or so nucleotides of the 'sarc' gene is a major goal of oncornavirologists today How such a protein might interact with the host cell is an open question. Some virologists expect it to be a nuclear protein which would effect regulation of DNA synthesis, whereas others feel it may act elsewhere, by insertion in the cell membrane, for example. In this case the transformation-specific cell surface antigen of virally transformed avian cells is already a candidate Since a nuclear antigen corresponding to papovavirus T antigen or EBNA of cells transformed by Epstein-Barr virus has not been identified in cells transformed by sarcoma viruses, I currently favour a non-nuclear role.

Maternal effects on development

from Michael H. C. Snow

During the past 50 years the attention of embryologists has been much taken up with induction and activation. For them these terms are descriptive of the intercellular and intracellular processes whereby, presumably as the result of information received (or lost), a tissue or cell is made to modify its course of development. To the bacterial geneticist, however, induction and activation imply the mechanisms involved in the control of gene expression. Because cell differentiation depends on qualitative changes in gene activity, the terms should eventually come to mean the same to both groups. But at present the bacterial geneticist can refer to precise interactions between inducing or activating molecules and the genes themselves, while this is not possible for the embryologist dealing with higher organisms

The current state of knowledge of these processes in embryonic development is brought into sharp focus by two recent papers. Toivonen *et al.* (*Differentiation,* **5**, 49; 1976) consider inductive interactions between tissues. Primary induction whereby neural tube formation by the ectoderm is triggered by the underlying mesoderm was discovered, in Amphibia, by Spemann and his colleagues in the 1920s. They later presented evidence that an unidentified chemical substance(s) produced by the mesoderm was the effective agent (Bautzmann *et al., Naturwissenschaften,* **20**, 971; 1932). Since then however, the existence of diffusible inductive agents has been the subject of much controversy, partly because of the difficulty experienced in repeating some of the original experiments, and more recently because Saxén and coworkers demonstrated the necessity for cell contact between tissues in the induction of kidney tubule formation (Lehtonen *et al., J. Embryol. exp. Morphol.,* **33**, 187; 1975). Nevertheless, it is now clear that cell contact is not required for the initiation of primary induction and that some diffusible macromolecular factor is involved. The exact nature of the inducer and its mode of action is still obscure.

Most if not all embryos depend for their early development on material deposited in the oocyte cytoplasm, which is subsequently used during cleavage stages. In some cases maternally derived cytoplasmic factors are required for the normal development of much later stages. Deficiences in the oocyte cytoplasm (for example, those resulting from mutation in the maternal genome) can therefore profoundly affect the development of the embryo. Several such maternal effect mutations are known in various organisms, such as the grandchildless mutant in *Drosophila pseudoobscura* (Spurway, *J. Genet.,* **49**, 126; 1948), shell coiling in the snail *Limnaea* (Conklin, *Anat. Anz ,* **23**, 577; 1903) the *O* mutant in the axolotl (Briggs and Cassens, *Proc. natn Acad Sci. U.S.A.,* **55**, 1103; 1966) and a recent example has been described in the DDK strain of mouse (Wakasugi, *J. Reprod. Fert.,* **33**, 283; 1973).

The interest in maternal effects stems from the observation that abnormal development occurs although the genetic constitution of the individual is normal. The error apparently results from a failure to activate certain genes during embryogenesis.

A particularly exciting example of a maternal effect gene, the *O* gene in the axolotl is the subject of Brothers' report in this issue of *Nature* (page 112). The crucial observations on the *O* gene are as follows. (1) Development is arrested in embryos derived from homozygous O females at the onset of gastrulation At this time much of the embryonic genome becomes active, in particular the genes coding for ribosomal RNA. (2) The product of the normal allele (O^+ factor) can be removed from the oocyte and on iniection into mutant eggs can correct the arrest at gastrulation. (3) The O^+ factor is a protein and curiously is most abundant in the oocyte nucleus. What Brothers has shown, by a series of very elegant nuclear transplant experiments, is that the time of action of the O^+ factor is restricted to a very short period in development of a few hours in the mid-blastula stage If the O^+ factor can be isolated and purified then the way is open to analyse the manner in which at least one inductive agent operates.

In this context it is worth noting some of the other changes found in embryos at the end of cleavage. For instance, a change has been reported in the nature of histone proteins in *Drosophila melanogaster* (Das *et al., J. Cell Biol.,* **23**, 423; 1964), in the snail, *Helix aspersa* (Bloch and Hew, *J. biophys. biochem. Cytol ,* **8**, 69; 1960) and in the mouse (Alfert, *Expl Cell Res., Suppl.* **6**, 227; 1958). Histones are known to be potent but nonspecific repressors of transcription. Non-histone proteins on the other hand, have been postulated as being involved in derepression (activation) (Wang and Kostraba in *The Role of RNA in Reproduction and Development,* (edit. by Niu and Segal) 324; North Holland, Amsterdam, 1973).

The onset of gastrulation is generally accompanied by a significant change in cell proliferation rate, and in the mouse this is coincidental with a change in chromosome replication behaviour (Takagi, *Expl Cell Res.,* **86**, 127; 1974, Snow, *Ciba Symp ,* **40**, in the press). Callan has shown that in Amphibia at least, large changes in the duration of the DNA synthesis phase of the cell cycle are likely to be associated with changes in replicon length rather than changes in the linear rate of DNA replication (Callan, *Proc. R. Soc., Lond.,* **B181**, 19; 1972, and in *Molecular Cytogenetics* (edit. by Hamkalo Papaconstantinou, 31, Plenum, 1973). DNA involved in replication is not available for transcription and the restriction in the number of replicating forks in the DNA may be necessary to permit transcription of large amounts of RNA. The O^+ factor could operate in either of these areas, or alternatively could be very much more specific and result perhaps in the activation of a specific gene. After 50 years of probing, a breakthrough on any front would be welcome. ☐

Role of ribosomal RNA

from Richard Brimacombe

The flurry of interest in bacterial ribosomal proteins over the past few years has tended rather to obscure the fact that about 60% of the bacterial ribosome consists of RNA, and many workers have tried to relegate the rRNA to a mere structural component. This attitude has arisen partly as a consequence of the dogma that proteins and not nucleic acids are the active agents in biological systems, but is also a result of the fact that, in contrast to the studies which can be made with individual ribosomal proteins, it is very difficult to devise functionally oriented experiments involving the large rRNA molecules. The idea that rRNA does indeed have an important functional role is of course not new; it was suggested some years ago by Crick and

On the lagoon

from Gillian Boucher

A NEW study of the behaviour of the tide within the lagoon of Venice, in itself not a revolutionary idea, promises to have far-reaching practical results in the Italian government's choice of the most suitable barrier to prevent flooding in Venice.

A. Goldmann, R. Rabagliati and P. Sguazzero of the IBM Scientific Centre in Venice in an article in the *Rivista Italiana di Geofisica* (**2**, 119; 1975) have computed the relation between the level of water outside the lagoon and the level at 14 points within the 50 km^2 lagoon. The data were provided by hourly readings of water level at the 15 stations during 1972 and 1973. Using spectral analysis, the authors first investigated the transfer of energy from the open sea to every lagoon station at each of a large number of frequency bands. This showed that only in three frequency bands—the long-term, the diurnal and the semi-diurnal—was the transfer of energy significant. The authors then calculated the gain or loss in the amplitude of the diurnal and semi-diurnal waves—those in which the astronomical components are predominant—and the time it took waves of these two frequencies to reach each station (the phase).

In 1971 the lagoon was sounded in detail: the soundings revealed that 75% of the lagoon is shallow water or marsh less than 2 m deep, intersected by the deep channels which make up the other 25%. When this information is combined with the tide data an interesting picture begins to emerge: on deep channels the semi-diurnal waves, although not the diurnal waves, actually increase in amplitude after entering the lagoon (the gain at the Grand Canal station is 6%); in shallow water on the other hand the waves lose amplitude, the semi-diurnal waves losing more amplitude than the diurnal ones. Propagation of waves is slower in shallow water and the waves of the diurnal tide are propagated more slowly than those of the semi-diurnal.

The detailed results, with the advantages of a long period of data collection, the almost contemporary sounding data, and sophisticated statistical techniques, provide a clearer picture of the lagoon than has ever been obtained before. One important use for them will be to show how the lagoon is changing by comparison with past and future results. But the results have already been used in another of the IBM projects, very recently completed· a mathematical model of the entire lagoon. The model, calibrated by the new tide results and other information, can reproduce the behaviour of water at any point and the effects of man-made changes in the lagoon. One of the first problems the model will be called upon to solve is the effect upon the lagoon of the various types of barrier which could be erected at its three entrances.

One of the scourges of Venice is the tide which, though small by Atlantic standards, frequently causes flooding because the city is so low-lying. To save the city from the salt-water inundations the Italian government has invited tenders for the construction of a sluice at the entrances to the lagoon; companies interested in tendering must do so by June 30 this year. Of the two basic types of barrier, the moveable and the fixed, the moveable (for example Pirelli's project for an inflatable barrier) are clearly superior but very much more expensive. A fixed barrier completely shutting off the lagoon is out of the question—Venice relies on the tide to wash away industrial and domestic pollution, and to prevent circulation of water would be devastating to both humans and buildings. So the choice is between a moveable barrier and some kind of partial fixed barrier which will lessen the quantity of water entering sufficiently to prevent flooding. Inevitably a fixed barrier will also reduce circulation. The IBM model will enable companies and the government to decide whether a satisfactory compromise can be obtained between the needs to damp the tides and to control pollution.

Orgel (*J molec. Biol.*, **38**, 367 and 380; 1968) that the primitive ribosome consisted primarily of RNA, with the proteins being added later to fulfil more sophisticated functions. More recently, the functional importance of RNA in the "modern" ribosome has been preached by a number of authors, most notably by Kurland (*Ribosomes*, 309, Cold Spring Harbor Monograph, 1974), and the purpose of this article is to review very briefly the present status of rRNA, with regard to both structure and function.

Little progress can be made nowadays in any nucleic acid problem without previous knowledge of the base sequences involved. In the *E. coli* ribosome, the sequence of the 5S RNA component has been known for many years (Brownlee *et al.*, *J. molec. Biol.*, **34**, 379; 1968), and the primary structure of the 16S RNA is now almost fully established (Ehresmann *et al.*, *Nucleic Acids Res.*, **2**, 265; 1975), although there is still a measure of disagreement as to the detailed sequences of some of the oligonucleotide degradation products (Magrum *et al.*, *Nature*, **257**, 423; 1975). Progress has also been made in the sequencing of the 23S RNA (Branlant *et al*, *Biochimie*, **57**, 175; 1975). The primary sequences themselves give a strong hint that the RNA is more than just a structural skeleton within the ribosome; the 5S sequence has been strongly conserved throughout evolution (reviewed by Monier, *Ribosomes*, 141, Cold Spring Harbor Monograph, 1974), and comparison of the oligonucleotide catalogues from 16S RNA molecules from different bacteria shows a remarkable degree of homogeneity (Woese *et al.*, *Nature*, **254**, 83; 1975), again indicating that substantial regions of the sequence have been conserved. The obvious inference is that particular oligonucleotide sequences are required to fulfil specific ribosomal functions, and this has tempted several authors to put forward hypotheses involving complementary base-pairing between regions of rRNA and other nucleic acid components of the protein synthesising system (for example, van Knippenberg, *Nucleic Acids Res.*, **2**, 79; 1975). Although these ideas are attractive, it must be borne in mind that in molecules the size of rRNA, any given nucleotide sequence of up to six bases would be expected to appear on a statistical basis, and solid experimental evidence to support this type of hypothesis is unfortunately very difficult to obtain.

Evidence has however been forthcoming in two cases. The first of these concerns the proposal made by Shine and Dalgarno (*Proc natn. Acad Sci. U.S A.*, **71**, 1342; 1974) that the 3′-terminal sequence of 16S RNA is involved in mRNA recognition. Here, Steitz and Jakes (*Proc. natn Acad. Sci. U.S.A.*, **72**, 4734; 1975) have been able to isolate a dissociable oligonucleotide complex consisting of the 3′-terminus of the 16S RNA and an RNA fragment from a protein initiator region of R17 phage RNA (see also News and Views, **260**, 12; 1976). The two fragments contained a seven-base complementary sequence The second case concerns the 5S RNA, where several lines of evidence suggest that binding of tRNA to the 50S ribosome involves a complementary base-pairing between the TψCG loop of the latter with 5S RNA (Erdmann *et al.*, *Biochem, biophys. Res. Commun*, **54**, 942; 1973). Here there is some conflicting evidence, as the relevant G-residues on the 5S RNA are not exposed (within the ribosome) to attack by kethoxal, a reagent which specifically attacks non-paired guanine bases (Noller and Herr, *J. molec. Biol.*, **90**, 181; 1974). This difficulty can of course be overcome by postulating appropriate conformational changes (Schwarz *et al.*, *Biochem. biophys, Res. Commun.*, **56**, 807; 1974).

Kethoxal has been successfully used as a probe for the accessibility of G-residues on the surface of the 30S ribosomal subunit (Noller, *Biochemistry*, **13**, 4694; 1974), and these studies have also provided information regarding the vexed question of the secondary structure of the rRNA. There is still no proven secondary structure for the 5S RNA, and, while a secondary structure has been proposed for *E. coli* 16S RNA (Ehresmann *et al.*, *Nucleic Acids Res.*, **2**, 265; 1975), there is at present little evidence to support it. Indeed the kethoxal data are to a considerable extent at variance with the proposed structure, and a further complication has recently arisen with the finding that specific regions of the 16S RNA are involved in stable long-range interactions with other parts of the molecule (Mackie and Zimmerman, *J. biol. Chem* , **250**, 4100; 1975). This suggests that secondary structure model-building based on a simple linear array of hairpin loops may be *a priori* invalid.

Many questions concerning both secondary structure and function of the rRNA will perhaps become clearer with a better understanding of the interactions between RNA and protein within the ribosome. This is one of the most important problems of ribosomology, but again it has not proved an easy one to approach. Most of the available data has been obtained by Garrett and Zimmermann and their co-workers from synthetic complexes between single ribosomal proteins and RNA (reviewed by Zimmermann, *Ribosomes*, 225, Cold Spring Harbor Monograph, 1974). These complexes are subjected to a mild nuclease digestion, following which the RNA region "protected" by the protein can be identified. The approach is of course limited to a study of those proteins which can individually form specific complexes with RNA, the "RNA binding" proteins, but it has nevertheless provided a great deal of information in a number of cases. The size and complexity of the RNA regions involved varies considerably; at one end of the scale are proteins such as S8 and S15 which are found in association with short regions of 16S RNA of the order of 50 nucleotides long. Similar short regions of 5S RNA have been found corresponding to proteins L18 and L25. At the other end of the scale are proteins S4 and L24, both of which interact with very large sections of 16S or 23S RNA approximately 400 nucleotides in length. How far these "binding sites", in particular the very large ones, reflect the situation within the intact ribosome remains to be seen

A hundred years ago

WE cannot see the force of some of the arguments with which Captain Moresby supports his plea for annexation [of New Guinea]. His strong attachment to the natives and his desire for their welfare we think mislead him as to how this is to be accomplished. If New Guinea is to be colonised by white men, all previous experience teaches us that the natives will inevitably suffer, will be demoralised, and ultimately extinguished. It is inexpressibly sad to think of such a fate overtaking these gentle and altogether superior natives of New Guinea; but how can it be helped, unless it is resolved to put a stop to the increase in the white portion of the world's population.

from *Nature*, **13**, March 9, 365; 1876.

For the examination of RNA–protein interactions within the ribosome itself, especially those involving proteins which are unable to bind individually to RNA, another approach is necessary. One method has been to isolate fragments from the complete ribosome following nuclease digestion, and to analyse those RNA sequences which interact with particular groups of proteins in the fragments (for example, Yuki and Brimacombe, *Eur. J. Biochem.*, **56**, 23; 1975); further development of this approach has however been severely limited by the ease with which the specificity of the RNA–protein interaction is lost. A more promising approach, now being undertaken by a number of laboratories, involves the development of suitable RNA–protein cross-linking techniques. One example has been the cross-linking of proteins to the 3′-terminus of the 16S RNA, by way of the periodate oxidation of the 3′-terminal ribose. The proteins concerned are S1 and S21 (Czernilofsky *et al.*, *FEBS Lett.*, **58**, 281; 1975), which is interesting in view of the foregoing discussion of initiation, since both these proteins are involved in mRNA binding. S1 has also been shown to bind to an RNA fragment from the 3′-terminus of the 16S RNA (Dahlberg and Dahlberg, *Proc. natn. Acad. Sci. U.S.A.*, **72**, 2940; 1975).

Cross-linking of protein to RNA within the bulk of the rRNA requires more general methods, but here also a measure of success has been recorded, such as the identification of some peptides of protein S4 which are in contact with the 16S RNA (Ehresmann *et al.*, *FEBS Lett.*, **58**, 106; 1975), or the identification of a region of 16S RNA which is in contact with protein S7 (Rinke *et al.*, *Eur. J. Biochem.*, in the press), in both cases after cross-linking induced by ultraviolet irradiation. These techniques clearly need a lot of refinement, but an extension of this type of study, coupled with the development of more sophisticated cross-linking reagents, seems at the moment to hold the most promise for the immediate future. The recent application of various physicochemical techniques to the protein topography problem is very rapidly giving us a firmer knowledge of the spatial distribution of the ribosomal proteins; it will not be too long before we have at least a first approximation as to how the rRNA is threaded through this protein matrix. This would be invaluable in studies of both structure and function.

Models from maps

from S. D. Dover

ANALYSIS of the electron density maps which are the results of an X-ray crystallographic investigation is the last stage in protein structure determination.

In the initial development of the subject maps were analysed by placing markers in regions of density corresponding to an identifiable feature, measuring the marker co-ordinates, and adding to or adjusting a wire model of the structure accordingly. The interpretation of a new part of the map frequently relied on the existing portion of the model This feedback was facilitated by the Richard's box (*J. molec. Biol.*, **37**, 225; 1968) a construction which enabled an image of the model in a half-silvered mirror to be superimposed on a stack of perspex sheets on which were drawn the electron density contours. Alterations or additions to the model were then seen directly in the context of the map and any unexplained or poorly fitted features were made obvious.

The use of computers as aids in the building of models started with Diamond's automatic procedures to fit a model to coordinates read from the map (*Acta Cryst.*, **21**, 253; 1966). This approach has been extended to the refinement of a model to fit an electron density map itself ("real-space" refinement), rather than guide coordinates (*Acta Cryst.*, **A27**, 436; 1971). Refinement is an essential part of the structure-solving process and Diesenhofer and Steigmann (*Acta Cryst.*, **B31**, 238; 1975) have taken Diamond's method farther by improving the phasing of the structure factors. They used the model fitted to a purely experimental electron density map to calculate structure factor phases for a new map. By repetition of this process the model and the phases were cyclically refined together.

Diamond and Levitt (*J. molec. Biol.*, **82**, 371 and 393; 1974) attacked another problem of the refinement of models, that of energy, both bonded and nonbonded, attractive and repulsive. In their work on the structure of lysozyme they alternated energy and real-space refinement finding that the alterations suggested by energy considerations tended to improve the fit to the electron density data.

This use of energy calculations in conjunction with refinement against an experimental map obviated one of the criticisms of those who advocated the building of an actual model and its improvement as the only way of introducing intramolecular and intermolecular interactions. Nevertheless the viewing of a model superimposed on an electron density map has been not only a precursor of refinement but also important itself. Even where methods of refinement have been used to extract as much information as possible from the diffraction data without recourse to model building, a model must be built to examine the biological implications of the structure.

The difficulties of constructing a very large Richard's box, of reading off the coordinates from one, of having either several boxes or being prepared rapidly to interchange models and density maps made the idea of a computer driven visual display system attractive Levinthal (*Sci. Amer.*, **214**(6) 42; 1966) started drawing on a visual display skeletal models of proteins which could be viewed from different angles or caused to rotate. The ability to alter or add to a computer drawn model and the simultaneous display of a three-dimensional density map has since been developed and in a number of laboratories (see for example *Fedn Proc.*, **33**, 2368: 1974 and *Science*, **190**, 1047; 1975).

Given a refinement system and a good catchnet to enable one to examine by eye those regions of the model which appeared to be problematical, the recent work by Greer (*J. molec. Biol.*, **100**, 427; 1976) would imply an ability to analyse completely an electron density map without ever actually looking at it in its entirety. One can envisage a protein structure so large that even with new display technology its map could not be viewed in one picture. The building of a model using the display system would require excessive searching across the boundaries of the displayed region. Preliminary automatic computer model building by Greer's method followed by examination using a stereoscopic visual display system would then provide a suitable preparation for refinement.

A large structure such as this would not be amenable to the building of a physical model after refinement. Studying the computer model would then also require a stereoscopic display system and techniques for searching through a large three-dimensional structure which can be seen, as it were, through a small window. Such a display system would facilitate comparison of structural results from other laboratories and the teaching of structural principles. It would, however, lack the presence of a good old-fashioned wire model. □

Contraception

from J. P. Hearn

A meeting on Contraceptives of the Future convened by R. V. Short and D. T. Baird was held by The Royal Society on February 18 and 19, 1976. The invited speakers examined the advantages, disadvantages and the problems of distribution of currently available methods for controlling fertility, and discussed new techniques that are being developed.

CONTRACEPTION is here to stay. In the past the natural checks on human populations were a relatively late age at puberty, high neonatal mortality, a long interval between births and a short life expectancy. Man has reversed all of these natural controls in most developed and developing societies. Menstruation now begins at about 11 years of age, neonatal mortality is very low, urbanisation and improvements in nutrition have more than halved the natural lactation-induced interval between births, and average life expectancy has almost doubled.

All these naturally occurring limiting factors were female orientated mechanisms, and since natural selection has always operated in the past to maximise reproductive potential, women may be physiologically ill adapted to spend the greater part of their reproductive lives in the non-pregnant state. As far as possible, new contraceptives should therefore be designed to mimic the physiological state found during periods of natural infertility in women. There are already many methods of contraception available but cultural, political and medical considerations make few of them universally acceptable so that there is a pressing need for new methods to be developed for both women and men. Ideally any new method should be long lasting, cheap, reversible, convenient and free from the need for continual medical supervision.

Expenditure on the development and application of contraceptives is only 2% of all the funds going to biomedical

Archaean-Proterozoic polar wandering

from Peter J. Smith

THERE is now considerable geological and palaeomagnetic evidence to suggest that there were no large relative movements of plate segments during the Proterozoic. There was almost certainly some internal deformation along mobile zones between rigid cratons, although any relative motion such a process may have involved was evidently too small to be resolved by current palaeomagnetic methods. In any event, the palaeomagnetic data analysed by Piper *et al.* (*Nature*, **245**, 244; 1973) showed that for the period 2,000–800 million years ago the apparent polar wandering paths for reconstructed Africa and North America (the two most widely studied continents) were in close agreement.

But what about the period before 2,000 million years ago? Until recently it would have been difficult to answer this question because appropriate palaeomagnetic data were few and many more of those that were available were assigned unreliable ages. According to Piper (*Earth Planet. Sci. Lett.*, **28**, 470; 1976), however, this situation no longer obtains, at least for all of the period before 2,000 million years. Not only are there now a considerable number of relevant palaeomagnetic poles available but many of them have been well dated, particularly by the Rb-Sr method.

Because igneous activity during the Precambrian was episodic, some time intervals are better represented in the palaeomagnetic record than others. The two best to date are 2,160–2,000 million years and 2,700–2,500 million years. Piper concludes that throughout both of these periods the combined poles from Africa and North America lie on a single apparent polar wandering curve when the two continents are reconstructed on the basis of the younger Precambrian palaeomagnetic data. In short, the two continents apparently acted as a single unit, albeit with some internal deformation undetectable palaeomagnetically, throughout the whole period 2,700–800 million years ago.

research. The current level of funding, an annual $120 million, has been steadily reduced over the past three years by inflation. Most funding comes from the developed countries, where the lower birth rates now achieved may inhibit governments from future spending on contraceptive research. But research in reproduction may also pay off in the treatment of infertility, which is the other side of the same problem At present basic research accounts for 60% of the funds, the development and application of contraceptives takes 30%, and the remaining 10% goes into training personnel and into testing for safety. This latest component will have to be increased in the future as ethical and drug administrative regulations have become increasingly stringent. Investment in contraceptive research is essentially long-term, and seldom commercially rewarding. Pharmaceutical companies are unlikely to spend as much on contraceptive research in the future since testing on several animal species, including monkeys, makes it already a great deal more expensive to bring a new contraceptive on to the market than, for example, a new drug for the treatment of heart disease. The problems of regulating human fertility will not be solved in the near future and by the early 1980s the level of expenditure will need to be about $500 million each year.

Undoubtedly the most effective and acceptable contraceptive available is the combined gestogen–oestrogen pill. Although this method has a few disadvantages and does not suit all women, it will continue to be the most important contraceptive used over the next ten years in the developed and developing countries. The ways in which it is introduced and marketed in developing countries require a great deal more thought, adapting the approach to a wide variety of cultural differences. The pill causes infertility by creating the hormonal state normally found during pregnancy. It may be possible to develop other types of pill to mimic the hormonal states found during lactation or before puberty, the other naturally occurring periods of infertility in women Condoms are still probably the most widely used method in many countries and although they are not so reliable, their simplicity and lack of any disadvantageous effects makes them the method of choice for many people. Intra-uterine devices and hormonal implants still require a considerable amount of development before they are as effective or as acceptable. Abortion in early pregnancy is clearly effective, but requires medical or paramedical supervision and is not a contraceptive. In some countries abortion has been used widely but to many people it represents an unacceptable policy of despair, a consequence of the failure to produce and distribute adequate contraceptive technology.

There have been advances in the field of surgical sterilisation, particularly in the female, that hold promise for a simple, reversible method Developments in colpotomy, culdoscopy and laparoscopy have minimised the surgical procedures involved and markedly reduced the time required for recovery Attempts to use removable clips on the oviducts may lead to "temporary sterilisation" as a means for spacing a family rather than an irreversible technique to be applied only when the family is complete. In the male, sterilisation by vasectomy is widely used but as yet reversibility is not generally possible. There has been an interesting trend in that sterilisation is becoming more accepted amongst women and now as many women as men are being sterilised when they have completed their families.

The World Health Organization, in its expanded programmes of research in human reproduction, is supporting research projects aimed at improving most of the currently available methods of fertility control and also at developing new methods. WHO and other organisations, such as the Population Council and the Ford Foundation, are supporting research into more reliable ways of predicting ovulation and so using abstinence during the critical stages of the natural cycle as a method of birth control. This approach is complicated as the human sperm can survive in the female genital tract for up to seven days, but if ovulation could be predicted more precisely such methods may help those who find other methods unacceptable for cultural or religious reasons. Research is also going on to examine naturally occurring plant substances that have been used as contraceptives in the past in some societies.

It seems unlikely that any new method of fertility control that fulfils the requirements of being long lasting, cheap and reversible will be widely available in the next 5-10 years but two new concepts that may develop relatively rapidly are a pill for men and immunological control of fertility in men and women. Tests on small numbers of men have shown that a combined gestogen–androgen pill will suppress spermatogenesis and not interfere with libido, but the variation in response to this treatment is too wide at present and further tests are necessary to ensure its efficacy and to examine any possible toxicity. At present it seems likely that this method will be reversible.

Studies on marmoset monkeys have shown that it is possible to immunise primates against a fraction of chorionic gonadotropin, a hormone normally produced in the earliest stages of pregnancy which is thought to stimulate the production of progesterone from the ovary. Immunised marmosets will remain infertile for many months, but a great deal more research into possible side effects is necessary before this method can be applied In particular it is necessary to show that the antibodies do not cross react with endogenous hormones nor have any effects on foetuses as the contraceptive effects of the vaccine wear out. In the meantime research in India has shown that human chorionic gonadotropin can be made antigenic in women and in the United States researchers have made synthetic fractions of chorionic gonadotropin that may, in the long term, enable the production of a non cross-reacting and highly specific vaccine. Further work is in progress to try to make the vaccine reversible. The fact that human hormones can be made antigenic in the human opens up the immunological possibilities of fertility control, but any vaccines that are developed against hormones or enzymes involved in the development or capacitation of human gametes will need to act specifically and not upset other components of the system.

If we accept that from now on we shall be dependent on artificial forms of contraception then tomorrow's contraceptives must be chosen with great care, as they will have a considerable impact on our general health and social well being. ☐

Sickle cell disease

by Stuart J. Edelstein

A symposium on Molecular and Cellular Aspects of Sickle Cell Disease was held in Dallas on December 10, 1975, under the sponsorship of the Sickle Cell Disease Branch of the National Heart and Lung Institute and the University of Texas Health Science Center.

Sickle cell disease is a genetic abnormality that is understood in many details: a base change A→C in the DNA of the β-globin gene leads to the Glu→Val change at the β-6 positions of haemoglobin. The mutant form, designated haemoglobin S, has diminished solubility in the deoxygenated state and self-associates into the long, rigid fibres that distort the red cells into the characteristic sickle shape and are responsible for the various symptoms of the disease. An earlier hope that cyanate treatment would provide a suitable therapy for controlling sickling crises has faded and the search for an anti-sickling agent continues. Such an agent could be found by the trial-and-error screening of many compounds or by design based on the molecular details of fibre formation which are now emerging and which were summarised at the Dallas symposium.

The day began with B. C. Wishner (Johns Hopkins University, Baltimore) reporting on the structure of a crystalline form of haemoglobin S that may provide clues to the contacts between molecules in the fibres. In the crystals, molecules are arranged in paired strands, with adjacent strands within each pair staggered by half a molecule and rotated by half a turn An. intriguing feature of this crystal structure is that the β-6 position lies at an intermolecular contact between the strands within each pair, and several other sites implicated in the sickling process are also at or near contacts. If the axis of the strands in the crystals corresponds to the fibre axis *in vivo,* the orientation of the molecules in the crystals also satisfies critical optical dichroism data. Thus the juxtaposition of molecules in the crystals could bear a close resemblance to the arrangements in the fibres (with minor adjustments for converting the planar alignment of the crystals to the helical alignment of the fibres).

The possibility of a close relationship between the crystals and the fibres was strengthened by the presentation of S. J Edelstein (Cornell University, Ithaca) on the structure of the fibres determined by electron microscopy, in collaboration with R. Josephs (Weizmann Institute of Science, Rehovot). The fibres were prepared by lysis of sickled cells directly with solutions of negative stain, revealing eight-stranded fibres with adjacent strands staggered by half a molecule as the predominant form in all 10 individuals with sickle cell disease examined The structure of the fibres was deduced from optical diffraction and Fourier transform analysis of the electron micrographs and is consistent with an assembly of four pairs of strands in the general arrangement found in the crystals studied by Wishner *et al.* Uncertainties remain, including whether adjacent pairs of strands would be parallel or antiparallel and why the eight-stranded, staggered-strand structure was not detected in earlier studies by Finch *et al* (*Proc. natn. Acad. Sci. U S A* , **70,** 718; 1973)

On the basis of solubility studies of artificial hybrid haemoglobin constructed of β–S and various α-chain mutant forms, R Benesch (Columbia University. New York) reported five new α-chain positions apparently involved in sickling The two positions with the strongest influence on sickling, α47 and α54, were among the α-chain locations predicted to lie at contacts from the model building based on the electron microscopic results noted above. Thus several lines of investigation are converging on the structural details of the fibres, and a definitive description may soon emerge. While such information should help in the design of anti-sickling agents, there are also likely to be many physical-chemical subtleties in fibre assembly yet to be appreciated. One such subtlety emerged from the presentation of A. N. Schechter (National Institutes of Health, Bethesda) concerning a synthetic peptide corresponding to the first 13 residues of the β–S chain. The peptide binds to an antibody elicited in response to haemoglobin S, but does not itself influence fibre formation. Conformational differences between normal haemoglobin and S were also reported by C. Ho (University of Pittsburgh) on the basis of nuclear magnetic resonance studies. Therefore some aspects of conformation may be critical, along with other possible factors related to intermediate structures and rate limiting steps in fibre assembly.

The 11 other presentations dealt principally with aspects of fibre assembly using various techniques to monitor assembly, including an elegant application of water proton relaxation rates reported by M. R Waterman (University of Texas, Dallas). Various stages in the assembly process were described on the basis of viscosity by H F Bunn (Harvard Medical School, Boston) and ultracentrifugation by R W Briehl (Albert Einstein College of Medicine, New York). W A. Eaton (National Institutes of Health, Bethesda) presented a particularly cogent analysis of the delay time, t_d, for fibre formation, in relation to the "supersaturation ratio", S, raised to a power, n, equivalent to the order of the reaction:

$$1/t_d=\gamma S^n$$

where S is defined as the total concentration of haemoglobin S divided by the

Light in dielectrics

from a Correspondent

FOR the past sixty years there has been disagreement about the ratio of momentum to energy carried by electromagnetic waves in dielectrics. Abraham said $1/nc$; Minkowski said n/c, where c is the speed of light *in vacuo* and n the refractive index, so that c/n is the speed of light in the medium. The question relates to the correct choice and interpretation of the energy-momentum tensor. Subsequent contributors though relatively few have been exceptionally distinguished. This is doubly surprising. First, electromagnetic theory leaves no genuine scope for controversy; second, when the fog began to clear around 1973, the question was found to turn on a clear and detailed description, on the molecular level, of what precisely is measured in any given experiment. In other words the apparent simplicity of the problem as originally formulated proved deceptive.

Continuing the early and especially elegant discussion by Ginzburg (*Sov. Phys* (Uspekhi) **16,** 434; 1973) and Gordon (*Phys. Rev.,* **A8,** 14; 1973), further steps towards clarifying the issue have now been published by Sir Rudolf Peierls (*Proc. R Soc. Lond.,* **A347,** 475; 1976) Central to the issue is the distinction between the purely electromagnetic momentum (which by itself would lead to Abraham's result), and the mechanical momentum induced in the molecules of the medium. In an infinite amorphous (fluid) medium a broad enough light pulse leaves no mechanical disturbance in its wake; but on reflection from an interface it deposits mechanical stresses and strains just upstream of the interface, and these must be considered carefully in accounting for any observations. Professor Peierls has found that to leading order in (n^2-1), the operative result is the mean of Abraham's and Minkowski's To higher order in (n^2-1), there may be need to reflect further on this result, which, (as Peierls himself discusses), is *prima facie* in conflict with some arguments in the classic text by Landau and Lifshitz (*Electrodynamics of continuous media,* Pergamon Press, 1960). For narrow beams (with width to length ratio less than the ratio between the speed of sound and light), there are other effects, some of experimental importance considered already by Gordon (op. cit.), and another fascinating one found by Professor Peierls, reminiscent of Cerenkov radiation, of sound generation by the light pulse.

One thing that will surely be needed soon is a systematic textbook-level discussion explaining *ab initio* what results are applicable in what circumstances. For instance, a very recent low-frequency experiment on a solid dielectric (Walker *et al* , *Can. J. Phys* , **53,** 2577; 1975) is accounted for by Abraham's result alone, while in many quantum-mechanical applications Minkowski's result, alone, can be used; the "momentum" implied by the latter is then analogous to the so-called "crystal-momentum" of phonons.

minimum concentration for fibre formation and γ is a kinetic coefficient. Since red blood cells remain for about 1 s in capillaries, the delay time is the critical factor in whether or not a cell sickles and since the order is extremely high (about 40th), small changes in the parameters contributing to S can greatly alter the delay time. For example, the analysis indicates that the delay time in sickle cell trait is about 25,000 times longer than for sickle cell disease. Thus individuals with the trait are essentially free of symptoms and even a small increase in the delay time, as produced by some therapeutic agent, could greatly ameliorate the clinical course of the disease.

The sickling process is also complicated by factors related to the cell membrane. This point was emphasised in the presentation of M. J. Messer (University of California, San Francisco) who discussed experiments on cell sickling monitored by filterability, light microscopy and electron microscopy. When sickling is initiated by rapid deoxygenation, cell rigidity is detected before intracellular fibres or shape changes in the cells appear.

In summary, while considerable progress is being made in sickle cell disease, the complexities of a highly co-operative anisotropic assembly reaction in the confines of a cell membrane are likely to hold many surprises. The latest findings as reported at the Dallas symposium should soon be available to interested readers in detail, since the organisers promise prompt publication of the proceedings. □

Calculating radiation risks

from a Correspondent

A meeting organised by the Society for Radiological Protection was held in London on February 3.

What risks are you prepared to accept and what risks does your society seem prepared to accept? These were among the questions tackled by W. D. Rowe (US Environmental Protection Agency). The problem of assessing the biological effects of exposing large populations to small amounts of ionising radiation is currently a live issue in radiological protection circles. The man rem is the unit for the quantity 'collective dose equivalent' used in discussions of this question and the theme of the Society's meeting was the application of the man rem concept. Rowe pointed out that a central issue was the association of man rems with risk. The risks were to be balanced against the benefit which the population derived from the practices giving rise to the exposure. There were different types of risk, those arising from the planned releases of radioactive materials and those resulting from accidental situations. Rowe went on to analyse the factors important in the evaluation of risks and accepted that value judgments were an essential part of this procedure. The Environmental Protection Agency had, for example, used collective dose for regulatory purposes. They had set standards and determined the cost of carrying these out by using what Rowe called "operational value judgments" to determine how much money should be spent on "health effect avoidance". He felt that such value judgments were useful in this context for although subjective they did lead to decisions and action. They could be challenged and discussed and had been found to be helpful for that reason.

Any consideration of collective dose must deal with the significance of the large numbers of man rems arising from very small doses to very large numbers of people. P. M. Bryant (National Radiological Protection Board) had some forthright suggestions to offer. She felt that as we were all exposed to natural background radiation and as its level varied, for example, with geographical location, for the purpose of determining collective dose it was not reasonable to integrate doses below a level which fell well within the variation of natural background. She considered that it should be possible to define processes giving rise to exposures of the public in terms of "practices" which were of such a nature that significant numbers of individuals exposed in the overlapping fringe areas of several practices did not unwittingly receive more than the standard deviation of the background, that is, 10 millirems per year. A practice so defined might be, for example, all the long lived nuclides discharged during the 30 years of the life of a nuclear power plant. Bryant thought that if a reduction in the 10 millirem was made by one order of magnitude to allow for the number of practices going on at any one time and by another order of magnitude to allow for considerations of the future, then the resulting 0.1 mrem per year could be used as a cut-off. Below this the doses would be deemed to be insignificant and would not be used in any integration to obtain collective dose equivalent where such integration is intended for making choices between one practice and another. It seemed to her that this cut-off level would assist in realistic cost/benefit analysis although she admitted that if her concept of "collective dose from a practice" were used the definition of the practice might sometimes present difficulties.

During his discussion of two methods of considering radioactive releases arising from the operation of nuclear-powered electricity generating stations, R. H. Clarke (CEGB Berkeley Nuclear Laboratories) commented that the Canadians neglected doses below 1% of the dose at the site boundary and the Americans also employed a cut-off by integrating only the doses received within 50 miles of the site. Releases could be considered in terms of the doses given to a hypothetical critical group of the public located at the site boundary close to the release point. If the doses to this group were kept within the limits recommended by international authorities, then it followed that the doses received by the rest of the population would also be considered acceptable. This in fact was the approach used at present by the Central Electricity Board, but Clarke pointed out that it was possible for the doses to the critical group to remain within the arbitrary limits, yet, by varying stack heights, the distance from the release point to the site boundary and the distribution of the population around the site, the collective dose equivalent from similar releases of xenon-133 could vary by two orders of magnitude. This indicated a weakness of the critical group approach and in future although the doses to the most exposed individuals would remain important, some kind of limitation on the population collective dose around the site might be a more realistic parameter for the design engineer to aim at.

R. H. Mole (MRC Radiobiology Unit, Harwell) speaking in his private capacity, said it was important to distinguish between the validity of using man rems for thinking about exposures and for adding units of risk, and the validity of converting man rems into cases of detriment or hurt in some sense. Alternative hypotheses concerning the slope of the dose response relationship had to be considered. He was personally inclined to accept the linear hypothesis and was therefore critical of those who proposed a cut-off. It seemed to him that there was no adequate scientific reason for rejecting linearity and he suspected that there must be some "cultural" reason for distrusting it. Perhaps people were uneasy about calculating risks on the basis of a hypothesis which could not be demonstrated to be true.

The meeting was concluded by Mole pleading for those who published estimates of collective dose to set out every step of their calculations and in particular to state the range of uncertainty of the final number. A salutory exercise, no doubt! □

review article

Possible role for cyclic nucleotides and phosphorylated membrane proteins in postsynaptic actions of neurotransmitters†

Paul Greengard*

The postsynaptic actions of some neurotransmitters may be mediated through cyclic nucleotides and cyclic nucleotide-dependent phosphorylation of specific membrane proteins in postsynaptic cells. In addition to providing a molecular basis for the actions of several neurotransmitters and of certain drugs affecting behaviour, the model suggests a mechanism by which neurotransmitter signals may be converted into electrophysiological responses in postsynaptic cells.

THE pioneer work of Sutherland, Rall and their colleagues firmly established that cyclic AMP acts as the intracellular mediator for the regulatory actions of many hormones on a variety of non-neuronal tissues[1]. There is more recent evidence that cyclic AMP also has an important role in the nervous system, where it seems to participate in certain types of communication between nerve cells. Cyclic AMP is implicated in at least three discrete processes in the nervous system, namely, mediation of the postsynaptic actions of certain neurotransmitters, regulation of the biosynthesis of certain neurotransmitters, and functioning of microtubules. Other evidence suggests that cyclic GMP is also involved in some types of synaptic transmission. This article summarises some of the evidence for a role of cyclic AMP and cyclic GMP as mediators of the postsynaptic actions of neurotransmitters and examines a possible mechanism for their action—regulation of the phosphorylation of specific proteins present in the postsynaptic membrane.

Cyclic nucleotides in synaptic transmission

Neurotransmitter molecules released from the terminals of the presynaptic axon induce a change in the membrane potential of the postsynaptic neurone by interacting with specific receptors on that neurone. This electrical change is referred to as the postsynaptic potential. How the activation of a postsynaptic receptor is transduced into the postsynaptic potential is still unknown; but it now seems that, in some instances, cyclic nucleotides are involved. Some of the experimental criteria that have been examined and found to support this view are presented in Table 1. Some of the neuronal systems for which a number of these criteria have been fulfilled are reviewed elsewhere[2].

One preparation that has been used to study the possible role of cyclic nucleotides in neuronal function is the mammalian superior cervical sympathetic ganglion. A diagram of the principal synaptic connections and the neurotransmitters believed[3–8] to occur within the superior cervical ganglion is included in Fig. 1, along with the postulated site of involvement of cyclic AMP and cyclic GMP in the production of the postsynaptic potentials. The postganglionic neurone in this ganglion receives three types of innervation. In the principal pathway innervating the ganglion, acetylcholine released from preganglionic terminals activates nicotinic cholinergic receptors on the surface of the postganglionic neurone, leading to the generation of a fast excitatory postsynaptic potential (f-e.p.s.p.). When several of these f-e.p.s.p.s summate, an action potential is generated and is propagated down the axon of the postganglionic neurone. There is evidence that generation of the f-e.p.s.p. does not involve a cyclic nucleotide. Indeed, since the f-e.p.s.p. is very rapid (of the order of a few ms), it seems *a priori* unlikely that its generation and termination would involve a series of enzymatic reactions of the type that seem to be associated with cyclic nucleotide-mediated processes.

There are two slow postsynaptic potentials which modulate the excitability of the postganglionic neurones: a prolonged hyperpolarisation or slow inhibitory postsynaptic potential (s-i.p.s.p.), and a prolonged depolarisation or slow excitatory postsynaptic potential (s-e.p.s.p.). In contrast to the generation of the f-e.p.s.p., the generation of these modulatory slow postsynaptic potentials does seem to involve cyclic nucleotides (Fig. 1). In one of the modulatory pathways, acetylcholine (ACh) released from preganglionic fibres activates a dopaminergic interneurone leading to the release of dopamine; the released dopamine activates a dopamine receptor on the surface of the postganglionic neurone leading, through a process which seems to involve cyclic AMP, to the generation of the s-i.p.s.p. In the other modulatory pathway, ACh released from preganglionic terminals activates muscarinic cholinergic receptors on the surface of the postganglionic neurone leading, through a process which seems to involve cyclic GMP, to the generation of the s-e.p.s.p.

Almost all of the criteria listed in Table 1 for mediation by a cyclic nucleotide of a postsynaptic potential have been fulfilled for the generation by cyclic AMP of the s-i.p.s.p. in the superior cervical ganglion. To cite just a few examples: (1) electrical stimulation of the preganglionic cholinergic fibres innervating the ganglion[9], or application of exogenous dopamine to ganglion slices[10], causes an increase in the cyclic AMP content of the ganglion (cytochemical studies indicate that this increase

---

†Adapted from a lecture presented at the Sir Henry Dale Centennial Symposium in Cambridge, UK, September 18, 1975.

Table 1 Some criteria for mediation by a cyclic nucleotide of a postsynaptic potential*

a Synaptic activation and cyclic nucleotide levels

1. Electrical stimulation of the presynaptic input should increase tissue levels of the cyclic nucleotide.
2. This increase in cyclic nucleotide level should be antagonised by pharmacological agents that block the postsynaptic potential.
3. The increase should not occur when transmitter release is prevented with low Ca^{2+}/high Mg^{2+}.
4. The increase should not occur when the postsynaptic cells are antidromically activated.

b Neurotransmitters and cyclic nucleotide levels

1. Levels of the cyclic nucleotide should increase when the intact tissue or blocks or slices of the tissue are exposed to the neurotransmitter thought to be responsible for the postsynaptic potential of interest.
2. This increase should be antagonised by agents that block the neurotransmitter-induced changes of postsynaptic potential.

c Neurotransmitters and adenylate (or guanylate) cyclase

1. A neurotransmitter-sensitive adenylate (or guanylate) cyclase should be demonstrable in cell-free preparations of the tissue.
2. Activation by the neurotransmitter of this neurotransmitter-sensitive adenylate (or guanylate) cyclase should be blocked by the same antagonists as in (*a*2) and (*b*2).

d Cytochemistry

1. Cytochemical techniques should demonstrate that cyclic nucleotide levels increase in the appropriate postsynaptic cells in response to synaptic activation.
2. Similarly, cytochemical techniques should demonstrate that cyclic nucleotide levels increase in the appropriate postsynaptic cells in response to the appropriate neurotransmitter.

e Phosphodiesterase inhibitors

1. Phosphodiesterase inhibitors should further increase the elevated levels of cyclic nucleotides achieved by activating the synaptic pathway, or by applying the putative neurotransmitter.
2. Phosphodiesterase inhibitors should potentiate the effects on the postsynaptic potential that follow activation of the synaptic pathway, or application of the putative neurotransmitter.

f Application of cyclic nucleotides

1. The cyclic nucleotide should mimic the physiological effects of activating the synaptic pathway and of applying the putative neurotransmitter.

*Taken from Beam and Greengard[2].

in cyclic AMP occurs primarily or exclusively in the postganglionic neurone[11]); (2) a dopamine-sensitive adenylate cyclase is present in homogenates of the ganglion[10]; (3) exogenous cyclic AMP, applied to the ganglion, causes hyperpolarisation of the postganglionic neurones, thus mimicking the hyperpolarisation seen on either preganglionic stimulation (the s-i.p.s.p.) or application of dopamine[12]; (4) phosphodiesterase inhibitors, applied to the ganglion, greatly increase the elevation of cyclic AMP seen on preganglionic stimulation[8] or application of dopamine[13], and also greatly increase the size and duration, both of the s-i.p.s.p.[12] and of the dopamine-induced hyperpolarisation[12]; (5) various adrenergic and cholinergic agents affect the s-i.p.s.p.[3,5,6,12,14], as well as the increase in cyclic AMP which follows preganglionic stimulation[8], in a fashion predicted by the scheme shown in Fig. 1. Analogous data have been obtained for cyclic GMP in the generation of the s-e.p.s.p.[11–13,15].

These studies indicate that cyclic AMP mediates dopaminergic transmission, and cyclic GMP mediates muscarinic cholinergic transmission, in the superior cervical ganglion. They also suggest that the dopamine receptor of the postganglionic neurone is a dopamine-sensitive adenylate cyclase, the activation of which leads to an increase in cyclic AMP. Finally, cyclic AMP and cyclic GMP, through generation of the s-i.p.s.p. and s-e.p.s.p., respectively, seem to regulate the membrane potential of the postganglionic neurone, and thereby modulate nicotinic cholinergic transmission through the ganglion.

Extensive electrophysiological, pharmacological, and cytochemical studies by Siggins, Hoffer and Bloom, have provided good evidence that cyclic AMP mediates transmission at the noradrenergic synapse on the cerebellar Purkinje cell[16–19]. Stimulation of the noradrenergic fibres to the Purkinje cell reduces its firing rate, an effect mimicked both by noradrenaline and by cyclic AMP applied iontophoretically. The inhibitory effects of stimulating the noradrenergic fibres, or of applying noradrenaline or cyclic AMP, are markedly potentiated by phosphodiesterase inhibitors. Moreover, the inhibitory effects are associated, in each case, with hyperpolarisation of the Purkinje cell and a decrease in membrane conductance. These results indicate that the inhibitory effects of activity in this noradrenergic pathway are mediated through cyclic AMP.

Biochemical characterisation of dopamine receptors in mammalian brain

The studies of the superior cervical ganglion outlined above suggested a possible approach to understanding the molecular nature of dopamine receptors in the brain. Within recent years there has been, for several reasons, a great deal of interest in dopamine receptors in the central nervous system (CNS). There is increasing evidence for dopaminergic transmission within the brain[20–30] and aberrations of dopaminergic transmission may have a major role in the aetiology of some diseases of the CNS. For instance, hypoactivity of dopaminergic pathways to the caudate nucleus of the brain seems to be at least partly responsible for the symptoms of Parkinson's disease[21]. Conversely, hyperactivity of dopaminergic pathways to the limbic region of the brain may contribute to the symptoms of schizophrenia[31–34]. In addition, the parkinsonian side effects frequently seen in patients given antischizophrenic drugs, and possibly the therapeutic effects of these drugs as well, are largely attributable to their ability to block dopamine receptors in the brain[20,23,29]. Since the dopamine receptor in the superior cervical ganglion seemed to be the dopamine-binding portion of a dopamine-sensitive adenylate cyclase[10], and since a dopamine-sensitive adenylate cyclase was also found in retina[35], a search for such an enzyme was undertaken in the caudate nucleus of the brain, a region rich in dopamine receptors.

An adenylate cyclase, activated by low concentrations of dopamine, was found in homogenates of the caudate nucleus[36]. The enzyme was also activated by low concentrations of apomorphine, a known dopamine-receptor agonist. In contrast, isoproterenol, an effective agonist at β-adrenergic receptors, but not at dopamine receptors, failed, even in high concentrations, to stimulate the enzyme, indicating the specificity of the enzyme activation. Furthermore, the activation of the enzyme by dopamine was strongly inhibited by two classes of antischizophrenic compounds known to be dopamine-receptor antagonists. In contrast, several other pharmacological substances, with no antischizophrenic or dopamine-receptor antagonist properties, failed to block the dopamine activation of the enzyme. The results of this study indicated that the dopamine receptor in mammalian brain (as in the superior cervical ganglion) might be the dopamine-binding portion of a dopamine-sensitive adenylate cyclase, suggested that activation of this enzyme could account for the action of some antiparkinson drugs, and suggested a molecular basis for the actions of antischizophrenic drugs.

Subsequent investigations in several laboratories have strengthened and extended these conclusions[37–46]. An adenylate cyclase has been found in the limbic region of the brain[37,38,43] with characteristics virtually identical to those of the caudate enzyme. Moreover, in studies using a vast array of known agonists and antagonists of the dopamine receptor, the ability of substances to act as activators or inhibitors of the dopamine-sensitive adenylate cyclase system has shown, with few exceptions, a remarkable parallel with their ability to act as agonists or antagonists of the dopamine receptor[37–46].

As an illustration of such studies, Fig. 2 shows the effect of

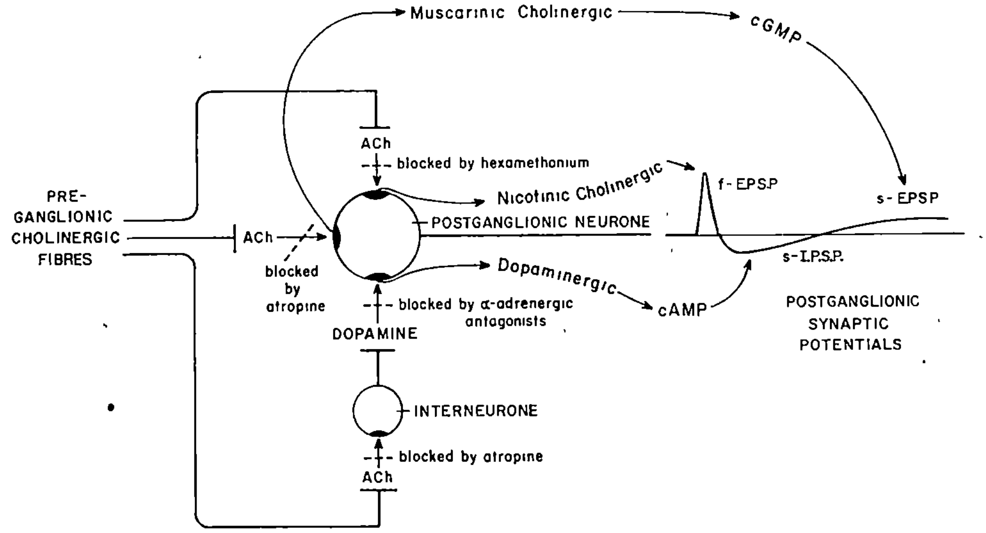

Fig. 1 A schematic diagram of the principal synaptic connections in the mammalian superior cervical ganglion, and the postulated role of cyclic nucleotides in the genesis of the postganglionic synaptic potentials. The diagram shows the relationship between the various neuronal elements; the neurotransmitters released at the various synapses; the sensitivity of the synaptic receptors to different classes of specific antagonists; the electrical signs that accompany activation of the various postganglionic receptors following preganglionic stimulation; and the postulated involvement of cyclic nucleotides in the production of the electrophysiological responses. Abbreviations used: ACh, acetylcholine; f-e.p.s.p., fast excitatory postsynaptic potential; s-i.p.s.p., slow inhibitory postsynaptic potential; s-e.p.s.p., slow excitatory postsynaptic potential. (Based on studies reviewed by Eccles and Libet[3], Volle[4], Libet[5], Greengard and McAfee[6], and Greengard and Kebabian[7]. Modified from Kalix *et al.*[8].)

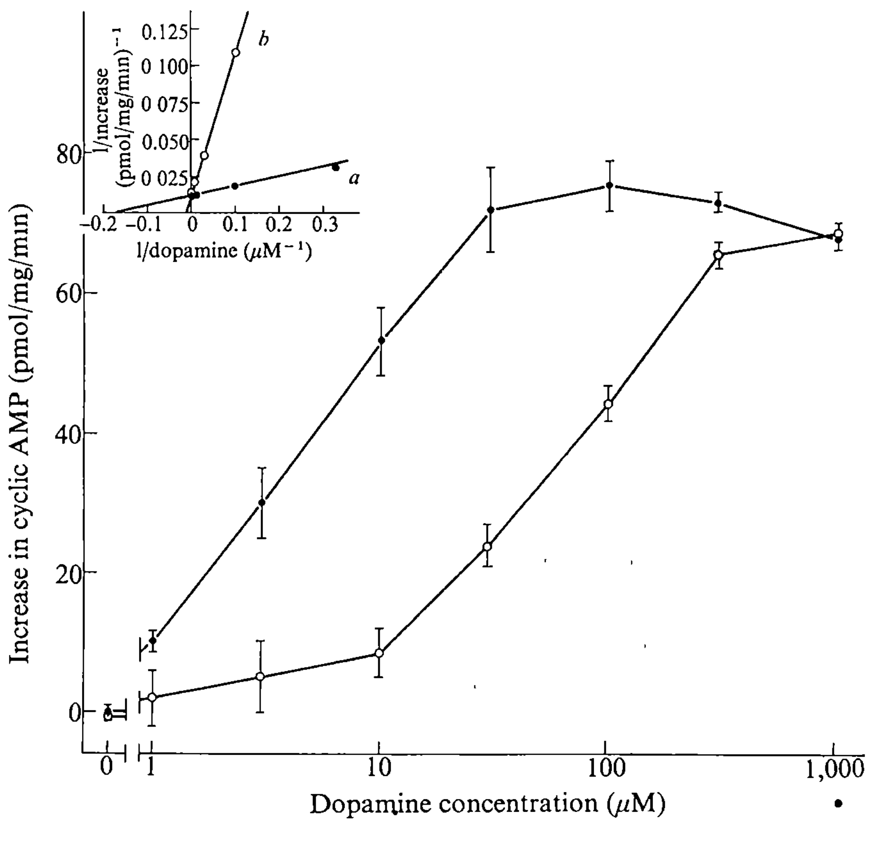
dopamine and of fluphenazine (a potent antischizophrenic drug and dopamine-receptor antagonist) on the adenylate cyclase activity of a subcellular fraction, rich in synaptic membranes, from the rat caudate nucleus. Dopamine caused a half-maximal increase in enzyme activity at about 4×10^{-6} M, which was competitively inhibited by fluphenazine. Moreover, fluphenazine was extremely potent as an inhibitor of the enzyme, with an inhibition constant (K_i) of 8×10^{-9} M (ref. 46). The inhibition of the enzyme by fluphenazine and related compounds occurred at concentrations two to three orders of magnitude less than those at which most other effects of these substances have been found.

These studies support the conclusion that the dopamine receptor, in at least some regions of the brain, as in the superior cervical ganglion, is part of a dopamine-sensitive adenylate cyclase. A corollary of this conclusion is that cyclic AMP mediates synaptic transmission at such dopaminergic synapses.

Finally, these studies indicate that inhibition by the antischizophrenic drugs of dopamine-sensitive adenylate cyclase in the caudate nucleus may represent the molecular basis for the

Fig. 2 Effect of various concentrations of dopamine, in the absence (●) or presence (○) of 1×10^{-7} M fluphenazine, on adenylate cyclase activity in a particulate fraction of rat caudate nucleus rich in synaptic membranes. In the absence of added dopamine or fluphenazine, 48.1 pmol of cyclic AMP were formed per mg wet weight of tissue per min; in the presence of 0.1 μM fluphenazine, 47.9 pmol of cyclic AMP were formed. The increase in cyclic AMP above basal level (that is, the level in the absence of dopamine or fluphenazine) is plotted as a function of dopamine concentration. Inset: double-reciprocal plot of cyclic AMP increase as a function of dopamine concentration from 3 to 300 μM. *a*, Control; *b*, 1×10^{-7} M fluphenazine. (Taken from Clement-Cormier *et al.*[46].)



parkinsonian side effects of these compounds, and suggest that a similar inhibitory action on the enzyme in the limbic region may be responsible for the therapeutic effects of these drugs.

The evidence that a cyclic nucleotide mediates synaptic transmission is perhaps strongest in the case of dopaminergic synapses, due in part to the large variety of known agonists and antagonists of the dopamine receptor available for study. Nevertheless, cyclic AMP has been implicated in the postsynaptic response to several other putative neurotransmitters, including noradrenaline (acting at β-adrenergic receptors), 5-hydroxytryptamine (5-HT), octopamine, and histamine [47–53]. Moreover, the actions of several drugs that affect behaviour, including LSD[54,55], morphine[56–58], and the antischizophrenic drugs discussed above, may be attributable to actions on specific neurotransmitter-sensitive adenylate cyclases. Finally, studies of the superior cervical ganglion[11–13,15] and of brain[59–61] suggest, in the case of one neurotransmitter, namely ACh (acting at muscarinic cholinergic synapses), that cyclic GMP may act as a mediator of synaptic transmission. These various results raise the question of the nature of the receptors for the cyclic nucleotides in the postsynaptic cells.

Phosphorylated proteins in synaptic membranes

The studies summarised in this section have been carried out within the framework of the hypothesis[62] that the diverse effects of cyclic AMP in various tissues are mediated through regulation of the activity of a family of enzymes known as protein kinases. This class of enzymes catalyses the phosphorylation of substrate proteins by ATP. The protein kinase hypothesis was proposed after the discovery of cyclic AMP-dependent protein kinases, first in muscle[63], and then in liver[64] and brain[65] and explains how cyclic AMP, a small molecule, may exert the large variety of biological effects attributable to it. According to this hypothesis, cyclic AMP need only regulate the activity of a single class of enzymes, the protein kinases; the specificity of the cyclic AMP action is then accounted for in terms of the specificity of the protein kinases and, particularly, of the substrate proteins which are phosphorylated by these protein kinases, in the various tissues.

The application of the protein kinase hypothesis to synaptic transmission in the nervous system is illustrated in Fig. 3. Three distinct roles of cyclic AMP and protein phosphorylation in neuronal function, for which there is now evidence, are illustrated. Two of these roles fall outside the main theme of this presentation, and will be described only briefly.

First, cyclic AMP-dependent protein kinase seems to be capable of regulating the biosynthesis of neurotransmitters in presynaptic terminals. Cyclic AMP has been shown to activate tyrosine hydroxylase[66–69], the enzyme that controls the rate of biosynthesis of the catecholamines dopamine and noradrenaline. The activation by cyclic AMP of tyrosine hydroxylase is almost certainly mediated through a protein kinase, since the activation by the cyclic nucleotide (1) requires ATP and Mg^{2+} (refs 70–73), (2) is mimicked by a purified preparation of protein kinase[70], and (3) is abolished by various specific and nonspecific inhibitors of brain protein kinase[70]. Future studies may demonstrate that the rate of biosynthesis of neurotransmitters other than the catecholamines is also subject to regulation by cyclic AMP-dependent protein kinases.

Second, cyclic AMP and protein kinase in nervous tissue may influence the microtubule system. The possibility that cyclic AMP-dependent protein phosphorylation affects microtubule function was first suggested by Goodman *et al.*[74]. Recently, evidence has been obtained[75] that highly purified microtubules from chick brain contain an intrinsic cyclic AMP-dependent protein kinase which catalyses the stoichiometric phosphorylation of a substrate protein (with an apparent molecular weight of 300,000) that is also an integral component of the microtubule system. Experiments are in progress, using *in vitro* systems, to determine whether the cyclic AMP-dependent phosphorylation of this high molecular weight protein affects some parameter of microtubule function, such

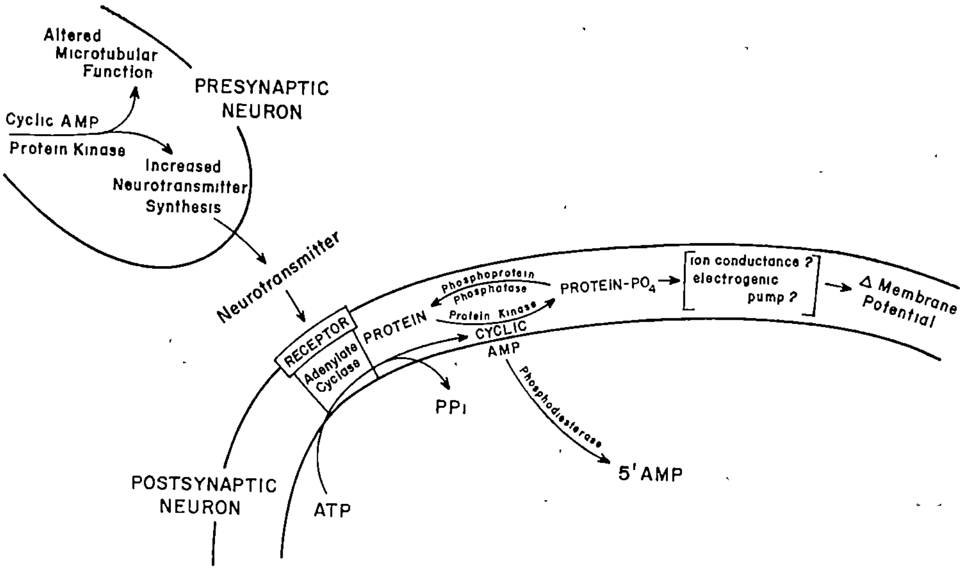


Fig. 3 Proposed roles for cyclic AMP and protein phosphorylation in neuronal function include regulation of neurotransmitter synthesis in presynaptic terminals (*a*), regulation of microtubular function (*b*) (indicated, purely for convenience, as occurring in the presynaptic axon; microtubules occur in dendrites, soma and axon of neurones), and generation of postsynaptic potentials (*c*). The sequence of events by which neurotransmitter, released from presynaptic terminals, produces an electrophysiological response in the postsynaptic cell is conceived as follows. The released neurotransmitter activates a neurotransmitter-sensitive adenylate cyclase present in the membrane of the postsynaptic cell, leading to the production of cyclic AMP in the immediate vicinity of the postsynaptic membrane. The newly formed cyclic AMP activates a cyclic AMP-dependent protein kinase present in the postsynaptic membrane This activated protein kinase catalyses the phosphorylation of a substrate protein, also present in the postsynaptic membrane, converting it from the non-phosphorylated to the phosphorylated state. A key element of this model is that this substrate protein controls the permeability of the postsynaptic membrane. Phosphorylation of the substrate protein leads, through a change either in ion conductance or in the rate of an electrogenic pump, to a change in membrane potential, the "postsynaptic potential". Since the postsynaptic potential is transient in nature, enzymatic machinery must exist which terminates this sequence of events. This enzymatic machinery includes a phosphodiesterase that hydrolyses the cyclic AMP to 5'-AMP and a phosphoprotein phosphatase that converts the substrate protein back to the non-phosphorylated form, leading to the termination of the postsynaptic potential.

as the rate at which these microtubules transport material along their length, or the rate of assembly or disassembly of the microtubules.

The third possible role, which is the main theme of this presentation, is in mediating the postsynaptic effects of neurotransmitters at certain types of synapse. An hypothetical sequence of events by which this may occur is presented in Fig. 3. Although the scheme is far from proven, a variety of evidence is compatible with the idea that the effects of cyclic AMP on the membrane properties of postsynaptic cells may be mediated through regulation of the state of phosphorylation of specific membrane proteins. I shall now summarise some of the evidence bearing on this issue.

The five proteins indicated in the postsynaptic neurone in Fig. 3, namely adenylate cyclase[76], phosphodiesterase[76–78], protein kinase[79], protein kinase substrate[80], and phosphoprotein phosphatase[81], are present in very high concentrations in those subcellular fractions of brain tissue that are richest in synaptic membranes. Cyclic AMP markedly stimulates the phosphorylation, by endogenous protein kinase, of two substrate proteins, designated protein I and protein II, present in these synaptic membrane fractions (Fig. 4)[82]. The phosphorylation of both proteins reaches a maximum within 5 s of incubation, the shortest reaction time that has been studied. Since the molecular events underlying synaptic transmission must be rapid, the rapid phosphorylation of these proteins is almost a prerequisite to considering seriously the possibility that one or another of them might be involved in the generation of postsynaptic potentials. Studies of these synaptic membrane proteins have yielded some provocative results.

Studies of the subcellular distribution of protein I indicate large amounts are present in synaptic membranes[82]. In contrast, protein I has not been found in any subcellular fraction of any non-nervous tissue examined[82]. Two other studies of protein I, now in progress in our laboratory, can be mentioned briefly. First, Suzanne Lohmann has obtained evidence that the amount of protein I is very low in neonatal rat cerebrum, and that it increases sharply 2–3 weeks postnatally, when there is also a marked increase in histochemically demonstrable synaptic structures[83]. Secondly, Tetsufumi Ueda has succeeded in solubilising protein I from a synaptic membrane fraction of bovine brain, and has purified it approximately 1,000-fold, calculated with reference to the solubilised extract. Starting with 1.3 kg of brain, he has obtained about 900 µg of apparently pure protein I. It should be possible to collect enough protein I to carry out a study of its structure and of its physicochemical properties, and to determine whether phosphorylation alters these properties. Such studies could provide clues to the chemical basis for the physiological changes observed in some postsynaptic membranes during synaptic transmission. Purified protein I, in its non-phosphorylated and phosphorylated forms, could also be added to model membranes to see if either form affects their permeability.

Moreover, antibodies to purified protein I are now being prepared with several aims in mind, including developing a sensitive radioimmunoassay for protein I, examining the possible effect of the antibodies on neuronal function, and determining the cytochemical distribution of protein I. It will be of interest to see whether such an immunocytochemical approach verifies the localisation of protein I in the postsynaptic membrane.

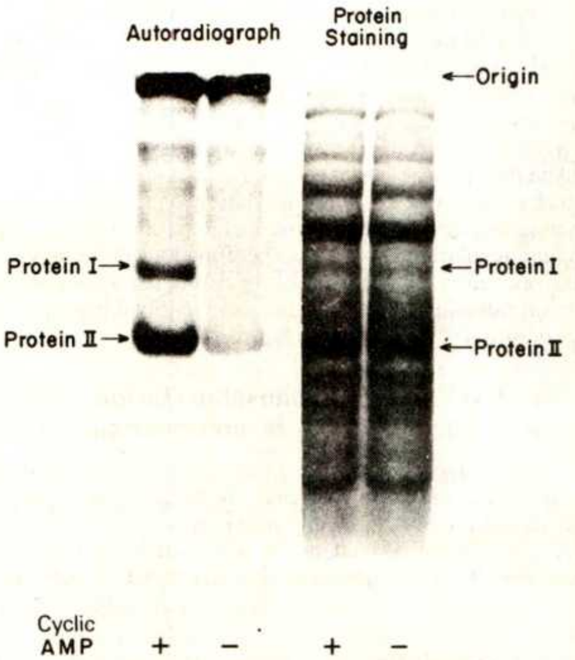

Fig. 4 Effect of cyclic AMP on the phosphorylation of endogenous membrane proteins in a synaptic membrane preparation from rat cerebrum. The synaptic membrane preparation was incubated with γ-^{32}P-ATP, in the absence or presence of cyclic AMP, for 15 s. The reaction was stopped by the addition of sodium dodecyl sulphate. The solubilised protein was then subjected to slab gel electrophoresis, protein staining, and autoradiography, to determine those protein bands into which radioactive phosphate had been incorporated. Autoradiograph is shown on the left side, and a photograph of the protein staining pattern of the dried gel is shown on the right side. The + and − signs at the bottom of the gel indicate the presence and absence, respectively, of 5×10^{-6} M cyclic AMP in the incubation mixture. Several dozen protein bands are visible in the protein staining pattern. A few of these bands incorporated radioactive phosphate, as indicated by the autoradiograph. Phosphorylation of two protein bands was markedly affected by cyclic AMP. The arrows identify the positions on the gel of these two protein bands, designated protein I and protein II, the apparent molecular weights of which are 86,000 and 48,000, respectively. (Taken from Ueda *et al.*[82].)

In contrast to the apparently unique localisation of protein I in neuronal tissue, protein II, or at least a protein with a number of properties similar to those of protein II, is present in membranes and cytosol of a variety of tissues. Certain properties of the protein II system suggest that it could be involved in molecular events underlying a variety of rapid physiological processes. For instance, the rate of phosphorylation and the rate of dephosphorylation of protein II are both stimulated by cyclic AMP[84]. Such a mechanism, while thermodynamically unappealing since the overall effect is to hydrolyse ATP, has the asset of providing a mechanism for a very short-lived pulse of phosphorylated protein. Recently, the protein II kinase–protein II–protein II phosphatase system has been solubilised from synaptic membranes[85]. A kinetic study indicates that the three proteins are present in the solubilised system, and presumably are present in the intact synaptic membranes, in the form of a complex. The existence of the three protein components of a protein phosphorylation–dephosphorylation system in the form of a complex in the synaptic membrane would overcome one theoretical problem associated with the idea that phosphorylation of membrane proteins may mediate the actions of some neurotransmitters. Thus, if the three proteins were separate from one another, and it were necessary to rely on diffusion for the substrate protein to interact with its kinase and phosphatase, the reaction rates might be too slow to underly events as rapid as those associated with the generation of a postsynaptic potential. By being in the form of a complex, the system is not limited by rates of diffusion and, therefore, the phosphorylation and dephosphorylation steps could be extremely rapid. Studies are in progress to determine whether the protein I system also exists as a complex in synaptic membranes.

It would be helpful, in evaluating the scheme shown in Fig. 3, to determine whether a correlation exists, in an appropriate intact neuronal preparation, between the time course of the phosphorylation and dephosphorylation of some membrane protein and the time course of the rise and decay of the postsynaptic potential. But the electrophysiological and the biochemical responses in neuronal tissue are so rapid that it is not feasible to carry out such a study at present. Cyclic nucleotides also are involved in regulating membrane function in many non-neuronal tissues. Fortunately, certain of these non-neuronal preparations have been found useful for testing the hypothesis that the demonstrated ability of cyclic AMP to regulate the permeability of cell membranes is mediated through control of the state of phosphorylation of specific membrane proteins. The results have proved of interest both for understanding regulation of membrane function in non-neuronal tissues, as well as for their possible relevance to an understanding of brain function. Some of the results obtained with such preparations will be summarised next.

Cyclic AMP, protein phosphorylation, and membrane permeability in non-neuronal systems

β-Adrenergic agonists, including isoproterenol, adrenaline, and noradrenaline, cause an increase in sodium and potassium fluxes across the plasma membranes of avian erythrocytes[86–88]. There is evidence[87,88] that cyclic AMP mediates this physiological response: β-adrenergic agonists increase the concentration of cyclic AMP in these cells and cyclic AMP mimics the effect of the β-adrenergic agents in increasing cation fluxes. Moreover, the response is slow enough to permit measurements of protein phosphorylation at various times in the course of the response. Experiments were therefore carried out with intact turkey erythrocytes preincubated with radioactive inorganic phosphate, to label the intracellular ATP pool, and then incubated in the presence of various test substances[89]. Exposure of intact turkey erythrocytes to β-adrenergic agonists for a period of a few minutes markedly affected the degree of phosphorylation of only one protein. This protein had an apparent molecular weight of 240,000 and was located in the plasma membrane. In a variety of experimental conditions, there was a good correlation between the phosphorylation of this membrane protein and the cation flux across the membrane.

The toad bladder is another preparation which has been used to explore the possibility that cyclic AMP may regulate membrane permeability by controlling the state of phosphorylation of a specific protein. Antidiuretic hormone (ADH) increases the sodium permeability of the apical membrane of toad bladder epithelium by a mechanism which seems to involve cyclic AMP. Thus, ADH causes an increase in the concentration of cyclic AMP in this epithelium and cyclic AMP mimics the effect of ADH in increasing sodium transport[90]. Using intact epithelial cells, a correlation has been found between the degree of phosphorylation of a specific protein, called protein D, and the rate of sodium transport, in a variety of experimental conditions in which the cyclic AMP levels were manipulated[91,92]. In addition, aldosterone, which causes a delayed increase in sodium transport across toad bladder epithelium, but apparently not by altering the concentration of cyclic AMP, also affects the degree of phosphorylation of protein D[93]. The effects of aldosterone, both on protein D phosphorylation and on sodium permeability, require *de novo* RNA and protein synthesis, whereas the corresponding effects of ADH, mediated through cyclic AMP, do not. Thus, both ADH and aldosterone regulate the sodium permeability of this tissue and also effect the phosphorylation of the same specific protein, although by different mechanisms.

Studies of a membrane fraction derived from the sarcoplasmic reticulum of myocardial cells have provided evidence that phosphorylation of a specific protein may be involved in regulation by cyclic AMP of Ca^{2+} transport across intracellular membranes in the heart[94–96]. The sarcoplasmic reticulum is believed to represent an uptake system for removing Ca^{2+} from the vicinity of the contractile components of muscle fibres. Cyclic AMP stimulates the active transport of Ca^{2+} into isolated vesicles derived from the sarcoplasmic reticulum. This effect of cyclic AMP may be a component of the mechanism by which β-adrenergic agonists shorten the duration of cardiac contraction. On addition of cyclic AMP to these isolated vesicles, a correlation is observed between increased rate of Ca^{2+} transport, stimulation of a Ca^{2+}–Mg^{2+}-dependent ATPase, and phosphorylation of a 22,000-dalton membrane protein[94–96]. This phosphorylated protein may act as a modulator of the Ca^{2+}–Mg^{2+} ATPase[95,96].

The results obtained with several biological systems studied to date are compatible with the proposal that regulation of the phosphorylation of specific membrane proteins is involved in the mechanism by which cyclic AMP alters ion transport across membranes. It must be emphasised however, that what has been demonstrated is correlation but not causality. The development of highly specific activators and inhibitors of membrane-bound protein kinases and protein phosphatases would be of substantial help in evaluating critically the nature of the relationship between protein phosphorylation and membrane permeability.

Cyclic GMP-dependent protein phosphorylation in smooth muscle

Recent studies with mammalian smooth muscle suggest that the effects of cyclic GMP on postsynaptic membranes, like those of cyclic AMP, may be mediated through regulation of the phosphorylation of specific membrane proteins. ACh, acting on muscarinic receptors, causes a rapid and large increase in cyclic GMP in smooth muscle[97,98]. A protein kinase specifically activated by low concentrations of cyclic GMP, rather than cyclic AMP, as well as endogenous substrate proteins for this cyclic GMP-dependent protein kinase, have been found in a membrane fraction from mammalian smooth muscle[99]. As shown in Fig. 5, a half-maximal increase in the degree of phosphorylation of two substrate proteins, designated protein GI and protein GII, catalysed by an endogenous protein kinase, occurred at about 4×10^{-8} M cyclic GMP, in a membrane fraction from the ductus deferens. A 10- to 20-fold higher concentration of cyclic AMP was required to stimulate phosphorylation of these membrane proteins to the same extent. Cyclic GMP-dependent phosphorylation of proteins GI and GII has been found in a membrane fraction from all types of smooth muscle examined[99]. In contrast, proteins GI and GII have not been found in the cell sap of smooth muscle nor have they been found in any particulate or soluble fraction of a number of other tissues examined. Thus, it would seem that proteins GI and GII are specific to certain membranes from smooth muscle. The fact that ACh increases the level of cyclic GMP in smooth muscle, and that low concentrations of cyclic GMP stimulate the phosphorylation of two proteins which seem to be specific to smooth muscle membranes, suggests that cyclic GMP, as well as proteins GI and GII, may be involved in mediating or modulating some of the physiological effects of ACh on smooth muscle.

Although cyclic GMP-dependent protein kinases were discovered several years ago[100–102], and have been demonstrated in a variety of tissues throughout the animal kingdom[100–106] including mammalian brain[101,103–105], smooth muscle is the only tissue in which any endogenous substrate proteins for this class of enzymes have yet been found. Demonstration of cyclic GMP-dependent phosphorylation of endogenous substrate proteins in neuronal tissue, by endogenous protein kinases, would be of considerable help in understanding the role and mechanism of action of cyclic GMP in the nervous system.

Multiple roles for cyclic nucleotides and protein phosphorylation in neuronal function

The data summarised in this article suggest that the postsynaptic actions of a number of neurotransmitters may be mediated through cyclic AMP or cyclic GMP. Moreover, it is proposed that the immediate targets of cyclic AMP and cyclic GMP are protein kinases whose activation results in the phosphorylation of specific proteins in the membranes of postsynaptic cells, and that the alteration of the degree of

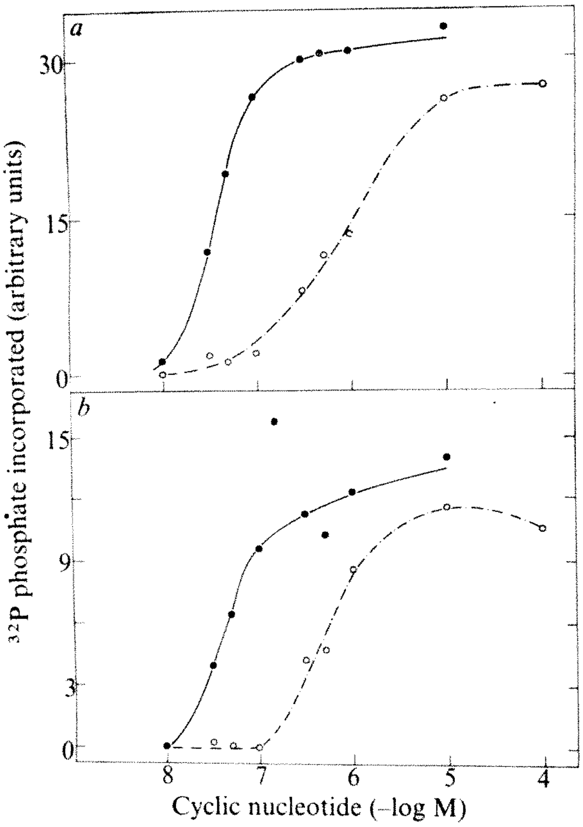

Fig. 5 Effect of various concentrations of cyclic GMP and cyclic AMP on the endogenous phosphorylation of proteins in a membrane preparation from guinea pig ductus deferens. The membrane preparation was incubated for 15 s with γ-^{32}P-ATP in the absence or presence of cyclic GMP (●; $K_a = 4 \times 10^{-8}$ M (*a*) or 5×10^{-8} M (*b*)) or cyclic AMP (○; $K_a = 8 \times 10^{-7}$ M (*a*) or 5×10^{-7} M (*b*)). The reaction was stopped by the addition of sodium dodecyl sulphate, and the solubilised protein was subjected to slab gel electrophoresis and autoradiography. Cyclic GMP markedly affected the phosphorylation of two protein bands, designated protein GI (*a*) and protein GII (*b*), with apparent molecular weights of 130,000 and 100,000, respectively. Incorporation of radioactive phosphate into these proteins was measured quantitatively by densitometric analysis of the autoradiograms. Results of those measurements are shown here. The data represent the increase in phosphorylation above that observed in the absence of added cyclic nucleotide, which amounted to 9.8 and 1.4 arbitrary units for protein GI and protein GII, respectively. (Taken from Casnellie and Greengard[99].)

phosphorylation of these membrane proteins produces the observed physiological effects of the neurotransmitters. It should, however, be emphasised that cyclic nucleotides and phosphorylated proteins may have many other roles in the nervous system. Two such roles include regulation of neurotransmitter synthesis and microtubular function, as discussed briefly above. The increase in cyclic AMP during nervous activity may also serve to mobilise carbohydrate and lipid reserves and thus to meet the increased energy demands associated with elevated functional activity. Cyclic AMP formed in response to neurotransmitters probably induces the synthesis *de novo* of a number of proteins with specific functional roles, including tyrosine hydroxylase[107–109] and *N*-acetyl transferase[110,111]. Finally, a 5-HT-mediated increase in cyclic AMP may be responsible for the increased neurotransmitter release that accompanies behavioural sensitisation in certain invertebrate nerve networks[112,113].

The biochemical mechanisms by which phenomena as varied as energy mobilisation, axonal transport, synaptic transmission, synthesis and activation of enzymes controlling neurotransmitter formation, and short term and long term information storage and retrieval are regulated in an orderly and coordinated fashion represent a challenging topic for future research in neurobiology. It seems likely that answers to many of the questions in this area will be found through understanding the regulatory and integrative role of cyclic nucleotides and phosphorylated proteins in the nervous system.

Laboratory investigation of tilt and seismicity anomalies in rock before failure

B. T. Brady

US Department of the Interior, Bureau of Mines, Denver Mining Research Center, Denver, Colorado 80225

Laboratory measurements of tilt and seismicity anomalies whose time durations are a few milliseconds are shown to precede failure in dry rock specimens. The observed tilt and seismicity behaviour is qualitatively similar to that reported to precede earthquakes. Test results suggest that this precursor time for laboratory specimens of this length may be independent of rock type, in agreement with theoretical predictions and other experimental data on rock failures including earthquakes.

A SCALE invariant theory of rock failure has been proposed that predicts precursor effects such as anomalous V_p, V_s and V_p/V_s behaviour and tilt before failure in rock[2]. In addition, because the theory does not vary with scale, these effects are predicted to occur on the laboratory scale over a time interval of a few milliseconds, and that this time interval will be independent of rock type[2,4]. Experimental evidence is presented below that indicates that tilt and seismicity precursors, whose characteristics are qualitatively similar to those observed before earthquakes, are observed a few milliseconds before failure of rock on the laboratory scale. Preliminary experimental results suggest this time interval may be independent of rock type.

Experimental procedure

Cylindrical samples of 5.39 cm diameter of a variety of rock types including Barre granite and Berea sandstone (reported here), oil shale, schist and marble were drilled, cut and ground to a final length of 13.5 cm. All specimens were deformed to failure under a confining pressure of 1.5×10^7 Pa (10^5 Pa = 1 bar) in a servo-controlled materials testing system. Tests were performed under deformation control with a displacement rate of 6.5×10^{-4} cm s^{-1}.

The load cell used in the testing programme was unique as both the x- and y-moments (M_x and M_y, respectively), in addition to the total load, F (z axis is load direction), could be measured and recorded on separate channels as a function of time. Bending moments, similar to tilts measured in regions prone to earthquakes, are measured about two perpendicular axes intersecting at the centre of the transducer and normal to the load axis. Moment and load changes were recorded on a visicorder and/or a digital memory scope (details of this equipment are available elsewhere[3]).

Acoustic emission, or equivalently, seismicity from the test samples was measured with a system (Dunegan/Endevco 3000) that included a log convertor (model 60) and a reset clock (model 402). The reset clock was modified to provide precision tuning pulses with a minimum pulse interval of 200 μs. The log converter produces a logarithmic scaling of both total emission and emission rate. A low mass ($\lesssim 1$ g) piezoelectric transducer with a ring-down time of ~ 20 μs was used to detect seismic emission from the test samples.

Experimental data

Figure 1 illustrates the variation with time of bending moment (M_x and M_y) for Barre granite (BG-T28) and Berea sandstone (BSS-5). Visicorder output of M_x and M_y as a function of time is shown in Fig. 1*b*. Photographs of both the time variation of

M_x and M_y for the first fracture in Berea sandstone (recorded on the digital oscilloscope) and the fractured test samples are shown in Fig. 1*a* and *c*, respectively. Note that the failure of the Barre granite specimen was a multiple (2) fracture event with the second fracture developing ~ 85 ms after the initial break. The failure of the Berea sandstone specimen, on the other hand, was a single fracture event. This observation should not be construed as suggesting that the existence of multiple or single fractures in failed rock is a function of rock type. Based on our tests, the occurrence of multiple compared with single fractures in failed rock depends only on such parameters as confining pressure, uniformity of loading and the existence of local inhomogeneities within the specimen. Moment and total load (F) variation with time for Barre granite specimens T14, T29 and T30 are displayed in the first column of Fig. 2*a–c*. Specimens T14 (Fig. 2*a*) and T30 (Fig. 2*c*) are single fracture events. Specimen T29 was a multiple (2) event. Moment and load changes for the first fracture in T29 are shown in Fig. 2*b*2 and *b*3.

The most prominent feature in both Figs 1 and 2 is tilting in the direction of eventual fault growth a few milliseconds before failure. This is followed by a reversal in tilt direction that culminates in specimen failure. The inferred initiation locations for failure (based on these moment changes) were substantiated by microscopic examination that showed increased crack concentrations in these locations (Fig. 1*c*). Note also that the total load in samples T29 and T30 decreases during this interval: the magnitudes of both the load decrease and moment changes within these specimens during this interval are ~ 2,500 N and 100 Nm, respectively. Also, the times of the tilt and load change anomalies are nearly identical. The tilt anomaly is, however, observed always to precede the load change, in this case, load decrease, by a time that is usually < 1 ms. Since the load changes within the specimen occur over such a small time, and because the primary hydraulic loading system of the machine cannot respond to deformation changes in $\lesssim$ 100 ms, load change within the specimen is transferred to the columns of the test machine. Thus, the sample continues to shorten during this time. It is not difficult to show theoretically that in these conditions the post-failure stiffness of the sample decreases during the anomaly time interval. Catastrophic failure occurs only when the post-failure stiffness of the sample equals the loading system stiffness[3].

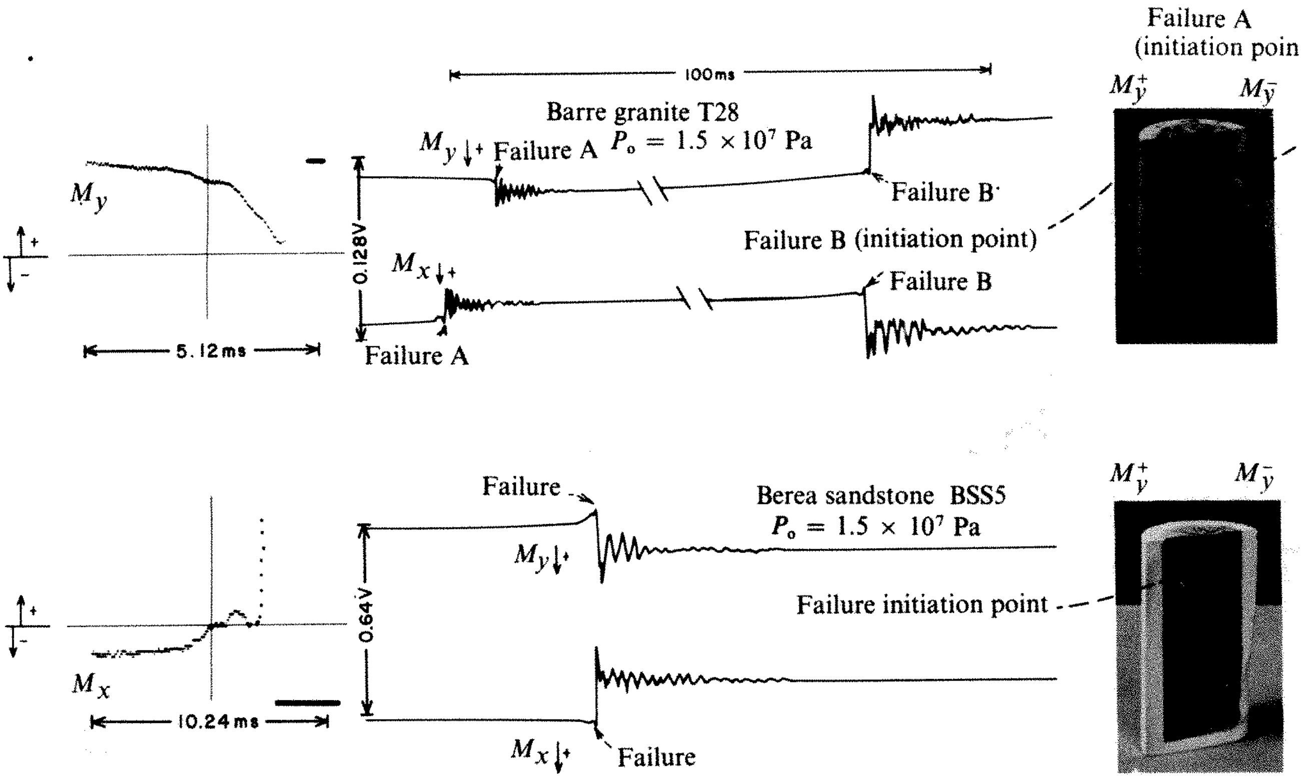

Fig. 1 Variation of M_y and M_x with time for Barre granite (BG-T28) and Berea sandstone (BSS-5). *a*, Photographs of digital oscilloscope output for moment variation. The conversion factor for the vertical scale (in volts) is 3.46×10^2 N m V^{-1}. *b*, Visicorder output of M_y and M_x against time; *c*, photographs of fractured test samples showing major fault zones.

Figure 3 displays moment (M_y) and acoustic emission variation [$N(t)$] with time for Barre granite specimens BG T23 (Fig. 3*a–c*) and BG T24 (Fig. 3*d–g*). Total emission count in Fig. 3*a–c* saturated the amplifier, thus accounting for the apparent constant emission rate against time. Note also that samples T23 and T24 were both multiple (2) fractures with times between the fractures of 55 ms and 40 ms respectively. The most prominent feature in Fig. 3 is the distinct decrease in the emission rate occurring simultaneously with the precursory tilt for each fracture in T23 and T24. The time durations of both the tilt and seismicity anomalies are ~ 1–2 ms. The seismicity decrease occurs during the tilt reversal before the formation of each fracture in Fig. 3.

Discussion

A scale invariant theory of failure governing the initiation and growth of faulting in rock has been proposed[2]. The scale invariant properties of failing rock provide an explanation of

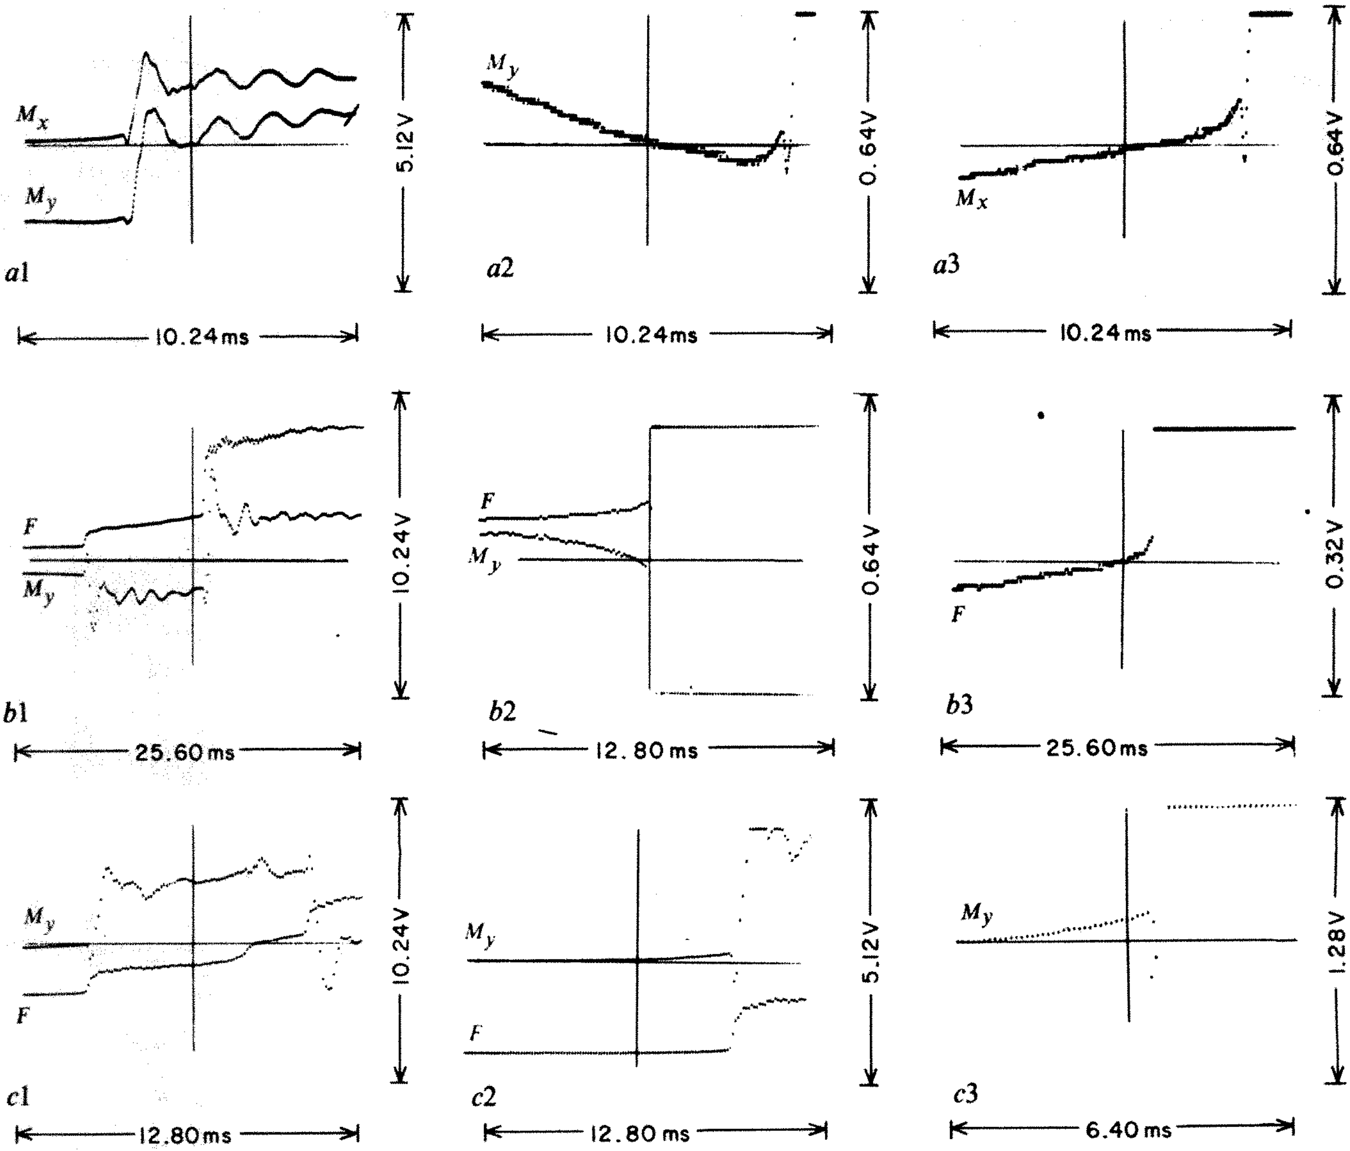

Fig. 2 Moment and load variation with time for Barre granite. *a*, BG-T14: vertical scale lengths for M_x and M_y are 8.65×10^2 N m V^{-1} and 1.03×10^3 N m V^{-1}; *b*, BG-T29: vertical scale lengths for F and M_y are 9.08×10^4 N V^{-1} and 5.86×10^2 N m V^{-1}, respectively; *c*, BG-T30: vertical scale length for F and M_y are 9.08×10^4 N V^{-1} and 5.86×10^2 N m V^{-1} respectively.

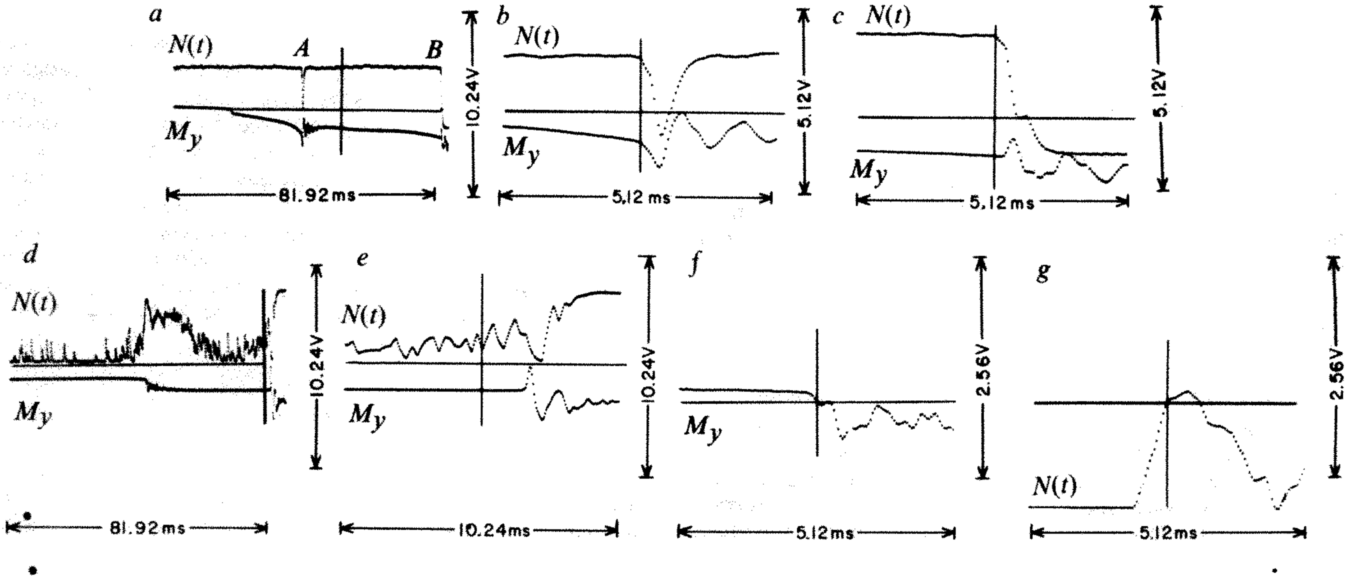
Fig. 3 Seismicity and tilt behaviour against time for Barre granite specimens T23 (*a–c*) and T24 (*d–g*). *b* and *c*, Specify tilt and seismicity for fractures *a* and *b*, respectively, of specimen T23. The conversion factor for M_y (lower trace) is 5.86×10^2 N m V^{-1}. Vertical scale $N(t)$ (upper trace) for seismicity denotes $\log_{10} n(t)$ and represents the total emission count occurring within each 200-μs time window. The conversion factor for the total count is $\log_{10} n(t) = 10\ V$, where V denotes voltage. Bandpass range is 0.3–1 MHz (*a–c*) and 1–2 MHz (*d–g*).



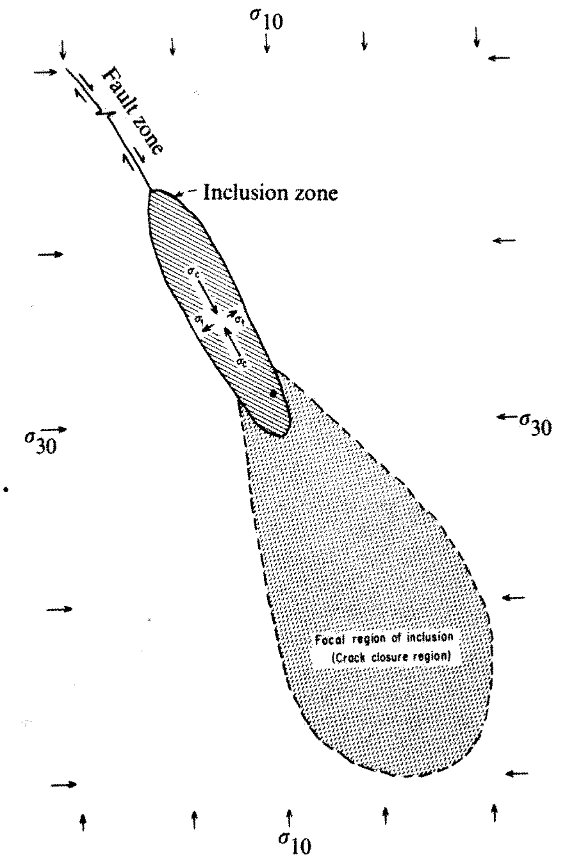


Fig. 4 Schematic illustration of fault zones, inclusion zone and focal region of the inclusion. Maximum and least principal stress applied at distances far removed from the inclusion boundary are indicated by σ_{10} and σ_{30}, respectively.

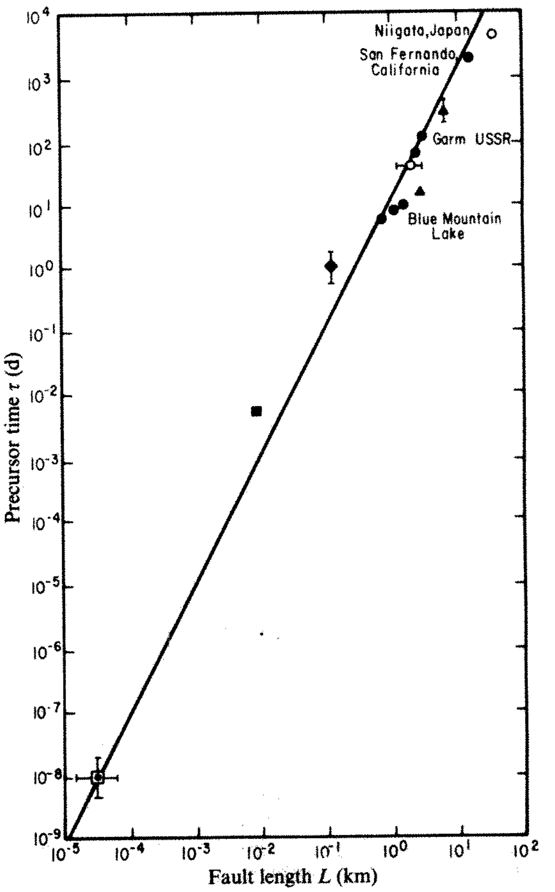

Fig. 5 Precursor time–fault length relationships for selected earthquakes, mine failures and laboratory failures. □, Laboratory seismicity and tilt measurements; ■ noise count for a coal-mine rock fall; ◆ rock burst; ● V_p/V_s anomaly; ▲, radon emission from Tashkent; ○, crustal movements.

why the precursor time–magnitude–'fault' lengths relationships hold for both mine failures and earthquakes[2]. Very briefly, the key hypothesis of this theory, termed the inclusion theory, is that the intense crack concentrations, experimentally observed to develop within localised regions in rock just before failure, can be mathematically modelled, and physically replaced by low modulus inclusions. The inclusions produce a threefold effect. First, the local principal stress axes rotate both within and outside the inclusion during the formation of the inclusion. Second, a state of tension stress is set up within and normal to the long axis of the inclusion, and third, the magnitude of the least principal stress increases in compression in the focal region of the inclusion, that is, the region into which the inclusion and its associated fault(s) will grow (Fig. 4). Thus, as the least principal stress increases, cracks (if present) in the focal region of the inclusion begin to close as the focal region begins to store strain energy, some of which will eventually be released as seismic radiation at the moment of failure. In this theory, the precursor time is defined to be the interval between the initiation of crack closure and failure, that is, the time between inclusion zone formation and the occurrence of catastrophic failure. The theory rests on the postulate that failure occurs when all cracks in the focal region of the inclusion close. At this point, the elastic contrast between the inclusion and its surroundings, the tension stress within the inclusion and the strain energy density throughout the focal region all attain their maximum possible values, and the process of catastrophic failure begins. Data in Figs 1, 2 and 3 support the hypothesis.

Anomalous tilt and seismicity behaviour before failure are predicted by the theory. For example, during the formation of the inclusion zone, tilting will be in a direction away from this zone. The tilt direction will reverse as cracks close in the focal region. Seismicity within the focal region of the inclusion will decrease in response to the decrease in the principal stress difference in the focal region of the inclusion. The theory also predicts that the time duration of these anomalies is independent of rock type and is a function only of the size of the failure. For example, a time anomaly on the order of a few milliseconds will occur before failure in laboratory size (~1–10 cm length) specimens.

Figure 5 illustrates precursor time–'fault' length for selected earthquakes[6], mine failures[1] and laboratory failures (based on the above experimental data). Fault length, assumed to be proportional to inclusion zone length for the laboratory specimens, was estimated to be in the range 1–10 cm. Note the time anomalies for the laboratory failures lie where predicted. Thus the scale-independent properties of the rock failure, at least within a precursor time interval of 10^{-8}–10^4 d or, alternatively, seven orders of magnitude in 'fault' length, seem to have experimental justification. Tests on other rock types, such as oil shale, schist, marble and hydrostone, suggest tilt precursor anomalies also of the order of a few milliseconds. Further study is, however, required to test adequately the prediction that anomaly time is independent of rock type.

Dr S. Edelman of the US Department of Commerce, Bureau of Standards provided the piezoelectric transducers.

Stable nuclear activation dependent on a protein synthesised during oogenesis

Ann Janice Brothers

Department of Zoology, Indiana University, Bloomington, Indiana 47401

A protein synthesised during oogenesis seems to be essential for the activation, during blastulation, of the nuclear genes essential for gastrulation and organogenesis. Nuclear transplantation experiments show that this interaction between the protein and the blastula nucleus produces a heritable state of nuclear activation.

It was established by the classical experimental embryologists[1-3] that the morphogenetic pattern of early development is already present in the cytoplasm of the fertilised egg. These morphogenetic substances are produced during oogenesis, stored in the egg cytoplasm and, after fertilisation, control the normal development of the zygote into the differentiated multicellular organism. The nature of these morphogenetic substances and the manner in which they function are unknown. Genes which exert maternal effects through modifications of the egg cytoplasm are therefore of special interest, since they provide a means of approaching the problem of how the egg cytoplasm acts in controlling early embryonic development[4-8].

The o^+ substance

A simple recessive maternal effect gene (*o* for ova deficient), has been discovered in the Mexican axolotl (*Ambystoma mexicanum*). Females homozygous for *o* produce eggs which always arrest at gastrulation, regardless of whether or not the normal allele is introduced by the sperm at fertilisation. The genetic lesion occurs within the ovary and its expression is not affected by the maternal environment[9]. This suggests a gene-controlled modification of the egg cytoplasm affecting fundamental events in early morphogenesis. This modification is known to be in the nature of a cytoplasmic deficiency. The injection of nucleoplasm from a normal oocyte nucleus (germinal vesicle) or cytoplasm from a normal mature egg (after the germinal vesicle breaks down) into a mutant egg completely corrects the arrest at gastrulation[10]. The active component recovered from the oocytes of widely separated amphibian species seems to be functionally equivalent in the regulation of early embryonic development[11].

The normal allele of the *o* gene seems to direct the synthesis of a substance during oogenesis. This o^+ substance is present in the germinal vesicle by early "lampbrush" stage and its synthesis continues through most of oocyte growth. After the breakdown of the germinal vesicle the o^+ substance is found in the cytoplasm of mature eggs[11]. The active factor cannot diffuse between the blastomeres[10], and is no longer present in detectable amounts after the late blastula stage, suggesting that it has become fixed to some cell structure, rendering it unextractable, or that it has been degraded. The substance seems to be a protein(s) or to depend on protein(s) for its activity[12,13]. Preliminary results indicate that it might be a high molecular weight acidic protein (G. M. Malacinski, personnal communication).

The first differences between the mutant and normal eggs appear at mid-blastula stage. Before this, mutant and normal eggs exhibit essentially the same pattern of protein synthesis, as compared by double isotope acrylamide gel electrophoresis experiments. At the late blastula stage, however, eggs retain the pattern of protein synthesis seen during earlier stages, whereas the normal eggs show an increased relative rate of synthesis of some proteins. This failure to alter or modulate the pattern of protein synthesis is also exhibited by mechanically enucleated amphibian eggs[14,15].

Amphibian development can proceed through blastulation without a functional genome; gastrulation, however, requires the presence of a nucleus[3,16]. In *Xenopus* a spurt of new gene activity during mid-to-late blastula stages produces a population of new transcripts before gastrulation[17]. Normal axolotl eggs show transcription of various RNAs at mid-blastula stage. In contrast mutant blastulae show no incorporation of ^{3}H-uridine autoradiographically[18], but may display small amounts of incorporation by biochemical fraction analysis (R. Steele, A.J.B. and G. M. Malacinski, unpublished). These results suggest that transcription in the mutant blastula may be defective. An analysis of the pattern of RNA synthesis in both normal and mutant eggs is in progress. The data indicate that the o^+ substance is a protein(s) synthesised during oogenesis, stored in the ooplasm, and acting after fertilisation to control early developmental events. The presence of this protein(s) in the egg cytoplasm seems to be essential for the normal activation, during blastulation, of the nuclear genes required for gastrulation and organogenesis. A test of the stability of this nuclear activation is reported here.

Stable nuclear activation

A test can be obtained of the heritability of the nuclear activation by transplanting nuclei (which have been exposed to the o^+ substance) from various stages of normal blastulae into mutant eggs (which lack the o^+ substance). If the activation is not stable, then the recipient eggs, should in all cases develop like typical mutants—all arresting in gastrulation. If the activation is heritable, then the activated nuclei, but not the unactivated ones, should promote normal development of the

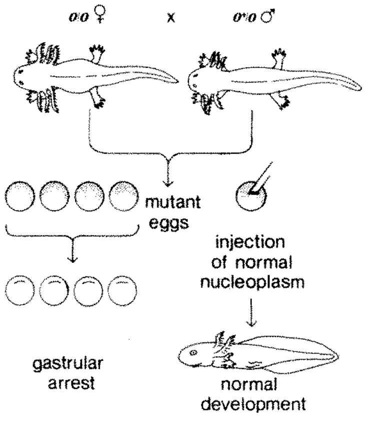

Fig. 1 A maternal effect mutation (*o*, for ova deficient) in the Mexican axolotl. Females homozygous for *o* produce eggs which always arrest at gastrulation. This gastrular arrest can be corrected by the injection of o^+ substance. This o^+ substance is produced during oogenesis under the direction of the normal allele of the *o* gene. The substance is found in the germinal vesicle and in the cytoplasm of normal mature eggs.

Table 1 Capacity of normal blastula nuclei to promote development of recipient mutant eggs

Developmental stage of the nuclear donor	Total (100%)	Number (%) of embryos surviving to each stage Complete blastula	Early-gastrula (stage 10)	Neurula	Post-neurula	Larva	Feeding larva (1 month post-hatching)
Fertile mutant eggs —no transplant	888	883 (99%)	883 (99%)	0			
Early blastula (stages 8–8¼)	234	130 (56%)	127 (54%)	0			
Mid-blastula (stage 8½)	87	41 (47%)	37 (42%)	25 (29%)	21 (24%)	18 (20%)	16 (18%)
Late mid-blastula (stage 8¾)	56	27 (48%)	24 (43%)	19 (34%)	16 (28%)	15 (27%)	13 (23%)
Late blastula (stage 9)	141	85 (60%)	69 (49%)	49 (35%)	46 (33%)	37 (25%)	28 (20%)
Late gastrula (stages 11½–12)	218	122 (56%)	75 (34%)	58 (27%)	43 (20%)	39 (18%)	25 (11%)
Control—transplants of nuclei from a normal blastula into an enucleated normal egg							
Early blastula (stage 8)	157	80 (51%)	75 (48%)	63 (40%)	54 (34%)	49 (31%)	37 (23%)
Late blastula (stage 9)	108	67 (62%)	66 (61%)	57 (53%)	48 (44%)	33 (30%)	29 (28%)
Mid-gastrula (stages 10½–11½)	98	56 (57%)	50 (51%)	36 (37%)	24 (24%)	22 (22%)	17 (17%)

A preliminary report of some of these results has been published in ref. 19. The nuclear transplants were done by an alteration (A. J. Brothers, unpublished) of the previously described techniques[20]. The staging series used is a modification of the stage series described by Harrison[21] and Carroll[18]. The modifications used in this paper are based on the developmental stage, measured by the time after first cleavage, at 18 °C. Stage 8=15–18 h. Stage 8¼=18–20 h. Stage 8½=20–22 h. Stage 8¾=22–24 h. Stage 9=24–29 h. The genetic markers used for the nuclear transplants were those governing pigmentation (*d*), (*m*) and in some instances recessive mutations affecting early development (*f*), (*g*) and a cell autonomous lethal (*ut*) (refs 4, 13).

recipient enucleated mutant eggs. Transplantation of nuclei taken from normal early blastulae shows that those nuclei cannot improve the development of the recipient mutant eggs. Nuclei taken from normal mid-to-late blastulae are, however, capable of promoting normal development of the mutant eggs. (A preliminary report on the stability of late blastulae nuclei to support the development of recipient mutant eggs has been published[19].) More complete results indicate that the stable alteration of the ability of the nucleus to support normal development is established at mid-blastulation. (Table 1).

Some of the animals derived from these transplants have been raised to sexually mature adults (Fig. 2). The spawnings from those animals developed normally and the genetic markers of the donor nuclei were expressed. A small amount of cytoplasm necessarily accompanies the transplanted nucleus. The contribution of this amount of cytoplasm to the correction is probably negligible, since at least 2% of the whole cytoplasm from a normal mature egg must be injected into a mutant egg in order to obtain correction[10]. Also, the active factor is no longer extractable from blastula stages, suggesting that it has become degraded or fixed to some cellular structure[12]. Most important however, is the observation that normal nuclei from early blastulae do not show any capacity to alter the mutant phenotype when transplanted into mutant eggs, whereas normal late blastulae nuclei can support normal development.

Crude nuclear homogenates[22] were made from normal late blastulae and aliquots were injected into fertile mutant and normal eggs. No correction of the phenotype of the mutant eggs were observed.

These observations suggest that the correction in the nuclear transplants is not fortuitously due to the accompanying cytoplasm nor is it due to some diffusible substance concentrated within the blastula nucleus. Therefore, the ability of normal late blastula nuclei to support development of the recipient mutant eggs must be a property of the intact nucleus itself.

Heritability of nuclear activation

A definitive test of the heritability of the activation was provided by serial clonal nuclear transplants of activated nuclei, using enucleated mutant eggs for recipients at each transplant generation (Fig. 3). The nuclei were transplanted into enucleated mutant eggs, and those transplants were allowed to develop to early-blastulae (stage 8). At this point those nuclei had undergone at least nine mitotic divisions[22] in the cytoplasmically deficient mutant eggs. Previous experiments had shown that nuclei from stage 8 blastulae had not yet exhibited activation, as measured by the capacity to promote normal development when transplanted into mutant eggs. Therefore, the serial clonal transplants would provide a test of whether or not a nucleus, once it has passed through the activation period, retains the capacity to support normal development through gastrulation and neurulation.

Some of the transplants in each series were taken at stage 8 to provide nuclear donors for the serial clonal transplants and a small portion of each nuclear donor blastula was also used for the determination of the autoradiographic pattern of ^{3}H-uridine incorporation. The nuclei were again transplanted into enucleated mutant eggs, creating serial transplant clones. Members of each of those clones developed into normal larvae and showed the expression of the genetic markers of the original donor nuclei (Table 2). These experiments demonstrate that the nuclear activation (the capacity to support the normal development of early morphogenetic events) is a stable and heritable condition for more than 30 mitotic generations.

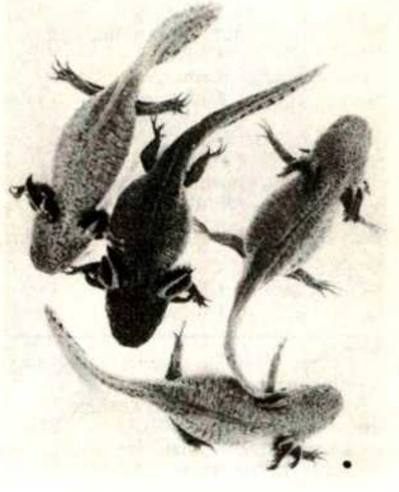

Fig. 2 Adult axolotls derived from nuclear transplants of stage 9 normal blastula nuclei into enucleated mutant eggs.

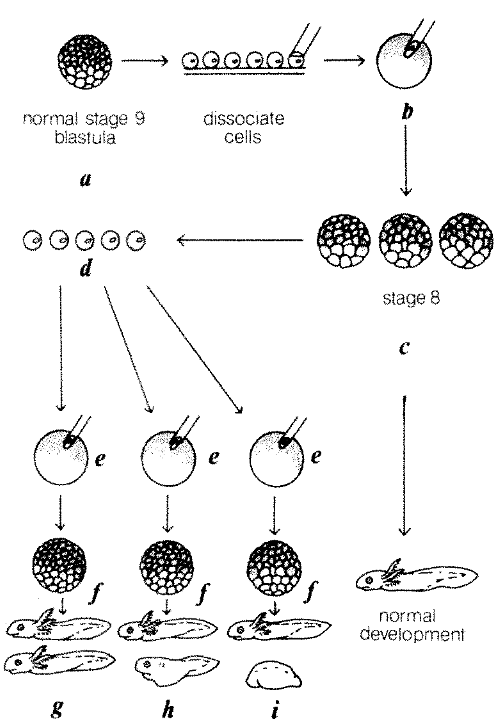

Fig. 3 Serial clonal nuclear transplants of activated nuclei using enucleated mutant eggs for recipients at each transplant generation. *a*, The nuclear donor is a normal stage 9, late blastula which shows intense ^{3}H-uridine incorporation in autoradiographs; *b*, the dissociated cells are used for nuclear transplants into an enucleated mutant egg; *c*, the nuclear transplants are allowed to develop to stage 8, early blastula stage. A few are sacrificed to serve as nuclear donors for the serial clonal transplants, and a portion of each nuclear donor blastula is taken for autoradiographic analysis. There is no detectable ^{3}H-uridine incorporation. *d*, The stage 8 nuclear donor blastula is dissociated in Ca^{2+}- and Mg^{2+}-free Steinberg's medium plus 0.005 M Na citrate, *p*H = 7.4 (ref. 48); *e*, serial clonal nuclear transplants are done, again using enucleated mutant recipient eggs; *f*, the serial clonal transplants are allowed to develop to stage 9, late blastula stage, where a few blastula from each serial clone are used for autoradiographic analysis. They show intense ^{3}H-uridine incorporation.

The capacity to express the nuclear genes necessary for gastrulation and organogenesis is stably altered, apparently independently of continued RNA synthesis (as measured by autoradiographic methods).

Normal early blastulae (stage 8) exhibit little or no nuclear incorporation of ^{3}H-uridine, but normal late blastulae (stage 9) show intense nuclear labelling. In contrast, mutant blastulae never show incorporation of ^{3}H-uridine autoradiographically[18]. Analysis of serial clonal transplants of normal late blastula nuclei into recipient mutant or normal eggs shows that the autoradiographic incorporation pattern of ^{3}H-uridine is the same as the pattern exhibited by control normal eggs.

In *Xenopus* rRNA, synthesis is not detectable until late cleavage or gastrula stages. Gurdon and Brown demonstrated that somatic cell nuclei which were synthesising rRNA, when transplanted into enucleated recipient eggs, did not continue synthesising rRNA in detectable amounts, but exhibited a pattern of rRNA synthesis typical of zygote nuclei[24]. Cytoplasmic influence on the pattern of gene expression has also been described for somatic cell hybrids and heterokaryons[25,26].

o^+ Substance interaction with nucleus

The ability of an embryonic nucleus to support development up through neural stages is dependent on an interaction with the o^+ substance. Injection of plasma containing o^+ substance into fertile mutant eggs enables them to develop normally, demonstrating that the nuclei of mutant eggs can respond to the o^+ substance[10–13].

Transplantation of nuclei from mutant blastulae into normal enucleated recipient eggs tested the question of whether or not nuclei retain the capacity to interact with the o^+ substance throughout early development. As nuclei of mutant eggs undergo cleavage they are not exposed to the o^+ substance, since those eggs lack it. The transplantation of such nuclei into normal eggs, which contain the active factor, represents the first contact that those nuclei have with the o^+ substance. The ability of those nuclei to support normal development would provide evidence that they responded to the o^+ substance in the cytoplasm of the recipient normal eggs.

The experimental results (Table 3) demonstrate that late-cleavage (stage 7) and early-blastulae (stage 8½) mutant nuclei

Table 2 Serial clonal transplants of activated nuclei into mutant eggs

		No. of embryos surviving to each stage					
	Total	Complete blastula	Gastrula	Neurula	Post-neurula	Larva	Feeding larva
Series *A*							
Late blastula, normal stage 9 nucleus ($o^+/o^+, fg/fg^+$) put into a mutant egg	18	9*	6	6	6	5	4
Clone 1*a*	13	3	3	3	3	3	3
Clone 2*a*	18	5	5	5	3	1	0
Clone 3*a*	19	12	11	10	10	5	4
Series *B*							
Late blastula, normal stage 9 nucleus ($o^+/o^+, d/d, ut/ut^+$) put into a mutant egg	43	21†	15	13	10	7	6
Clone 1*b*	15	9‡	7	5	5	4	4
Clone 2*b*	17	10‡	6	4	2	1	1
Clone 3*b*	18	13‡	9	7	5	5	4
Clone 4*b*	13	9‡	6	5	2	2	1

*Three blastulae taken at stage 8 to serve as donors for nuclei for the clonal transplants (1*a*–3*a*) and for autoradiographic analysis of ^{3}H-uridine incorporation.

†Four blastulae taken at stage 8 to serve as donors for nuclei for the clonal transplants (1*b*–4*b*) and for autoradiographic analysis of ^{3}H-uridine incorporation.

‡A few stage 9 blastulae taken from each clone to check for autoradiographic incorporation of ^{3}H-uridine.

A preliminary report of the results obtained from series *A* serial clonal transplants has been published[19].

Table 3 The capacity of the embryonic nucleus to interact with the o^+ substance in the egg cytoplasm

Developmental stage of the nuclear donor	Total (100%)	No. (%) of embryos surviving to each stage						
			Cleavage		Blastula			
		Uncleaved	Abnormal	Normal	Partial	Complete	Neurula	Larva
Transplantation of a mutant blastula nucleus into an enucleated normal egg								
Late-cleavage (stage 7)	39	3 (8%)	11 (28%)	25 (64%)	8 (20%)	23 (59%)	18 (46%)	12 (31%)
Early-blastula (stages 8–8¼)	53	4 (8%)	4 (8%)	45 (84%)	6 (11%)	39 (73%)	29 (54%)	19 (36%)
Late mid-blastula (stage 8¾)	38	2 (5%)	6 (16%)	30 (79%)	18 (47%)	12 (31%)	0	—
Late-blastula (stage 9)	67	44 (66%)	23 (34%)	0	7 (10%)	0	0	—
Control—transplantation of a normal blastula nucleus into an enucleated normal egg								
Late-blastula (stage 9)	36	6 (17%)	5 (14%)	25 (69%)	4 (11%)	25 (69%)	19 (53%)	12 (33%)

have the capacity to respond to the o^+ substance and that this response acts to alter the expression of the mutant phenotype. After advanced mid-blastula (by stage 8¾) this capacity is lost; nuclei at this stage of development and older are no longer capable of supporting normal development if they have not been previously exposed to the o^+ substance. Mutant late blastulae (stage 9) show few or no mitoses, or incorporation of ^{3}H-thymidine[18]. Transplantation of those nuclei into normal eggs indicates that they are incapable of supporting normal cleavage. This suggests that late-blastula nuclei which have not been activated by an exposure to the o^+ substance are injured and are unable to function properly, even when exposed to normal cytoplasm.

Mode of action of o^+ substance

Cytoplasmic control of gene expression has been amply documented[24–28]. The migration of proteins between the cytoplasm and the nucleus has been reported for amoebae[29], insects[30–31] and amphibians[32–34], as well as for many heterokaryons[35]. Recent experiments have demonstrated the differential accumulation of certain classes of protein in nuclei[31,36]. The association of proteins with DNA or the chromosomes, and the subsequent modification of DNA or chromosome behaviour has been described for various systems[41–43].

The o^+ substance seems to be a protein, which is apparently needed to establish the stable activation of the capacity to express the genes required to support normal development through gastrulation and organogenesis. It is tempting to speculate that the o^+ substance might be a regulatory protein, such as Davidson and Britten discussed in their model for eukaryotic gene regulation[44]. The experimental results reported in this paper show that the nuclear activation is dependent on the presence of the o^+ substance within the cytoplasm of the fertilised egg. But these experiments do not show whether there is a direct interaction of the o^+ substance and the embryonic genome. Experiments to settle this issue are now in progress. In addition, the pattern of RNA synthesis in both normal and mutant eggs is currently under examination. It is expected that this approach will provide some insight into the possible relationship between the nuclear activation and gene expression.

Sonneborn's elegant experiments on the inheritance of mating type in *Paramecium* provide another demonstration of a cytoplasmically controlled stable nuclear determination. The sensitive period for this nuclear determination is restricted to one point in the nuclear "life cycle". During this period a cytoplasmic factor acts to produce a genetic alteration in the macronucleus (T. M. Sonneborn, personal communication). This is a stable alteration and is heritable through all subsequent clonal generations, even if the nucleus is later exposed to cytoplasm from the opposite mating type[45].

Cellular determination is endowed with a high degree of stability[25,46]. Once it is established, the capacity to express a specific state of determination can be inherited over many cellular generations, even though the differentiated functions are not expressed[46,47]. The pattern of gene expression can be controlled and modified by cytoplasmic or extracellular factors[25,27,41–43].

In the axolotl the o^+ substance is produced during oogenesis, and the presence of this protein(s) in the egg cytoplasm is essential for the establishment of a stable nuclear activation. The sensitive period for this activation is restricted to one point during embryonic development. Apparently this alteration of the capacity to support development is the result of the activation of the nuclear genes required for gastrulation and neurulation. The isolation and characterisation of the o^+ substance provides an opportunity to examine the manner in which a morphogenetic substance functions.

I thank R. Briggs, R. R. Humphrey, G. M. Malacinski and T. M. Sonneborn for discussions and comments. This work was supported by the National Science Foundation and the National Institutes of Health.

Injected nuclei in frog oocytes provide a living cell system for the study of transcriptional control

J. B. Gurdon, E. M. De Robertis & G. Partington

MRC Laboratory of Molecular Biology, Hills Road, Cambridge CB2 2QH, UK

Human HeLa nuclei injected into Xenopus *oocytes synthesise RNA continuously for up to 1 month, and some of this RNA is translated into HeLa proteins. Nuclear proteins extracted from other cells enter the injected nuclei. This living cell system can be used for the study of transcriptional controls.*

THE identification of chromosomal molecules that regulate gene transcription requires experimental systems in which the function of purified macromolecules can be tested efficiently. Cell-free systems which engage in transcription from isolated nuclei or chromatin are usually characterised by low efficiency (rate of transcription *in vitro* compared with that of the same nuclei *in vivo*), few new initiations (compared with *in vivo*), and sometimes inaccurate reading[1,2] (choice of DNA strand and initiation or termination points). Even in the best systems involving isolated nuclei (for example, ref. 3), transcription has almost ceased within 2 h, and much of the labelled RNA obtained results from completion of chains initiated *in vivo*, rather than from new initiations *in vitro*. We have therefore explored the usefulness of living frog oocytes, which can be injected with nuclei and/or purified macromolecules as a system for investigating transcriptional controls. Earlier work has shown that *Xenopus* blastula nuclei continue to synthesise RNA for 3 d after injection into oocytes[4]. At the level of protein synthesis, reinitiation takes place on mRNA injected into oocytes for up to 2 weeks, as a result of which each molecule of mRNA may be translated up to 100,000 times[5]. We conclude from our results that human cultured cell nuclei injected into oocytes are transcriptionally active for up to 1 month, that some of their genes are expressed as newly synthesised proteins, and that they take up injected and endogenous proteins from the surrounding oocyte cytoplasm.

Persistence of injected nuclei in oocytes

The fate of ^{3}H-thymidine (TdR)-labelled HeLa nuclei in *Xenopus* oocytes has been followed by autoradiography after fixing and sectioning. Oocytes of *Xenopus laevis* were prepared, injected and cultured as described previously[4,6,7], at 19 or 25 °C. In these conditions, oocytes appear morphologically normal for up to 1 month and injected nuclei remain intact. During the first few days after injection, nuclei undergo a substantial enlargement of eight times or more in volume, and their chromatin becomes dispersed (Figs 1*b* and 2*b*). Nuclei injected into the cytoplasm of an oocyte usually come to lie close to the oocyte nucleus (germinal vesicle) (Fig. 1*b*). With practice, it is possible to inject nuclei into the germinal vesicle (oocyte's nucleus), which is obscured in living oocytes by pigment and yolk; in most such experiments nuclei are deposited in an intact germinal vesicle or in the region where it breaks down. In these conditions, the injected nuclei can enlarge enormously (up to 100 times in volume), and may occupy the whole of the space inside the germinal vesicle whose chromosomes are displaced (Fig. 1*a*).

We have found that several different methods can be used successfully to prepare nuclei for injection. In all cases the nuclei injected are surrounded by cytoplasm; however, for convenience, they are referred to here as nuclei. The method used for many of the experiments reported here is to suck cells into a small pipette so that the cell is ruptured, but cytoplasm not removed from around the nucleus—the method used to transplant nuclei to eggs[6]. It is essential however, not to prepare nuclei with the aid of detergents such as Triton X-100 or Nonidet P40; nuclei prepared in this way always die a few days after injection into oocytes. We usually inject about 200 HeLa nuclei into each oocyte.

Injected nuclei synthesise RNA for many days

Oocytes containing injected nuclei have been labelled by incubation in medium containing ^{3}H-guanosine (^{3}H-G) and ^{3}H-uridine (^{3}H-U) or by a second injection of ^{3}H-guanosine triphosphate (^{3}H-GTP). After the desired time, labelled oocytes are fixed, sectioned and autoradiographed. In all, oocytes tested for RNA synthesis (more than 200), nuclei injected into the cytoplasm or germinal vesicle were heavily labelled (Fig. 2*d*), whether the labelling period was as short as 30 min (after ^{3}H-GTP injection), or as long as 36 h. Furthermore, nuclei seemed to synthesise RNA continuously throughout incubation. Even when oocytes containing HeLa nuclei were incubated in non-radioactive medium for 28 d at 19 °C and then in medium with ^{3}H-U and ^{3}H-G for a further 24 h, the injected nuclei were labelled strongly.

The amount of labelling over injected nuclei can be compared with that of the oocyte's germinal vesicle which serves as a convenient internal standard. For all labelling periods (0.5–24 h

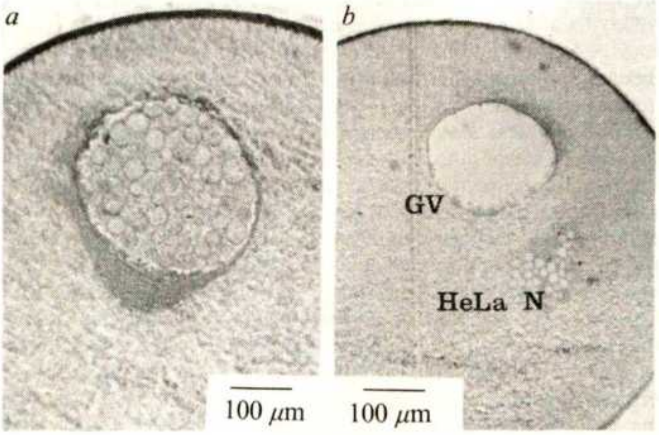

Fig. 1 *Xenopus* oocytes containing injected HeLa cell nuclei. GV, Germinal vesicle or nucleus of the oocyte; HeLa N, injected HeLa nuclei. *a*, GV filled with numerous enlarged HeLa nuclei; *b*, HeLa nuclei in the cytoplasm of an oocyte with an intact GV. Some of the nuclei in (*b*) are shown at a higher magnification in Fig. 2*b*. Oocytes were fixed 3 d after injection of nuclei. Cells used to provide nuclei were suspended in 0.25 M sucrose and 2 mM $MgCl_2$. HeLa cells were grown in plastic bottles by standard procedures, and checked for PPLO periodically.

at 1–28 d after injection), HeLa nuclei were more heavily labelled than the nucleoplasm of the germinal vesicle, but less so than the nucleoli in the germinal vesicle (Fig. 2*c* and *d*). It is also observed that greatly swollen nuclei (those injected 4 or more days previously) are about as heavily labelled, per area of section, as small, unswollen nuclei (those injected within the previous day). Nuclei therefore seem to increase their rate of RNA synthesis in proportion to their enlargement during incubation in oocytes. This effect is in striking contrast to the dilution of label observed during the enlargement of nuclei containing prelabelled DNA. Very rough estimates, based on the known rate of RNA synthesis by amphibian oocytes[8,9], indicate that the HeLa nuclei synthesise RNA at a rate which is at least the same in oocytes at 19 °C as in HeLa cells at 37 °C (refs 10 and 11). Sometimes a few of the injected nuclei fail to enlarge; after a few days they become pycnotic and cease to synthesise RNA.

The incorporation of ^{3}H-U+^{3}H-G or of ^{3}H-GTP by injected nuclei as just described is assumed to represent RNA synthesis, for the following reasons. The labelling of injected nuclei and of the oocyte germinal vesicle with its nucleoli is almost entirely eliminated by treatment with RNase before autoradiography. The germinal vesicles and especially nucleoli of *Xenopus* oocytes are known to be very active in RNA synthesis and inactive in DNA synthesis[12–14], and their pattern of labelling in these experiments was as previously observed. The possibility that label over injected nuclei represents the accumulation in them of RNA synthesised in, and transported from, the germinal vesicle is unlikely for two reasons. First, injected nuclei show the same level of labelling relative to the germinal vesicle after very short (30 min) or very long (36 h) labelling periods. Second, the injection of HeLa nuclei containing labelled RNA into unlabelled oocytes does not result in transfer of this RNA to the germinal vesicle, a fact which argues against a significant exchange of labelled RNA between nuclei in the same oocyte.

The results described so far indicate that HeLa nuclei remain transcriptionally active for at least 1 month. Since they seem to synthesise RNA at a substantial rate, we assume that extensive reinitiation of transcription takes place during this period.

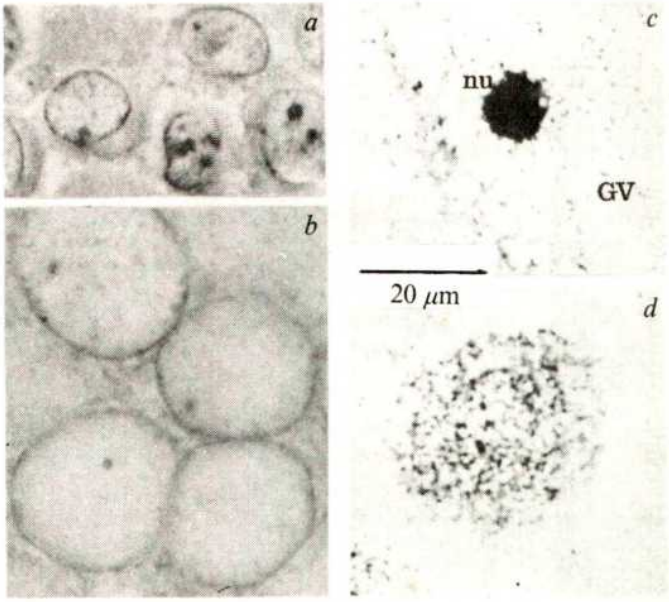

Fig. 2 HeLa nuclei in *Xenopus* oocyte cytoplasm. *a*, HeLa nuclei 5 min after injection; *b*, swollen HeLa nuclei 3 d after injection; *c*, autoradiograph of the germinal vesicle (GV) and a nucleolus (nu) of an oocyte; *d*, autoradiograph of a HeLa nucleus in oocyte cytoplasm. Both (*c*) and (*d*) show the same oocyte which, 3 d after injection of HeLa nuclei, was incubated in ^{3}H-U and ^{3}H-G for 24 h. In (*d*), the HeLa nucleus is more heavily labelled than the nucleoplasm of the oocyte but less heavily than the nucleolus (obscured by grains).

Some HeLa genes are expressed in frog oocytes

Although HeLa nuclei actively synthesise RNA in frog oocytes, the results described so far do not show that this RNA includes mRNAs which code for any identifiable gene products. We have used two-dimensional isoelectric focusing—sodium dodecyl sulphate gel electrophoresis, the high resolution method of O'Farrell[15]— to detect HeLa-coded proteins in oocytes containing injected nuclei. Oocytes injected with HeLa nuclei were incubated in culture medium[6,16] containing mixed ^{14}C-amino acids. Proteins were extracted from the labelled oocytes, electrophoresed in two dimensions, and the resulting slab gels were dried and fluorographed[17,18].

Xenopus oocytes, labelled with a ^{14}C-amino acid mixture, give a highly reproducible distribution of proteins (Fig. 3*a*). When oocytes with and without HeLa nuclei were labelled for 6 h immediately after injection, and their proteins were compared, no difference was observed. But when oocytes with and without HeLa nuclei were incubated for 3 d at 25 °C, labelled for 6 h and analysed by the same procedure, some extra proteins were seen in the nucleus-injected oocytes. One of these proteins, named 66/6.04 (because it has a molecular weight of 66,000, and an isoelectric point of 6.04), is strongly labelled (compare Fig. 3*b* and *c*). Proteins synthesised by HeLa cells include one with these properties, but mouse myeloma cells, and oocytes injected with myeloma nuclei (labelled after 3 d), do not (Fig. 3*e*). To characterise further this protein, region 66/6.04 was cut out from a two-dimensional gel of proteins synthesised by intact HeLa cells and from another gel of proteins from oocytes previously injected with HeLa nuclei. Material eluted from this region was treated with cyanogen bromide, and the resulting peptides were analysed by isoelectric focusing. The peptides obtained from oocytes with HeLa nuclei and from intact HeLa cells are very well matched (Fig. 4); no detectable radioactivity was obtained from the labelled material extracted from region 66/6.04 of slab gels of uninjected oocytes. A labelled spot in position 66/6.04 has appeared in all eight independent two-dimensional analyses so far made of proteins from oocytes injected with HeLa nuclei 3 or more days previously, and in none of seven analyses of oocytes which did not contain HeLa nuclei. The spot appears whether nuclei are deposited in the cytoplasm or germinal vesicle of oocytes. We conclude that at least one HeLa protein is synthesised in oocytes injected with HeLa nuclei.

The HeLa nuclei injected into oocytes are, in effect, ruptured whole cells, and contain much of the original cells' cytoplasm. Protein 66/6.04 might therefore have been synthesised from cytoplasmic mRNA injected with the nuclei, but the following lines of evidence, although necessarily indirect, argue against this possibility and indicate that it is due to new transcription.

The new spot does not appear until about 3 d after injection, but any injected mRNA would be expected, from past experience[5,7,19], to be at least as active immediately after injection as at 3 d. This suggests that insufficient 66/6.04 message is carried over with the nuclei to be detected by two-dimensional electrophoresis during the first day after injection.

It could be argued that the observed time course might also arise if the injected nuclei were to contain mRNP particles or RNA precursors that would be translated only after processing inside the oocyte. To explore this possibility, we tested directly the amount of message carried over with our nuclear preparations. Oocytes were injected with RNA isolated from 4,000 HeLa cells prepared as for nuclear injection, that is, with 20 times more RNA than was carried in with the number of nuclei injected to give a clearly visible spot in position 66/6.04. The recovery of HeLa RNA was monitored by adding a known amount of globin mRNA to the HeLa cell extract, and obtaining a 60% recovery of its activity by translation[7,19] in the injected oocytes. The RNA-injected oocytes showed no detectable synthesis of protein 66/6.04 in the course of 3 d, even though they had received, after allowing for recovery,

Fig. 3 Fluorographs of two-dimensional gels of *Xenopus laevis* oocyte proteins. Oocytes were labelled for 6 h in 2 μl per oocyte of medium containing 250 μCi per ml of L-(^{14}C-U) amino acid mixture (57 mCi per matom), 3 d after injection of nuclei (25 °C). The oocytes were homogenised in 10 mM Tris–HCl, *p*H 7.4, 5 mM MgCl$_2$, ribonuclease A 25 μg ml^{-1} and deoxyribonuclease I 25 μg ml^{-1}. After standing for 10 min on ice, the samples were made 50 mM (*a–c*), or 100 mM (*d* and *e*) in NaCl and the yolk platelets were removed by centrifugation at 1,000*g* for 5 min. The isoelectric focusing dimension was performed as described before[15] and electrophoresed for 18 h at 400 V. The second dimension was run in 15% polyacrylamide gels as described by Knowland[37]. Some of the oocyte proteins are lettered from V to Z to help comparison. In addition to the proteins induced by the injected nuclei, the oocyte background shows minor variations due to differences in the extraction procedures (for example, the double spot at Y in *d* and *e*). *a*, Oocytes injected with saline. The rectangle indicates the area magnified in fluorographs *b* to *e*. *b*, Uninjected oocytes; *c*, oocytes injected with HeLa nuclei. The arrow indicates protein 66/6.04. *d*, Oocytes injected with HeLa nuclei and α-amanitin; *e*, oocytes injected with nuclei of a mouse myeloma cell line.

about 12 times more HeLa RNA than would be carried in with injected nuclei. In addition to this experiment, the α-amanitin experiment (below) and the fact that HeLa nuclei containing adenovirus genomes at the height of their transcriptional activity do not stimulate the synthesis of adenovirus proteins in oocytes (below), also argue strongly against the processing possibilty.

If protein 66/6.04 is coded by RNA synthesised after the nuclei are injected into the oocyte, its synthesis might be expected to be sensitive to α-amanitin, an inhibitor of eukaryotic RNA polymerases[20]. Oocytes were injected with HeLa nuclei, with or without α-amanitin, cultured for 3 d, and then labelled with ^{14}C-amino acids. The synthesis of protein 66/6.04 was eliminated in the α-amanitin-treated oocytes (Fig. 3*d*) but not in the controls. Enough α-amanitin was injected to give an intracellular concentration of 10 μg ml^{-1}, found previously to inhibit the synthesis of RNAs other than 28S, 18S and 4+5S in *Xenopus* oocytes[21–23]. Several controls were performed in the same experiment. (1) Oocytes treated with α-amanitin as above showed a greatly reduced RNA synthesis over the germinal vesicle and injected nuclei, as judged by autoradiography. (2) The injected nuclei in α-amanitin-treated oocytes were morphologically normal. (3) To prove that the α-amanitin did not inhibit the translation of mRNA, purified rabbit globin mRNA was injected into some of the oocytes containing HeLa nuclei at the same time as α-amanitin, and found by one-dimensional gel anaylsis to be translated as efficiently as in other similar oocytes not injected with α-amanitin.

We conclude that protein 66/6.04 is synthesised in oocytes containing HeLa nuclei, by a coupled transcription–translation process. It seems that insufficient of the mRNA for this protein is injected with nuclei to give a labelled spot in position 66/6.04; this protein appears only when more mRNA has been synthesised by HeLa nuclei in oocytes in the course of about 3 d.

Gene expression by HeLa nuclei in oocytes is selective

Are all genes active in HeLa cells also expressed in oocytes containing HeLa nuclei? Several of the major proteins synthesised by HeLa cells are not distinguishable by two-dimensional analysis from major proteins synthesised by *Xenopus* oocytes, and the activity of these genes cannot therefore be determined in these experiments. At least sixteen major proteins are distinguishable, however. Of these, two in addition to 66/6.04 are synthesised in oocytes 3 d after injection of HeLa nuclei, but we have not detected the synthesis of the other 13. Since most kinds of vertebrate mRNA are translated efficiently after injection into *Xenopus* oocytes (for example, refs 6, 24 and 25), we presume that many genes active in intact HeLa cells become inactive in oocytes, at the transcriptional or post-transcriptional (but pre-translational) levels.

To investigate the possibility that genes in injected nuclei may be transcribed but not translated, we have injected oocytes with HeLa nuclei prepared 6 or 12 h after infection with human adenovirus type 5 at a high multiplicity. RNA synthesised by these oocytes was labelled 3 d after nuclear injection, and hybridised to purified adenovirus 5 DNA in conditions of DNA excess. Over 10^6 c.p.m. of RNA was extracted from each sample of oocytes and about 50,000 c.p.m. was used for each hybridisation reaction. The same background level of hybridisation was observed with ^{3}H-RNA from oocytes containing infected nuclei as with ^{3}H-RNA from controls. Effective operation of the hybridisation methodology and recovery of RNA was demonstrated by extracting RNA from oocytes previously injected with ^{3}H-RNA from 18-h adenovirus-infected cells. A very low level of adenovirus transcripts would not have been detected by the procedures used. This result, however agrees with that of protein analyses. Oocytes containing 6-h or 12-h adenovirus-infected HeLa nuclei synthesise protein 66/6.04, but do not synthesise two major adenovirus proteins (hexon and penton) which would have appeared in two-dimensional gel positions 115/6.10 and 70/7.00. Nor are the infected cell-specific polypeptides which would have been seen in positions 95/6.10, 78/6.00 and 65/6.25 synthesised by these oocytes. Apparently the adenovirus genome becomes transcriptionally inactive soon after infected nuclei are injected into oocytes, even though transcription by some HeLa genes in the same nuclei persists.

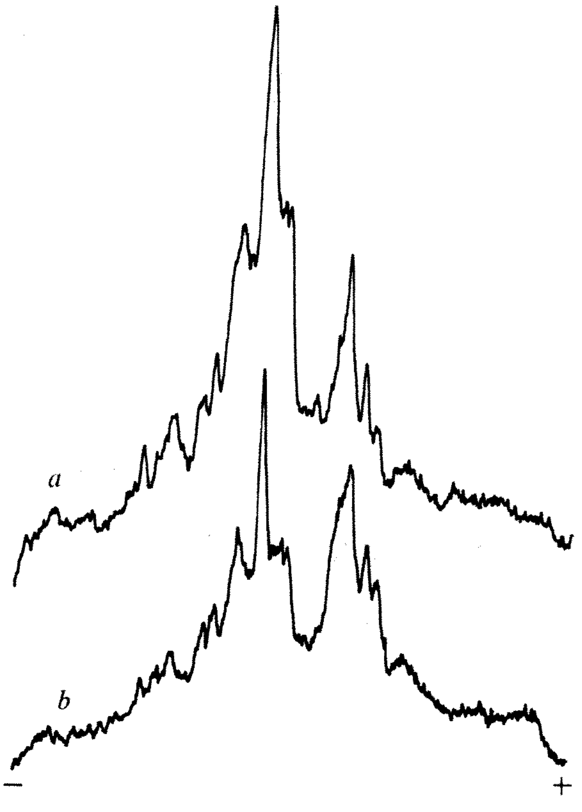

Fig. 4 Isoelectric focusing of cyanogen bromide peptides of protein 66/6.04. Total ^{14}C-proteins were electrophoresed in two-dimensional gels. After autoradiography the 66/6.04 region was cut out, homogenised and suspended in 70% formic acid containing cyanogen bromide (200 μg ml^{-1}). After shaking at 20 °C for 12 h, the gel particles were centrifuged; the supernatant was lyophilised twice, dissolved in pyridine–acetate buffer, *p*H 6.5, incubated at 60 °C overnight (to open the homoserine-lactone ring), and dried again. The samples were analysed by isoelectric focusing in a 4% polyacrylamide slab gel containing 2% ampholines (*p*H range 3.5–10) and 9 M urea. After fixing in 15% trichloroacetic acid, the gel was fluorographed and the film scanned in a Joyce-Loebl microdensitometer. *a*, Peptides from protein 66/6.04 of oocytes injected with HeLa nuclei; *b*, peptides from protein 66/6.04 of HeLa cells.

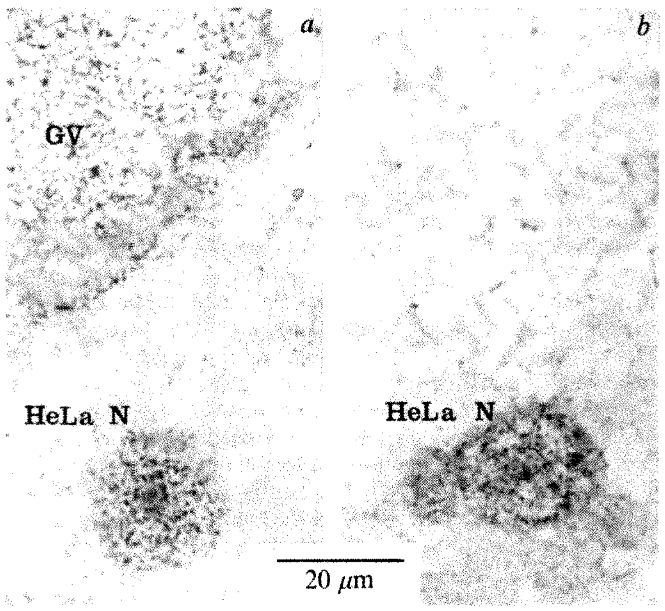

Fig. 5 *a*, Autoradiograph of an oocyte containing a HeLa nucleus. The oocyte was injected with HeLa nuclei; 5 d later it was injected with ^{125}I-labelled calf thymus histones (less H1) and incubated for a further 16 h before fixation. The HeLa nucleus (HeLa N) is about as heavily labelled as an equivalent area of the oocyte's nucleus (GV), and much more strongly labelled than the surrounding cytoplasm. *b*, Autoradiograph of a HeLa nucleus (and the edge of another one) in an oocyte; the oocyte was incubated in ^{3}H-leucine for 2 h and in unlabelled medium for a further 24 h, 4 d after it had been injected with HeLa nuclei. The nuclei are labelled much more strongly than the surrounding cytoplasm.

Uptake of proteins by injected HeLa nuclei in oocytes

If nuclei injected into oocytes are to serve as a test system for the function of macromolecules, it is essential to know that these molecules can gain access to the nuclear genes being studied. The following experiments show that some endogenous as well as introduced proteins rapidly enter HeLa nuclei from oocyte cytoplasm. Oocytes, injected with nuclei 4 d previously, were incubated in ^{3}H-leucine for 2 h, and then in excess unlabelled medium for 24 h. Autoradiography showed that the injected nuclei were strongly labelled well above the cytoplasmic background level (Fig. 5*b*). Since nuclei do not synthesise protein, they must have accumulated proteins synthesised in the cytoplasm; the fact that these proteins remained in the nuclei during a 24-h chase suggests that they may become associated with some intranuclear structures—possibly chromosomes. In another experiment, purified calf thymus histones labelled with ^{125}I (ref. 26) were injected into oocytes containing enlarged HeLa nuclei. The oocytes were fixed 24 h later, sectioned and autoradiographed. Both the injected nuclei and germinal vesicle were strongly labelled (Fig. 5*a*). The results of these experiments are supported by previous work: egg cytoplasmic proteins accumulate in endogenous or injected nuclei[27-29], whether or not puromycin is used to suppress protein synthesis, and ^{125}I-histones accumulate in oocyte germinal vesicles[30,31]. Bonner[32] has shown that non-histone proteins from an oocyte germinal vesicle selectively accumulate in the germinal vesicles of other injected oocytes. We conclude from these results that nuclear proteins will enter injected nuclei in oocytes and therefore gain access to chromosomes whose genetic activity they may regulate.

Applications and prospects

The experimental system described can be used to test the gene-regulating activity of purified macromolecules which do not readily enter cells. High resolution two-dimensional gels and subsequent peptide analyses of separated proteins provide a sensitive test for changes in the activity of many different genes in the injected nuclei. Macromolecules whose effect is to be investigated can be injected into oocytes with the test nuclei. Oocytes may then be cultured for several days, so that the injected proteins may enter nuclei and associate with genes. Changes in gene activity can then be measured by subsequent labelling and analysis of newly synthesised RNAs or proteins.

It is very desirable to study changes in the activity of genes in injected nuclei, rather than changes in the activity of oocyte genes; this is because changes in the transcriptional activity of oocytes genes would be hard to detect over the very high background of proteins being synthesised from preformed, stable mRNA of which there is large stock in oocytes. The major advantages of this living cell system over cell-free systems with isolated nuclei are the very long persistence of transcription (for several weeks) and the more natural circumstances in which presumed regulatory molecules can function. The special advantage of frog oocytes over other living cell assay systems, such as injectable fibroblasts[33] or fused vesicles[34], is that sufficient label is incorporated by a few oocytes (importantly, a few injections) for a detailed biochemical analysis of newly synthesised RNAs or proteins. For each protein analysis described in this article, we have used material from five or less oocytes.

In addition to using *Xenopus* oocytes as a living test tube in which to test molecules regulating transcription, two directions in which this type of work may be fruitfully pursued are the following. One is to try to replace whole nuclei by chromatin or purified DNA, the efficient transcription of which might substantially increase the information obtainable from chromatin reconstitution experiments. The introduction of purified macromolecules into living frog oocytes and eggs has given encouraging results in preliminary investigations[35,36]. The other is to develop a system in which inactive genes can be made active in experimentally analysable conditions. This might be achieved by injecting into oocytes somatic nuclei from a tissue in which oocyte-active genes are repressed. The activation of such genes could be seen if nuclei from one strain or species were transplanted into oocytes of another in which the two-dimensional distribution of proteins is clearly different.

We thank Drs R. A. Laskey and W. C. Russell for help with experiments involving adenovirus. We also thank Drs R. A. Laskey and J. S. Knowland for advice, and Miss J. Price for assistance. E. De R. is supported by a CNICYT (Argentina)–Royal Society exchange programme and by a fellowship of the Jane Coffin Childs Memorial Fund for Medical Research.

Developmental shifts in the synthesis of heterogeneous nuclear RNA classes in the sea urchin embryo

Lewis M. Dubroff* & Martin Nemer

Institute for Cancer Research, Fox Chase Cancer Center, Philadelphia, Pennsylvania 19111

Three molecular classes with different properties can be distinguished in the heterogeneous nuclear RNA (HnRNA) of sea urchin embryos. The relative proportions of these classes, which we have previously designated α, β and γ HnRNA, undergo marked changes during development from morula to early gastrula. Such changes suggest the existence of more than a single HnRNA function, as well as specific roles for different HnRNA classes in embryonic development.

THE functions of heterogeneous nuclear RNA (HnRNA) may well be elucidated by investigating the involvement of HnRNA in embryonic development. Such an approach is made promising by our demonstration that HnRNA in the sea urchin embryo is not a uniform class of molecules, but is comprised of distinct molecular types[1]. In the study reported here we asked whether development is characterised by shifts in the synthesis of these distinct molecular types of HnRNA.

Early sea urchin development involves (1) the rearrangement of the cells of the morula to form the hollow sphere of the early blastula; (2) rotation of the ciliated blastula inside its ferti-

---

*Present address: Mayo Clinic, Rochester, Minnesota 55901.

lisation membrane; (3) lysis of the membrane to yield a hatched blastula; (4) migration of mesenchyme cells into the blastocoel, and (5) invagination to produce a gastrula. The early stages (1–3) do not seem to depend on the transcription of the embryonic genome, in so far as development to the blastula stages can proceed normally when RNA synthesis is blocked[2]. In spite of the appearance of newly synthesised mRNA in polyribosomes[3,4], the proteins synthesised during this period are minimally different from those made in the absence of RNA synthesis, that is, exclusively from maternal RNA templates[5]. This apparent absence of an immediate influence of morula and blastula transcription does not exclude an effect on later morphogenesis. Indeed, there are intriguing critical periods during early development, in which a transient block on transcription[6,7] exerts a morphogenetic influence only later, just before or after gastrulation. Thus early stage RNA transcripts may be more important for later development than for early stage protein synthesis. Our fractionation of HnRNA into molecular types may prove useful for analysing the nature and significance of these early RNA transcripts.

Table 1 Comparison of the percentage of molecules binding to poly(U) in HnRNA prepared from mixed and unmixed lysates of embryos at various stages

	Poly(U) filter binding					
	Experiment 1		Experiment 2		Experiment 3	
Developmental stage	Early blastula ^{3}H	Mesenchyme blastula ^{14}C	Morula ^{3}H	Mesenchyme blastula ^{14}C	Morula ^{3}H	Mesenchyme blastula ^{14}C
Method of preparation						
Mixed lysate	25	37	40	36	22	28
Individually prepared	20	39	40	36	27	39

Early blastula and morula embryos of *Lytechinus pictus* were labelled for 60 min with ^{3}H-uridine, and mesenchyme blastula embryos were labelled for 60 min with ^{14}C-uridine. HnRNA was prepared from a portion of each batch of embryos. Immediately after lysis of embryos, lysates of early blastula and mesenchyme blastula embryos, and morula and mesenchyme blastula embryos were mixed in 5:1 portions in each case. Nuclei and HnRNA were then prepared from each of these mixed lysates. Preparation of intact nuclei from embryos at different stages of development requires different lysis conditions because of large changes in nuclear volume during early embryogenesis[18]. Embryos were washed with 1 M dextrose, suspended in 30–60 volumes of 2 mM $MgCl_2$, and then passed through a hypodermic needle[1], except that an 18-gauge needle was used for morula (4 h), 20 for early blastula (7 h), 21 for mid-blastula (10 h), 22 for rotating blastula (13 h), and 23 for hatched blastula (16 h) and mesenchyme blastula (21 h). Nuclei were purified as before[1]. Electron microscopy revealed that some ribosomes remained attached to these nuclei. A small amount of rRNA of apparent cytoplasmic origin could also be detected when HnRNA preparations were sedimented. This rRNA can be eliminated by pelleting nuclei in a solution containing 0.005 M EDTA in addition to the 1% Triton X-100 solution previously described[1]. Preparation of HnRNA and the method of binding to poly(U) filters have also been described[1]. RNA was assayed as uridine incorporation in alkaline-labile, acid-precipitable material.

The molecular classes that we have characterised and quantified in the sea urchin embryo[1] have been defined as follows: (1) αHnRNA contains internal oligo$(A)_{25}$ and oligo$(A)_{12}$ stretches, (2) βHnRNA contains a 3′ terminal poly$(A)_{175}$ segment and internal oligo$(A)_{12}$ stretches and (3) γHnRNA lacks both poly$(A)_{175}$ and oligo$(A)_{25}$. These molecular classes have characteristic mean S values of 37, 30 and 36S, respectively, and are apparently not artefactually derived from larger molecules. The study reported here shows that the βHnRNA, which probably bears a precursor relationship to polyadenylated mRNA, is not synthesised in constant proportion as development proceeds. This observation contrasts with the constant amount of polyadenylated HnRNA in resting and growing fibroblast cells[8]. Indeed, the relative rates of synthesis of all three molecular types undergo pronounced changes as a function of embryonic development. Such compositional changes in HnRNA reinforce our concept that HnRNA molecules, in addition to differing in specific nucleotide sequences, fall into classes which are very likely responsible for separate physiological functions.

Integrity of HnRNA from early stages

Unambiguous measurements of changes in the percentages of α, β and γHnRNA during early development depend on an assurance of the integrity of HnRNA extracted at each embryonic stage. Mixing experiments were performed to test for the absence of miscible (soluble) degradative agents. The integrity of HnRNA can be monitored by binding mixed preparations to poly(U), in so far as the amount bound would be reduced by the cleavage of portions of the molecule from oligo(A)- or poly(A)-containing HnRNA segments. Early blastulae and mesenchyme blastulae with different isotope labels were lysed, portions of the lysates were mixed, and the poly(U) binding of HnRNA mixtures was compared with that of the HnRNAs prepared from the original lysates (experiment 1, Table 1). The percentages of poly(U) filter-bound HnRNA from individually prepared HnRNAs clearly differed for the two stages, 20–25% for the early blastula and 37–39% for the mesenchyme blastula. We conclude that the lower value for the earlier stage is not attributable to the presence of miscible degradative agents, because the value of the mesenchyme blastula HnRNA was not significantly reduced as a result of having been prepared from a mixed lysate.

This mixing protocol can be used to choose between divergent values, such as the 40 and 22% (experiments 2 and 3, Table 1) for two preparations of morula HnRNA. The lower value can probably be attributed to the action of degradative agents, since mixing the low binding morula HnRNA with mesenchyme blastula HnRNA reduces the binding value of the latter from 39 to 28% (experiment 3). In contrast, the morula HnRNA of high value (experiment 2) does not affect the mesenchyme blastula HnRNA value. The poly(U) binding of morula HnRNA is then approximately equal to that of mesenchyme blastula HnRNA. In our conditions of preparation, enzymes able to degrade HnRNA in exogenous nuclei may in certain cases be active at the morula stage but not at the early blastula stage or mesenchyme blastula stage. The integrities of HnRNAs were also compared by sedimenting total HnRNA in denaturing solvent[9]. Slightly higher S values were obtained for HnRNA of 13-h rotating blastulae (34–36S) compared with 20-h mesenchyme blastulae (28–30S). The lower mean S value for total HnRNA in the later stage embryo may be attributed to an increase in the proportion of βHnRNA, which possesses the smallest mean S value of the three HnRNA classes[1].

Developmental changes in HnRNA composition

The HnRNA which binds to poly(U) filters consists of at least two general classes, αHnRNA containing oligo(A) and βHnRNA containing poly(A)[1]. These components can be resolved by elution with a gradient of logarithmically increasing concentration of the denaturing solvent formamide and decreasing salt concentration, the αHnRNA being eluted at 15% and the βHnRNA at 40% formamide. These observations were made with HnRNA from 13-h prehatched, rotating blastulae[1], and the elution profile for this stage has been re-

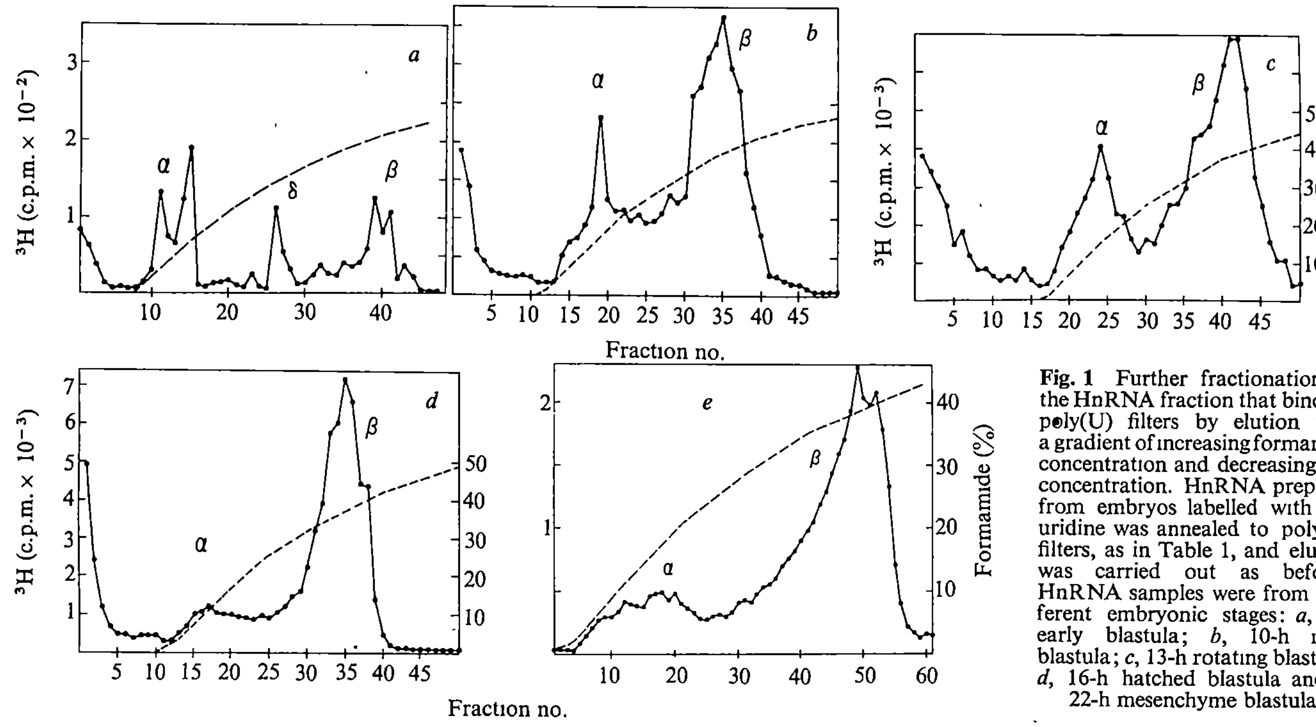

Fig. 1 Further fractionation of the HnRNA fraction that binds to poly(U) filters by elution with a gradient of increasing formamide concentration and decreasing salt concentration. HnRNA prepared from embryos labelled with ^{3}H-uridine was annealed to poly(U) filters, as in Table 1, and elution was carried out as before[1]. HnRNA samples were from different embryonic stages: *a*, 7-h early blastula; *b*, 10-h mid-blastula; *c*, 13-h rotating blastula; *d*, 16-h hatched blastula and *e*, 22-h mesenchyme blastula.

produced in Fig. 1*c*. Here and in earlier stages (Fig. 1*a* and *b*) the αHnRNA represents a substantial proportion, at least 30%, of the labelled HnRNA bound to poly(U). In later blastula stages (Fig. 1*d* and *e*) the proportion of αHnRNA is considerably diminished, with the βHnRNA very much predominant. The ratio of βHnRNA to αHnRNA increases some 2–4-fold during development from early to late blastula stages. Details of the elution profiles reveal that the αHnRNA tends to be resolved into two peaks. Another peak, eluted at 30% formamide, is especially evident in the 7-h early blastula (δ, Fig. 1*a*). The component can be made to bind partially (~50%) to oligo(dT) cellulose[9]. This behaviour resembles neither that of αHnRNA, which does not bind to oligo(dT), nor that of βHnRNA, which binds completely to oligo(dT)[1]. Further characterisation of the δ component is in progress (unpublished results of L.M.D.)

We have shown previously that the α, β and γ classes of HnRNA could be separated and quantitated by virtue of their binding properties to oligo(dT)–cellulose and poly(U) filters[1]. βHnRNA binds oligo(dT)–cellulose through its poly(A) segment. αHnRNA binds through oligo(A) segments to poly(U), together with βHnRNA; however, it does not bind to oligo(dT)–cellulose. Thus the percentage of αHnRNA is obtained by subtracting the percentage bound to oligo(dT)–cellulose (βHnRNA) from the percentage bound to poly(U) filters (α + β HnRNA). γHnRNA will not bind to poly(U) filters.

Analyses of HnRNA preparations from early blastula (7 h), rotating blastula (13 h) and mesenchyme blastula (21 h) embryos exemplify the measurements of differential binding (Table 2). The HnRNA from each stage was separated into fractions bound and not bound to oligo(dT)–cellulose, and these fractions were further examined for bindability to oligo(dT)–cellulose or poly(U) filters (Table 2). For each of the embryonic stages the bound fraction (11%, 16% and 33% for the respective stages above) was almost completely retained on

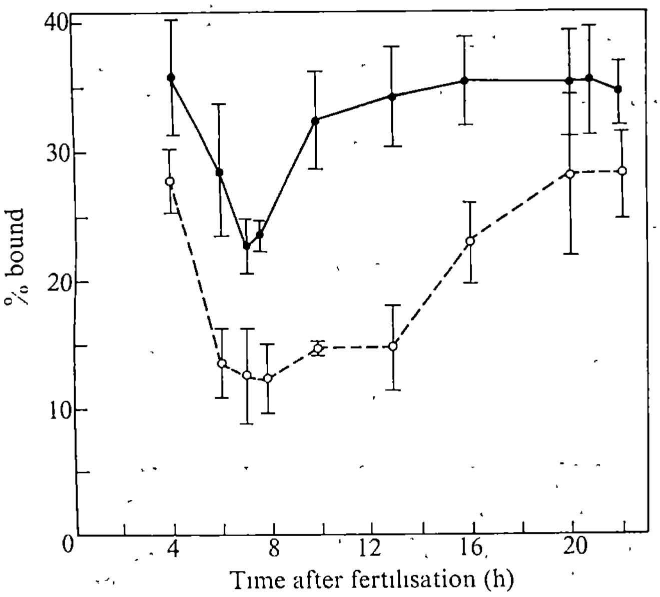
Table 2 Binding measurements of RNA and oligo(dT)–cellulose-fractionated RNA to oligo(dT)–cellulose and poly(U) filters

RNA tested	% Total HnRNA bound to oligo(dT)–cellulose	% Total HnRNA bound to poly(U) filter	% Not bound
HnRNA from 7-h early blastula	11 (βHnRNA)	24	76 (γHnRNA)
Rerun HnRNA bound to oligo(dT)	10	10	
Rerun HnRNA not bound to oligo(dT)	<0.1	14 (αHnRNA)	
Sum of rerun HnRNA		24	
HnRNA from 13-h blastula	16 (βHnRNA)	36	64 (γHnRNA)
Rerun HnRNA bound to oligo(dT)	16	15	
Rerun HnRNA not bound to oligo(dT)	<0.1	15 (αHnRNA)	
Sum of rerun HnRNA		30	
HnRNA from 21-h mesenchyme blastula	33 (βHnRNA)	37	63 (γHnRNA)
Rerun HnRNA bound to oligo(dT)	32	31	
Rerun HnRNA not bound to oligo(dT)	<0.1	5 (αHnRNA)	
Sum of rerun HnRNA		36	

HnRNA was from embryos labelled for 60 min with ^{3}H-uridine. Assays of binding to poly(U) filters and oligo(dT)–cellulose have been described previously[1]. RNA was assayed as uridine incorporation in alkaline-labile, acid-precipitable material in all fractions. See text for definitions of α, β and γHnRNA. The 14% in α and the 11% in βHnRNA in the 7-h early blastula must be corrected for the approximately 3% in the δ component, estimated from Fig. 1*a*. Since approximately half of the δ component binds to oligo(dT) together with βHnRNA and the other half is not bound, in company with αHnRNA (unpublished results of L.M.D.), the corrected values are approximately 12% in αHnRNA and approximately 9% in βHnRNA.

a subsequent passage through oligo(dT)–cellulose or poly(U) filters, and the unbound fraction remained unbound after a second passage through oligo(dT)–cellulose. Repassage of the unbound fraction through poly(U) filters, however, resulted in the binding of part of this fraction to an extent representing 14%, 15% and 5% of the respective total HnRNAs. At each stage this additional HnRNA plus the HnRNA bound to oligo(dT)–cellulose, was approximately equivalent to the percentage of the total HnRNA bound originally by poly(U) filters. Therefore, HnRNA that is bindable to poly(U) filters comprises two classes at each stage, distinguishable by their binding properties to oligo(dT)–cellulose. Quantitative differences are observed in the content of α, β and γHnRNA classes in the 7-h morula, 13-h rotating blastula and 21-h mesenchyme blastula as follows: αHnRNA comprises 12%, 15% and 5% at these successive stages, βHnRNA is 9%, 16% and 33% and γHnRNA represents 76%, 64% and 63%, respectively.

Fig. 2 Labelled HnRNA from various stages of development bindable to oligo(dT)–cellulose columns and poly(U) filters. Embryos at various stages of development were labelled with 10–100 μCi ml^{-1} of ^{3}H-uridine for 60 min. HnRNA prepared from these embryos was bound to oligo(dT)–cellulose (○) or poly(U) filters (●). Each symbol represents the mean and standard deviation derived from determinations on 5 to 18 batches of embryos for each stage. The points represent the average stage at which the 60 min incubations were terminated.



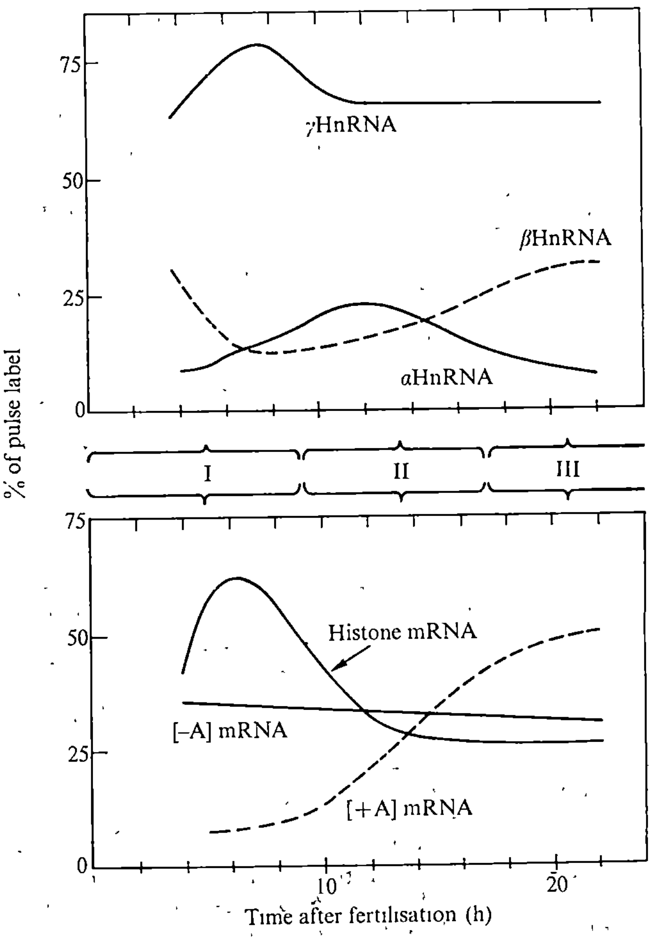


Fig. 3 Changes in the percentage incorporation in HnRNA and mRNA classes during development. The curves in Fig 2 are used to generate continuous developmental curves of α, β, and γHnRNA. αHnRNA is measured as the difference between poly(U) filter binding and oligo(dT)–cellulose binding. βHnRNA is that which binds to oligo(dT)–cellulose, and γHnRNA is that not bound to poly(U). Included also are the curves for relative incorporation of uridine in mRNA (non-4S and non-ribosomal RNA in polyribosomes) for 9S putative histone mRNA, poly(A)-containing mRNA ([+A] mRNA) and mRNA lacking poly(A) ([–A] mRNA), according to Nemer[11]. Between the developmental curves, three characteristic developmental periods are approximated: I, an early period of rapid cell division of the morula and early blastula; II, a middle period of relative quiescence that includes rotation of the embryo and hatching from its membrane. During this period the embryo is uniquely sensitive to actinomycin treatment, in so far as gastrulation is later inhibited[7]. III, A period of development of the mesenchyme blastula leading into gastrulation.

The quantitative changes in HnRNA composition, particularly in the relative incorporations in α and βHnRNA, can be evaluated by two methods, either graphically estimating components eluted by formamide from poly(U), as in Fig. 1, or the differential binding to oligo(dT)–cellulose and poly(U) filters, as exemplified by Table 2. Measurements can be made easily on a multitude of samples by the method of differential binding. The percentages of labelled HnRNA bound to oligo(dT)–cellulose and poly(U) filters are recorded in Fig. 2 for numerous batches of embryos from the 4-h morula to the 22-h mesenchyme blastula stage. The amounts of HnRNA bound to these two polymers differ widely from each other and fluctuate differently during development. The fraction bound to oligo(dT)–cellulose is a direct measure of the βHnRNA, whereas the difference function between these two curves represents αHnRNA. The γHnRNA fraction is not bound to poly(U) filters, and thus its relative incorporation during development is represented by the inverse of the curve for binding to poly(U) filters. Continuous curves for each of these HnRNA components, drawn from these data are given in Fig. 3. They seem to demonstrate three periods during early embryogenesis, each characterised by a distinctively different pattern of HnRNA synthesis. During the first period, from cleavage to early blastula (to approximately 9 h), relative incorporation in γHnRNA, the most prevalent component, attains a maximum value. HnRNA composition during the early part of this period is uncertain, due to the variable degradation of 4-h morula HnRNA noted in Table 1. Futhermore, the relative contributions of α and βHnRNAs are slightly lower than represented by the method of differential binding (Fig. 2), due to the presence of the δ component (Fig. 1*a* and *b*). The relative amounts of α and βHnRNA were therefore quantified from elution profiles, such as those in Fig. 1. They have similar amounts of incorporation at the 7-h early blastula stage and their sum displays a minimum value inversely related to the γHnRNA maximum. At stages beyond 9–10 h, the definition and quantitation of α and βHnRNA by the method of differential binding is fairly unambiguous. In the second period, from the mid-blastula (10 h) to hatched blastula (16 h), αHnRNA reaches a maximal value and declines; γHnRNA has a constant value throughout this and the next period;

βHnRNA increases gradually. In the third period, involving development through mesenchyme blastula (22 h), βHnRNA increases sharply and αHnRNA continues to decline.

HnRNA changes and cellular physiology

These results show that different molecular types of HnRNA can be distinguished. Furthermore, relative incorporation in the distinct HnRNA classes, which we have designated α, β and γ, varies as a function of embryonic development. Control experiments indicate that this variation does not reflect preparational artefacts of degradation or contamination. Considering that the 60-min labelling time is at least four times longer than the turnover time for total nuclear RNA[10], these changes in relative incorporation can be regarded as changes in steady-state populations rather than metabolic turnover differences among the classes at different stages. In addition, they may reflect precursor–product relationships among different nuclear and cytoplasmic RNA classes. The nature and timing of developmental shifts in the synthesis of each of these classes may furnish clues about their separate functions.

(1) The relative syntheses of βHnRNA and poly(A)-containing mRNA[11] increase concomitantly during development from early blastula to mesenchyme blastula (Fig. 3). These changes might be expected to support changes in protein synthesis that accompany extensive and obvious morphogenetic differentiation, especially the appearance of the three germ layers. The changes in HnRNA may be related to changes in mRNA synthesis, involving selective transcription, nuclear poly(A) polymerase activity[12] and the processing of mRNA precursor molecules.

(2) The relative rate of synthesis of γHnRNA attains a peak value at the early blastula stage, a time of maximal rate (per embryo) of DNA and histone synthesis[13], and of the relative synthesis of putative histone mRNA (Fig. 3). This lends credence to the proposition that histone mRNA, which lacks poly(A), is derived from precursors in the poly(A)-deficient γHnRNA class. Only a small portion of the γHnRNA, however, can be involved, since γHnRNA continues to represent the most prevalent HnRNA component even in later stages, when histone and histone mRNA syntheses are much less prominent. The bulk of γHnRNA seems to be involved in processes other than histone mRNA synthesis.

(3) The relative incorporation in αHnRNA peaks at the mid-blastula stage, the period between the beginning of rotation within the fertilisation membrane and hatching. This seems to be an interval of relative quiescence, following the period of intense cell division (and γHnRNA synthesis) and preceding the events leading to gastrulation (including increased βHnRNA synthesis). But it is during this period only that inhibition of transcription results in a block of gastrulation, which occurs much later[6,7]. Thus, this is a critical period of RNA synthesis for the occurrence of a complex future developmental event. There is no evidence for or against the involvement of any individual RNA class. If, however, we consider the developmental changes in the three classes of HnRNA and the three (not necessarily homologous) classes of mRNA in Fig. 3, we must conclude that only αHnRNA attains a characteristic prominence during this critical period. The circumstantial evidence in this chronology suggests the novel hypothesis concerning the role of transcription in the programming of development: that a special class of HnRNA molecules (αHnRNA) functions to predetermine the outcome of later developmental events (gastrulation).

The involvement of αHnRNA could entail the recognition of distinct chemical properties[1], consistent with the operation of developmental signals. It remains to be determined whether or not translatable nucleotide sequences are present in αHnRNA. If this were so, then the critical function of αHnRNA might be to supply templates for immediate or future translation. Alternatively, the regulatory function of such an HnRNA class might not depend on its giving rise to mRNA, but on its intrinsic properties. Theoretically, HnRNA molecules or their derivatives might activate and coordinate gene activity[14], influence mRNA translation[15], or interact with chromatin and influence chromosomal structure[16,17].

letters to nature

Test of pulsar acceleration mechanisms

An elegant mechanism to explain the high velocities of pulsars has been proposed by Harrison and Tademaru[1,2]. Based on the observations that the interpulses seen in some pulsars are located asymmetrically between the main pulses, they assume that pulsar magnetic fields arise in general from off-centred dipoles. The asymmetric radiation reaction produced by such an inclined off-set rotating dipole accelerates the pulsars in a direction parallel to their spin axes and gives the observed velocities. Any verification of the above hypothesis hinges on the possibility of determining, and comparing, the angle projected by the spin axis on the sky S with the observed direction of motion of the pulsar V. According to Harrison and Tademaru's model[1,2], these directions would coincide ($V = S$). We wish to point out here that a measure of the spin axis projected direction is given by the intrinsic angle of polarisation of the radio emission at the centre of the integrated pulse profile, and that these polarisation data do not support the hypothesis in most cases.

It may be remarked here that in those pulsars from which asymmetrically located inter-pulses are seen, this mechanism will be weak, if operative at all, since the magnetic dipole is almost at right angles to the rotational axis. Furthermore, asymmetrically located inter-pulses cannot result from merely

offsetting a dipole field; the direction of emergence of the field lines from the surface must be modified such that these directions for the two poles are not at 180°.

Competing acceleration mechanisms predict different relations between V and S. For example there is evidence that in visual binaries the spin axes of the individual stars are preferentially aligned perpendicular to the orbital plane[3]. The sling shot acceleration mechanism for runaway stars proposed by Blaauw would then produce motion perpendicular to the spin axes of the stars ($V = S + 90°$), if a similar alignment takes place in close binary systems producing pulsars. On the asymmetric supernova explosion hypothesis discussed by Shklovsky and Michel[4], it is not clear if a preferred direction of ejection relative to the spin axes would be expected.

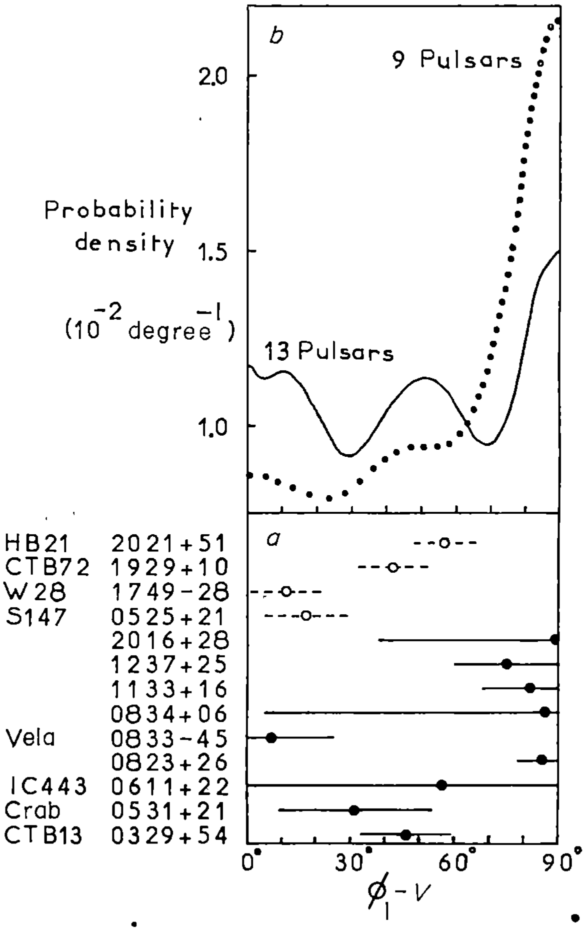
The angle V can be found from proper motion measurements[5–7], from the angular displacement of pulsars from their associated supernova remnants, or from interstellar scintillation observations[7]. We have collected the available measures of V and φ_I, the intrinsic angle, and on this basis we will assess here the relative importance of the various proposed acceleration mechanisms.

We make two general assumptions: firstly, as in most theories of pulsar radio emission, we attribute the systematic sweep of the plane of the average polarisation to the changing aspect of the projected magnetic field in the radiating region as the pulsar rotates, and assume that there is a constant relation between the projected field direction and the plane of polarisation. Secondly, we assume that at pulse maximum, there will be a constant difference between the projected magnetic field direction (and hence the plane of polarisation) and the projected direction of the spin axis, independent of other parameters such as velocity of rotation or inclination of the spin axis to the plane of the sky. In such cases $\varphi_I = S + k$ can be used as a measure of the projected spin axis.

There is evidence in the case of the Crab Nebula that the constant k is zero. If the magnetic field in the nebula as a whole is wrapped toroidally about the pulsar spin axis[8], then measurements[9] of the optical polarisation of the nebula imply a spin axis at position angle 140°. This is in close agreement with the intrinsic position angle[10] of the pulsar radio emission (145 ± 20°). It may be noted that the value $k = 0$ is just that predicted by those polar cap models[11] in which the radio emission comes from (coherent) curvature radiation. Thus, in summary, for many pulsar models $\varphi_I = S + k$, and a preferred value of $\varphi_I - V$ would imply a directed ejection of pulsars from supernovae. If, as seems likely, $k = 0$, then a preferred value of $\varphi_I - V = 0°$ is expected from Harrison and Tademaru's hypothesis, and $\varphi_I - V = 90°$ for the sling shot or runaway star mechanism.

Table 1 gives the available values of $\varphi_I - V$, expressed |180°|. The supernova that has been associated with each pulsar is indicated in column 2, with ? to indicate doubtful cases. The type of observation leading to the adopted value of V (column 3) is shown in column 4. Sc denotes an interstellar scintillation measurement, PM a measured proper motion

Fig. 1 *a*, Plot of the difference ($\varphi_I - V$) between the intrinsic position angle of polarisation φ_I at the centre of the pulse profile and the direction of proper motion V. Values dependent on doubtful associations are dotted *b*, The differences $\varphi_I - V$ of Fig. 1*a* plotted as a probability distribution, taking into account the different weights of the various measurements as given in column 8 of Table 1 ——, All data; . . . . , with uncertain supernova remnant associations excluded.



(either by pulse-timing or interferometry), and D indicates a measured displacement of the pulsar from the centre of the associated supernova remnant. Pulsar positions were taken from the compilation of Manchester and Taylor[12], and the supernova remnant positions were obtained from published radio maps. The source of the values of φ_{I} (column 6) is indicated in column 7. In some cases, lower errors in extrapolating to zero wavelength have been obtained by taking high frequency observations[13–15] and correcting for Faraday rotation by using published Rotation Measures derived independently from low-frequency observations[10,16]. For these pulsars two references are given in column 7. For PSR2021+51 a position angle of polarisation of 38 ± 5° at 1,665 MHz has been taken from ref. 15 and corrected using a Rotation Measure[16] of $-6.5\ \mathrm{m}^{-2}$.

The values of $\varphi_{\mathrm{I}} - V$ (in the range 0°–90°) from Table 1 are displayed in Fig. 1*a* and are shown as a probability distribution in Fig. 1*b* in an attempt to allow for the different weights of the various measurements. There is a preponderance of values of $\varphi_{\mathrm{I}} - V$ close to 90° in the full curve containing all the data. The peak in probability density at $\varphi_{\mathrm{I}} - V = 0$ in Fig. 1*b* comes largely from data for pulsar–supernova associations which are not very well established, S147, W28, HB21 and OTB72. If these data are not included (dotted line), then the preferred direction $\varphi_{\mathrm{I}} - V = 90°$ becomes much more pronounced. If we now apply the condition that the polarisation and the spin axis are related as predicted by the curvature radiation polar cap models, and supported by observations of the Crab Nebula and the pulsar PSR0531+21, this correlation indicates that the acceleration mechanism proposed by Harrison and Tademaru is clearly not dominant.

The distribution in Fig. 1*b* seems to favour a 'sling shot' or similar mechanism or a 'spin-aligned' ejection of pulsars from supernovae. The scatter of values about 90° can be attributed to observational errors, the residual influence of the Harrison and Tademaru mechanism, or more likely to random effects of which at least two can be envisaged. Firstly, any significant proper motion of the parent star before the supernova explosion will make a contribution to the motion of the pulsar. Secondly, an intrinsic scatter of the spin angular momentum of the parent star about the normal to its orbital plane can be expected on the sling-shot hypothesis.

Although the dotted line distribution of Fig. 1*b* is clearly peaked at 90°, we note that for the two pulsars whose association with supernovae is least questioned, (the Crab and Vela), $\varphi_{\mathrm{I}} - V$ is very close to zero and in fact responsible for the tail of the distribution. This raises the possibility that there might be a difference between pulsars associated with supernovae and those not. Support for the possibility that not all pulsars are created in supernova explosions is provided by the case of the binary pulsar PSR1913+16 which has no observable associated remnant, although it is the second fastest pulsar known[17]. Perhaps the asymmetric radiation reaction mechanism operates only on pulsars created in supernovae, because the rotational speeds attained initially might be very much higher than those for pulsars created through accretion in binaries, for example.

We thank Dr A. G. Lyne for supplying the data on proper motions[7] before publication.

Angular momentum diffusion and the initiation of cyclones

IT is possible to explain[1,2] the intensification of a cyclone vortex once the stream lines in a weak depression close around a core of higher vorticity, but it is less clear how the process starts. Scorer[3] proposed that convection might diffuse angular momentum within a field of initially uniform rotation to localised regions, thereby concentrating cyclonic vorticity. Experiments failed to demonstrate the effect[4–7], and although strong vortices could be produced through the breaking of inertial waves[8], the effects were open to misinterpretation. We present here new experimental results showing that first, angular momentum or relative vorticity can be diffused at a rate comparable with the diffusion of relative velocity (turbulent 'viscosity'). This distinctive property seems to be intrinsic to weak turbulence in rotation, and can be parameterised very simply. Second, such diffusion occurs only when the turbulence is sufficiently weak to be constrained by rotation to an essentially two-dimensional structure. This might explain the failure of earlier experiments. Our results could have many applications to geophysics, including tropical cyclogenesis.

The experiments were conducted in a transparent, plane-ended cylinder of uniform height h (22.8 cm) and radius a (14.8 cm) mounted axially on a turntable (with rotation rates Ω between 3 and 11 rad s^{-1}), completely filled with a homogeneous fluid (water, or a glycerine–water solution). The bottom was regularly perforated by 199 holes of 2.21 mm bore, at 2 cm spacing. Each hole connected through tubing to one of two manifolds, 49 holes at 4-cm regular spacing going to one and the remainder to the other (Fig. 1*a*). Fluid (with a few polystyrene beads suspended in it for visibility) was pumped between the manifolds to induce a radially uniform, regular, small scale mixing pattern without mean advection in the radial plane. The convective geometry was varied by closing some jets or by pump reversal. Figure 1*b* shows array geometries. In some experiments using array III, a false top was put in the container to vary h.

Horizontal velocities in the central third of the cylinder were measured photographically. Without rotation, the jets caused the paths shown in Fig. 2*a*. Figure 2*b* shows the effect of rotation with the same jet conditions. Particle concentrations reveal intense vortices, always cyclonic, drifting slowly within the rotating frame, apparently through mutual interaction or by weak relative rotation of the fluid body (usually $<0.01\ \Omega$), independently of their position relative to the jets. The structure was usually well established within 30 rotation periods after pumping started. Once formed, vortices usually kept their identity. They merged occasionally, but others would form to keep the population constant. The vortices aligned themselves parallel to the rotation axis and extended from top to bottom.

Since particle paths were roughly circular and coaxial near the vortices, a mean relative circumferential velocity v could be measured as a function of local radius r from the origin of the vortex centre. This was expressible as an absolute azimuthal velocity $V = \Omega r + v$ in an irrotational frame.

Randomly chosen vortices were measured for a variety of conditions of Ω, h, pumped volume flux M, number of jets N, and kinematic viscosity ν. The profile at V as a function of r plotted logarithmically, had a similar shape for all results

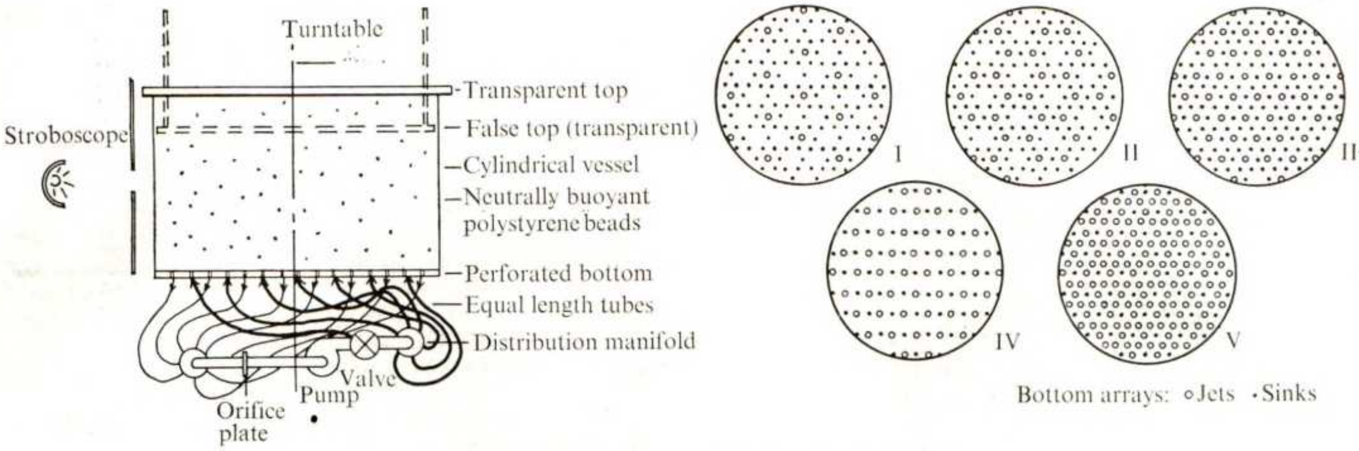

Fig. 1 Experimental arrangement and pumping arrays.

and thus could be aligned, within experimental accuracy, to a 'similar' profile (Fig. 3*a*).

$$V/Q = f(r\Omega/Q) \tag{1}$$

when scaled by a suitable parameter Q having the dimensions of velocity. Q was found to depend linearly on $w\rho/\delta$, where w is the vertical convective velocity scale ($= M/\pi a^2$), ρ is the r.m.s. jet spacing ($= aN^{-1/2}$) and δ is the scale of the viscous boundary layer on the end walls, defined here as $(\nu/\Omega)^{1/2} + w/2\Omega$. As a limit to the magnitude of Q, coherent vortices seldom formed when

$$w_j/\Omega h > 1.15 \pm 0.05 \tag{2}$$

where $w_j = w\rho^2/a_j{}^2$ defines a mean maximum vertical velocity at jet exit and a_j is the jet radius.

Every feature of these results can be explained as follows: To conserve angular momentum in a steady axisymmetric system the torque coming from the turbulent stress must balance the momentum change caused by the radial divergence, i.e., $\mathrm{d}(Tr^2)/\mathrm{d}r = \gamma Ur\,\mathrm{d}(Vr)/\mathrm{d}r$ where T is the mean tangential stress and γ is density; the radial mean velocity U is induced by end-wall boundary layers and has magnitude $\nu\delta/h$.

At its simplest, externally imposed turbulence is characterised by a single horizontal velocity scale q. T may depend both on q and the mean flow quantities, and by dimensional considerations, 'universal' similarity profiles as in equation (1) can generally occur only when Q is proportional to qh/δ. If, through rotational constraint, the turbulence approaches two-dimensionality, horizontal and vertical velocity scales become simply related and $q \propto w\rho/\delta$, consistent with equation (2), so $Q = cw\rho/\delta$ (c is some constant) precisely as observed.

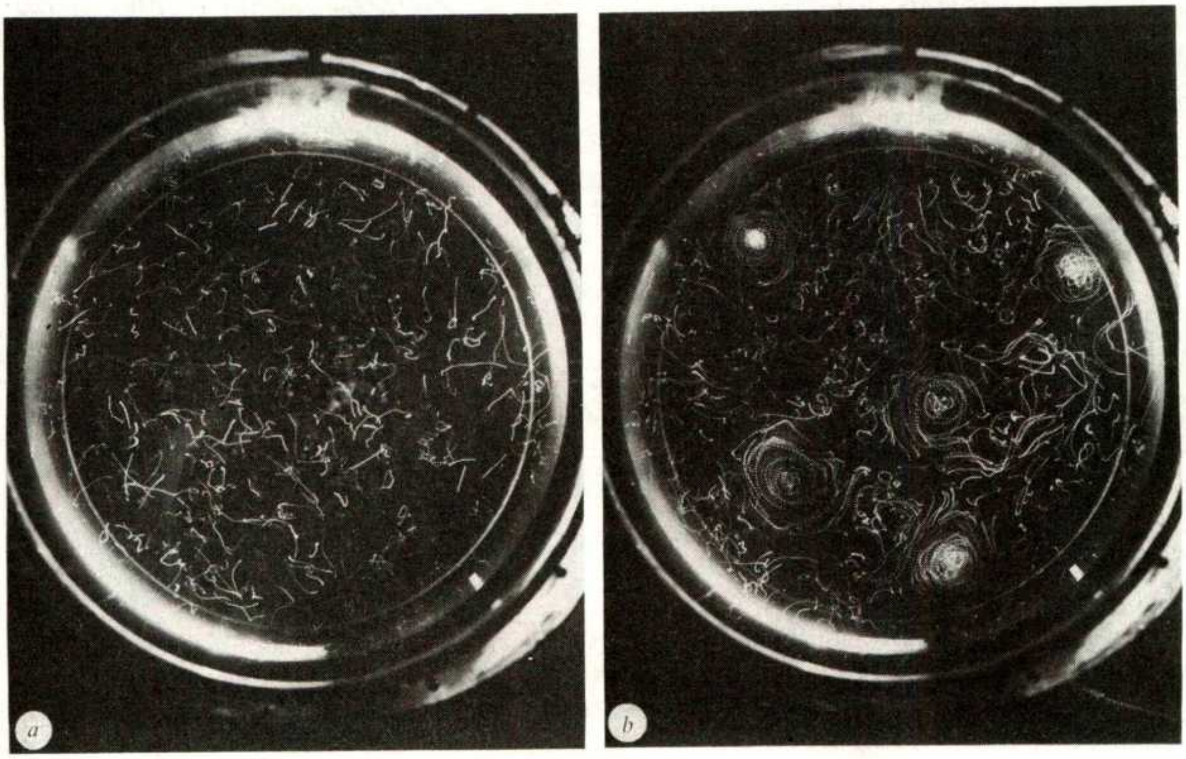

Fig. 2 Particle movements, ~1 s exposure in 50-Hz stroboscopic light by a camera mounted axially on the turntable, with array III; pumping rate for both figures is the same, corresponding to $w = 0.3$ cm s^{-1}. *a*, No rotation. Particle movements are random and short in scale. *b*, Rotation 8.24 rad s^{-1}, after pattern development. Intense cyclonic vortices, dissociated from the bottom jets, are sustained.

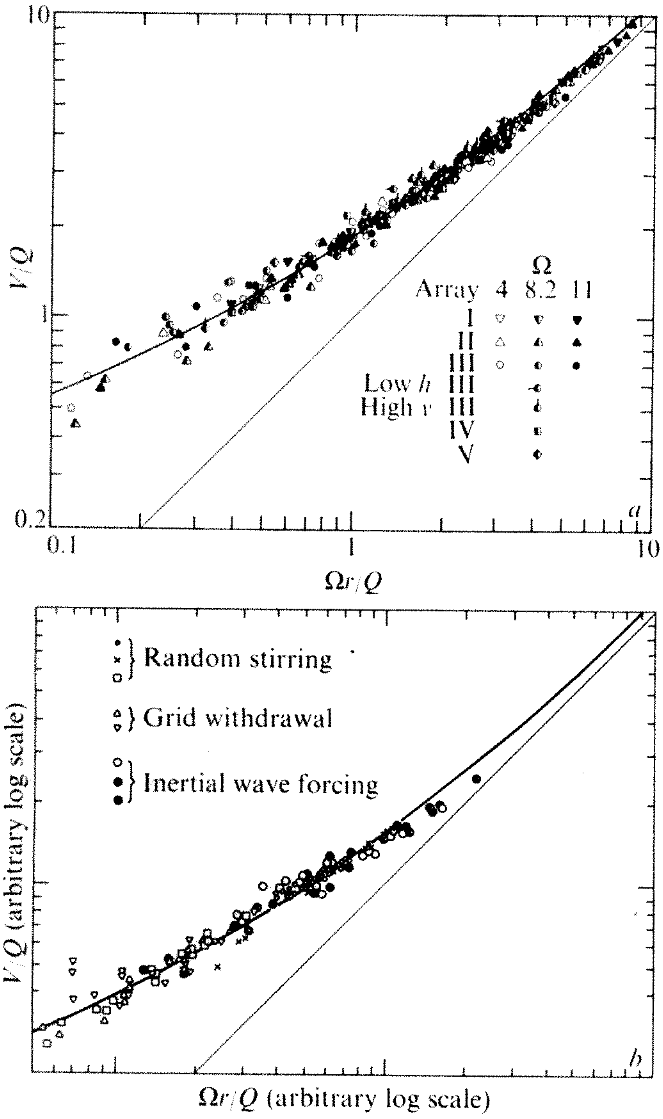

Fig. 3 Absolute azimuthal velocity V as a function of radius r from vortex core, for experimental conditions listed (logarithmic coordinates). V and r are scaled for each data set by velocity Q. Solid rotation Ω is delineated by a faint solid line. The bold line is the theoretical 'universal' absolute velocity profile arising with a constant ratio (2/3) between angular momentum diffusivity and turbulent 'viscosity'. *a*, Randomly chosen vortices with the experimental arrangement described; *b*, with alternative mixing methods: (1) after random excitation, $\Omega = 1.4$ rad s^{-1}; (2) after sudden axial withdrawal of a grid comprising 1-cm-wide battens in a 4×4 cm square plane array (performed by M. Riefman); (3) Continuous resonant forcing of inertial waves following the method of McEwan[8] (performed by W. McKimm) $\Omega = 8.2$ rad s^{-1}.

The essential influence of rotation is reflected in the law defining T, the mean tangential stress. If angular momentum were conserved during radial mixing the quantity, T would vary linearly with $r^{-1}\mathrm{d}(Vr)/\mathrm{d}r$, but in isotropic turbulence behaving like laminar viscosity, T would be proportional to $r\mathrm{d}(Vr^{-1})/\mathrm{d}r$. Between these extremes universal profiles arise only when the two terms are in constant proportion $\xi : 1$. Then equation (1), with T so specified, can be solved numerically. The curve of best fit, $\xi = 2/3$, $C = 0.82$ is shown in Fig. 3*a*. Figure 3*b* shows the fit to vortices produced after cessation of mechanical stirring, or by inertial wavebreaking as used before[8]. Agreement is uniformly good. This explanation implies that the eddies of rotationally dominated turbulence are constrained to a specific anisotropic form. This explains how the diffusion properties can be characterised by a single velocity scale. Note that positive potential vorticity[9] diffusion could not yield our profile.

The significance of the foregoing in tropical cyclogenesis is gauged by considering a disturbance in which the net atmospheric rotation is $2.5\times10^{-5}\,\mathrm{s}^{-1}$, $h = 12$ km, w is 1 cm s^{-1} and 3 cm s^{-1} between clouds at cloud base and in the deep convection zone respectively. Cloud spacing $2\rho = 20$ km and δ is ~ 200 m.

The depression would then be intensified significantly by 0.5 mbar over a 570-km radius, and the vorticity increased to $1.4\times10^{-4}\,\mathrm{s}^{-1}$ at a 10-km radius in a one-week time scale, independently of any thermodynamic advective effects. The condition in equation (2) is exceeded in active cloud columns where $w_j/\Omega h$ is ~ 10, but not in the intercloud volumes. Considering the ease with which the controlling variables can be quantified, further observation and simulation studies seem worthwhile.

Support for part of this work as Rossby Fellow at the Woods Hole Oceanographic Institution is acknowledged.

Rock volatility and aerosol composition

On the basis of recent measurements, I propose here that part of the Earth's aerosol burden comes from the volatilisation (sublimation) of the components of surface rocks, in addition to the well known man-made contribution. Calculations on a simple kinetic model indicates that vapour pressures of $\sim 10^{-11}$ atm could support the observed atmospheric concentration of copper.

Analyses of the inorganic constituents contained in aerosols and rains show a remarkable similarity in abundance patterns (Table 1). In general, the sequence of decreasing concentrations for a group of heavy metals is: Pb, Zn, Cu, Mn and Ni. The measurements cited were made in both hemispheres and on several continents, in urban and rural areas and in all seasons of the year. It is thus difficult to relate these findings to pollution sources, particularly for the heavy metals in the South Pole atmosphere[1]. The above sequence does not resemble that found in crustal rocks or soils (Table 1), where, for example, the concentration of manganese is an order of magnitude greater than that of the other four metals.

Two lines of evidence support the hypothesis that the fractionation responsible for such distributions involves a selective volatilisation. First, emission spectrographers have long been aware of the selective volatilisation of the elements and their compounds[2]. This depends on the matrix in which the elements are bound. For sulphides, oxides, sulphates, carbonates, silicates, and phosphates, the distillation rankings are similar: Pb, Zn, Cu, Mn and Ni, listed in order of decreasing volatility. This applies, however, to extrapolation from high temperatures: vapour pressures for lower temperatures have not yet been measured for this suite of metals and their compounds (there are isolated measurements of only some of the more volatile species). Also, these metals exist in nature in forms other than those used for emission spectroscopic studies. Nonetheless, the matching of the two sequences seems significant.

Kinetic theory shows that even their low vapour pressures are sufficient to account for steady state fluxes of these species

Table 1 Trace metal concentrations in aerosols, rains and crustal rocks*

	Pb	Zn	Cu	Mn	Ni
Mean concentrations in South Pole atmosphere[1] (10^{-12} g m^{-3})	630	30	36	10	
Average concentrations in aerosols collected in San Francisco Bay area[12] (10^{-9} g m^{-3})		136	50	17	
Average concentrations in US precipitation[13] (parts per 10^9)	34	107	21	12	4
Average concentrations in Tucson air[14] (10^{-6} g m^{-3})	0.47	0.15	0.41	0.013	0.021
Average concentrations in rain at Wraymires, UK[15] (10^{-6} g l^{-1})	39	85	23	8	6
Average concentrations in air at Wraymires[15] (10^{-9} g kg^{-1})	87	80	26	11	6
Crustal abundance[16] (p.p.m.)	10–15	32–58	37–72	670–1,000	37–72
Soils[17] (%)	1×10^{-3}	5×10^{-3}	2×10^{-3}	6.7×10^{-3}	4×10^{-3}

*Concentrations are taken directly from references and have not been corrected to a simple set of units in as much as their order is of significance.

to the atmosphere[3]. The rate of loss of a substance, W, from a surface is given by

$$W = p\,(M/2\pi RT)^{1/2}$$

where p is the vapour pressure of the substance with molecular weight M, and T and R are the absolute temperature and gas constant respectively. Multiplying W by σ, the land surface area in cm^2 (3.14×10^{18}) and by f, the fraction of the substance in crustal material gives a continental flux. This may be compared with a flux value calculated to give an observed atmospheric burden A in the troposphere, where its tropospheric residence time τ is determined by the removal of the substance with rain. The flux Φ is $\Phi = A/\tau$

then

$$A/\tau = p(M/2\pi RT)^{1/2}\,\sigma f$$

For a substance whose concentration in the atmosphere is C (g cm^{-3}) and the volume of the atmosphere is v, $A = Cv$, but v/σ is the height of the atmosphere h (the average tropospheric height is taken as 13 km). Thus, the equation reduces to

$$p = (h/\tau)[2\pi(RT/M)]^{1/2}(C/f)$$

If τ is taken as ten days, we get

$$p = 3.4\times10^{-2}(T/M)^{1/2}(C/f)$$

Computed values of p may be obtained from the data in Table 1. For Cu, an atmospheric concentration of 50×10^{-15} g cm^{-3}, and a crustal abundance of 50 p.p.m. yields vapour pressures for its species of 6.6×10^{-11} atm at 300 K and 12×10^{-11} atm at 1,000 K. We note that DDT has been dispersed around the Earth primarily in the vapour phase[4], and its vapour pressure is $\sim 2 \times 10^{-10}$ atm (ref. 5) at 300 K. Its mean concentrations in the air over the Sargasso Sea[4] were $\sim 0.42 \times 10^{-16}$ g cm^{-3}.

The role of sublimation in dispersing chemical species around the Earth in the major sedimentary cycle may be significant for such elements as mercury, selenium and arsenic. Weiss *et al.*[6], from rain and atmospheric analyses, suggest that the amount of mercury entering the atmosphere from the degassing of the lithosphere is $\sim 0.25 \times 10^{11}$–1.5×10^{11} g yr^{-1}. The flux of mercury from the continents to the oceans in rivers appears to be much less than that of the continents to the atmosphere. The former flow is estimated to be $\leqslant 3.8\times10^9$ g yr^{-1}. Weiss *et al.*[6] also surveyed man-made mercury pollution. Most probably comes from sulphide mining, which could give a flux of 2×10^9 g yr^{-1}. Thus natural degassing may be a primary path of mercury from the continents to the atmosphere and thence to the oceans.

Atmosphere particulates, collected from the northern, equatorial and southern Atlantic Ocean, southern and eastern China Sea, and various coastal localities, have concentrations (on a gram per gram basis) of Pb, Zn and Sn which are one order of magnitude higher than those in average crustal materials[7], which may be attributed to an anthropogenic source. These three elements could, however, be introduced also by natural degassing, as many of their compounds are volatile.

There is other evidence to support the volatility hypothesis. A large number of Cu and Pb minerals are associated with fumarolic incrustations compared with the number of Mn and Ni minerals[8], and high values of Cu and Pb were, in general, found in atmospheric emissions from Hawaiian volcanoes[9]. Also, anomalously high concentrations of Cu, Pb and Zn were observed in rain which fell in the vicinity of sulphide ore deposits in the Maritime Province[10]. The rain presumably collected these metals from the atmosphere. I note also that rain can introduce halide ions to rock surfaces. The possible formation and subsequent volatilisation of heavy metal halides can enhance rock volatility in as much as such species have higher vapour pressures than their oxides, carbonates and silicates. The relative volatilities of substances have been used to explain the compositions of lunar soils[11].

It therefore would be valuable to determine experimentally the vapour pressures of heavy metals from a suite of common rock types. Such results might lead to more sophisticated field studies to ascertain the role of rock volatility in the major sedimentary cycle and the influence of such processes on the composition of surface seawaters. The upper levels of the mixed layer may receive spikes of volatile chemical species from the continents through rain, whose effect on biological processes could be significant.

Changes in Canadian national visibility

MAN-MADE pollution can have important effects on public health and the climate[1–3]. The latter, particularly, is a long term effect, and necessitates long term study over wide areas. Here we report the measurement of one relevant

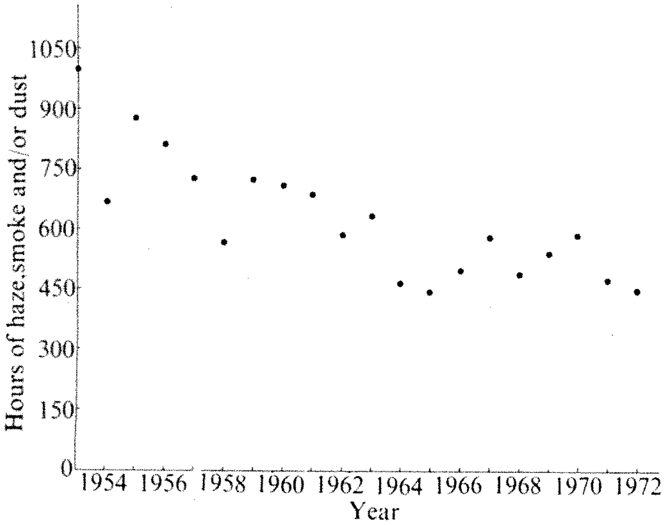

Fig. 1 Weighted average hours of haze, smoke and/or dust per year for major Canadian cities. The data were weighted by the metropolitan populations.

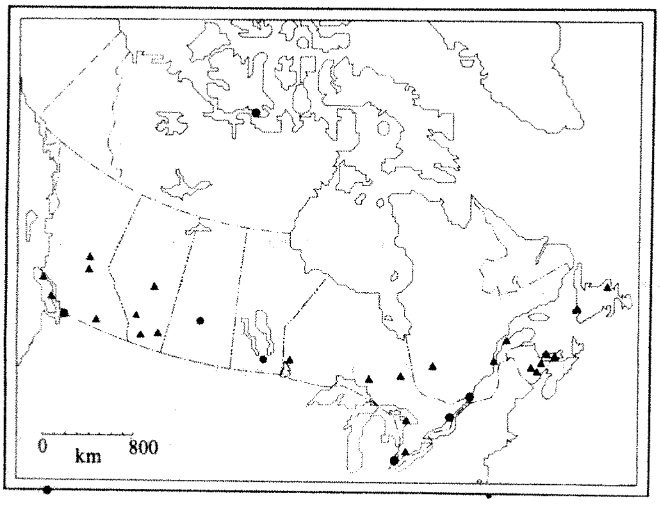
parameter, visibility, at Canadian airports. There are more than 70 usable sets of data. We have found that from 1953 to 1963 there was a general increase in visibility, but, since that date the visibility has remained roughly constant. We attribute both effects to pollution.

Previous work on time trends in visibility and related variables (such as atmospheric turbidity) have generally been limited to a small number of stations and for a short period of time (ref. 4 and other references available on request). Because the data were taken at many different times and places, it is difficult to draw statistically sound judgments on large scale trends. Holzworth (unpublished) has been one of the few to evaluate this quantity on a national basis (for the USA), and determined that visibilities did not deteriorate significantly over a period of ~ 15–20 yr.

Visibility may be affected by a number of pollutants, or change naturally. For example, decreases in visibility have been associated with the presence of ammonia, sulphates, and nitrates[5,7], as well as smoke and other particulates, and models of the relationship of pollutants to visibility have been devised[8]. Visibility measurements themselves have limitations as indicators of pollution levels, because of the effects of humidity, winds and other atmospheric conditions. The difficulties have been carefully discussed by Miller *et al.*[9] and Charlson[10].

Fig. 2 Points with steady increases or decreases in the number of hazy hours for the period 1953–72. The Spearman rank correlation test was used. Others, not showing a steady trend, are excluded. ▲, An increase; ●, a decrease.



There are several ways of evaluating any such trends. To take into account how humans, rather than geographical areas, are affected by changes in visibility, we have weighted the results for each city by its metropolitan population. This was done in computing the points in Fig. 1. The 17 cities included comprise, as of the last census, about half the national population. Other ways of calculating average visibility, for example by dividing observation hours by cumulative miles of visibility (excluding hours in which precipitation occurred), give very similar results to Fig 1. (ref. 11).

Figure 1 indicates that for major Canadian cities, the visibility tended to improve from 1953 to about 1963, when it tended to level off. A pair of lines of regression, both with 1963 as an end point, were calculated. The 1953–63 line had a slope about six times that of the later period.

To find effects on visibility over a wide area, rather than that in cities, we have considered the results of all 71 stations, most of which are not near large cities. For analysis, the Spearman rank correlation method was used, with the annual number of hazy hours compared year by year. Those stations whose change was statistically significant at the 0.05 level are shown in Fig. 2; others are excluded. Large areas, relatively less populated, show a steady increase in hazy days. While some large cities and one northern station have apparently increased their visibility over the two-decade period, the nation as a whole has not shown this trend.

While the visibility at major Canadian cities improved over the first decade of the period considered, there was little or no improvement in the second decade. The explanation for the left-hand portion of Fig. 1 is probably the replacement of coal with less obviously polluting fuels like oil and natural gas; the same phenomenon has been observed in the UK[12] and elsewhere. The post-1963 results are probably caused by a combination of the increased use of all fuels and slight decreases in the amount of pollutants per unit of energy produced. These changes have occurred without national laws on the subject, in contrast to the UK.

The fact that 24 stations of the total of 71 showed a steady increase in haze indicates that visibility outside the metropolitan areas is not improving. This may arise from a worldwide decrease in visibility of an order too small to show up in Fig. 1. The difference between the metropolitan and non-metropolitan trends may explain divergent opinions[13,14] about similar atmospheric data.

The changes described here can induce significant climatic changes. In turn, climatic changes may produce alterations in visibility. By using similar data, we may eventually be able to judge the relationship of world visibility changes to the world climate.

I thank Derek Winstanley for useful suggestions.

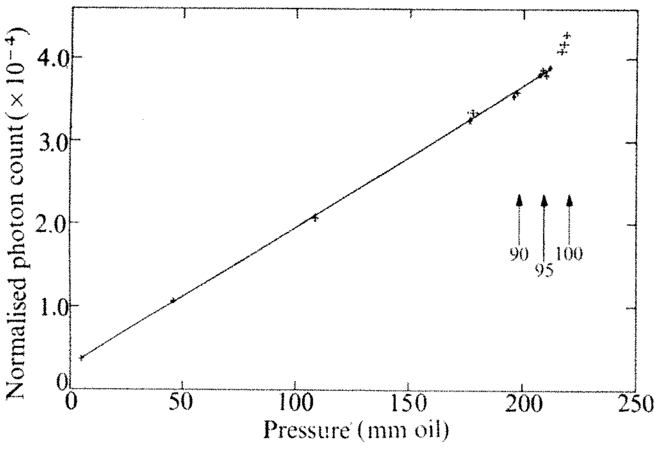
Light-scattering experiments on water vapour at pressures approaching saturation

THE existence of dimers in water vapour at pressures approaching saturation has been postulated for some years and a number of observations have been interpreted in terms of them[1-4]. The relative dimer concentration is expected to increase sharply with increasing percentage saturation and decreasing temperature[1,3]. From speed of sound measurements, a dimer concentration of 8 parts per 10^3 has been reported at 50 °C and 90% saturation[3]; this might be expected to increase to $>20‰$ at 95% saturation and 20 °C. It may be supposed that the polarisability of the water dimer will be considerably larger than that of the monomer, and therefore, using an assumed value for polarisability, an estimate of the dimer concentration at a given temperature and vapour pressure can be made by comparing the quadratic term in a plot of the light scattered as a function of pressure with the known second virial coefficient. In early experiments, using a large multi-pass scattering cell, a very large quadratic term was observed. This arose, however, largely from a rapid increase in the elastic scattering from water-contaminated surfaces as the vapour pressure in the cell approached saturation. We have now eliminated this spurious scattering by selecting spectroscopically only those photons which exhibit a frequency shift due to Brillouin and Raman scattering.

In these experiments two particular difficulties were found: elimination of parasitic light by spectral analysis leads to a large reduction of an already weak signal, and the peculiar problem of reliable pressure measurement with water vapour. Because of surface adsorption, the pressure changes considerably after charging a system with vapour. It was found that long periods, often >1 h, were required before 1% stability could be established in our cell. The consequently long experimental periods thus necessitated very good stability of optics and laser power and constancy of detector response. (For a discussion of high precision photon counting applied to light-scattering studies see ref. 5.)

In our experiments the beam from an argon ion laser (300 mW; 488.0 nm) was directed through a small cell, containing variable amounts of water vapour, and light scattered at 90° to the beam (containing Raman, Brillouin and Rayleigh components) was detected after passing through a confocal, piezo-electrically scanned, Fabry–Perot etalon of free spectral range 375 MHz and finesse ~ 60. The photon counts were registered in a multi-channel analyser. Frequency-shifted light, scattered from the vapour, was selected by counting only photons between Rayleigh peaks. A reference beam, using the same collection system and detector served as a monitor from which small corrections could be made for fluctuations of laser power or detector sensitivity.

Fig. 1 Variation of inelastic scattered light with water vapour pressure at 20.2 °C. A least-squares parabola (indistinguishable from a straight line at this scale) is fitted to the data points up to 95% SVP. Error bars indicate s.d. in photon counts and observed pressure variations. Arrows indicate % SVP.



A representative set of results is shown in Fig. 1 with a least-squares quadratic fit to all data points up to and including the cluster of four observations close to 95% saturation vapour pressure (SVP). The parabola is of the form $S = aP + bP^2$ (where S = photon count and P = pressure) and we find the quadratic term (bP^2/aP) has the value of $2.2 \pm 1 \times 10^{-3}$ at 95% SVP. Values of the second virial coefficient B in water vapour, and its division between a van der Waals' component B_1 and a 'dimer' component B_2, have been given in ref. 4. These suggest that at 95% SVP and 20 °C, $\sim 0.45 \times 10^{-3}$ of the quadratic scattering can be attributed to the increased concentration of monomers because of the van der Waals' attraction (B_1); the remainder $1.75 \pm 1 \times 10^{-3}$ must be attributed to scattering from dimers. The assumption that scattering from a dimer is twice that from the monomer leads to a fractional concentration of dimers of $0.88 \pm 0.5 \times 10^{-3}$—an order of magnitude less than the earlier reported values[3]. On the other hand, the values of B_2 given in ref. 4 would suggest a fractional dimer concentration of only 0.82×10^{-3} at 20 °C and 95% SVP —a value supported by our light-scattering measurements. Alternatively, by adopting this latter value for the concentration, we can calculate the scattering from a dimer as 2.2 times that from a monomer—a figure which is probably quite reasonable in consideration of the likely polarisability of a linear or chain-like dimer[7]. Our experiment consisted of a search for small effects in quasi-elastic scattering, and its accuracy is limited by the peculiar problems of working with water vapour. It seems likely that a Raman scattering experiment should be more definitive, with the possibility of associating specific spectral features with the water dimers.

In conclusion, we note that Fig. 1 shows a number of readings at, and very close to, SVP. In these observations it is likely that significant condensation occurred in the cell, and that small (<0.2 °C) temperature fluctuations during each experiment contributed significantly to small pressure variations. Owing to the possibility of water droplet formation on the windows these results must therefore be interpreted with caution in spite of our monitoring technique. One might, however, expect relatively large concentrations of dimers and multimers at SVP and, as a consequence, the increased scattering which is observed.

Major magmatic activity as a key to predicting large earthquakes along the Sagami Trough, Japan

MIHARA-YAMA is a basaltic stratovolcano on Oshima, an island lying about 20 km off the coast of Izu Peninsula in central Japan (Fig. 1). I attempt here to show that the magmatic activity of Mihara-yama could be used to predict

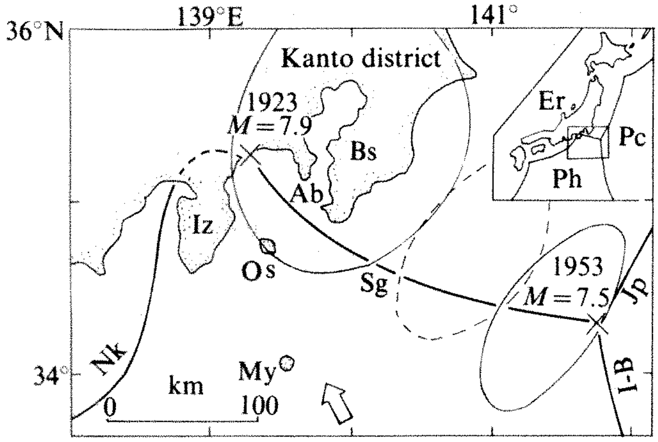

Fig. 1 Large earthquakes that have occurred along the Sagami Trough during this century. The aftershock area is enclosed within the solid line, and the seismicity gap is enclosed within the broken line (see ref. 6). ×, Epicentre of the large earthquake; arrow, direction of slip of the northern Philippine Sea Plate[3]; Sg, Sagami Trough; Nk, Nankai Trough; Jp, Japan Trench; I-B, Izu-Bonin Trench; Os, Oshima; My, Miyakejima; Ab, Aburatsubo; Bs, Boso Peninsula; Iz, Izu Pensinula. Inset: Ph, Philippine Sea Plate; Pc, Pacific Plate; Er, Eurasian Plate.

large earthquakes along the Sagami Trough. There is apparently a causal relationship between eruptions of Mihara-yama and the earthquakes.

The floor of the summit crater of Mihara-yama rose approximately 400 m before the Great Kanto Earthquake of 1923 ($M=7.9$) and the Bosooki Earthquake of 1953 ($M=7.5$), (see ref. 1). Both earthquakes occurred along the Sagami Trough, which extends from the Japan Trench, 180 km south-east of the Boso Peninsula, through Sagami Bay to the city of Odawara on the coast (Fig. 1).

The Sagami Trough forms a border between the Philippine Sea Plate and the Eurasian Plate (ref. 2 and Fig. 1). It is a right-lateral fault with an underthrusting component[3] indicating subduction of the Philippine Sea Plate. Stress between the two plates causes seismic activity along the trough. I have noticed that subsidence of the southern Kanto district around Aburatsubo occurs concurrently with a north-westerly movement of the Philippine Sea Plate. Marked drops in the altitude of the area were recorded before the earthquakes of 1923 and 1953. Further, on both occasions, as the land mass dropped, the floor of Mihara-yama's summit crater rose as much as 400 m, and the volcano erupted.

The earthquakes occurred almost concurrently. The crater's floor fell when the Aburatsubo area rose again after the earthquakes (Fig. 2). It has been suggested that the magma is squeezed up by the compressional crustal strain[1]. I conclude therefore, that the increased compressional crustal stress along the trough forces a downward movement of the Aburatsubo area and squeezes up the magma beneath Mihara-yama, and that, consequently, large earthquakes occur to release strain along the trough. Such activity is regarded as one contributing factor to a major eruption and earthquake.

Mihara-yama's volcanic activity is apparently related to that of Miyakejima, a volcanic island about 80 km south of Oshima. When crustal stress builds up along the trough, Miyakejima begins a cycle of activity of volcanic earthquakes with three frequency maxima, erupting during the second maximum (Fig. 3). Volcanic earthquakes result as stress concentrates beneath the smaller volcano. The stress, though not strong enough to trigger a major eruption of Mihara-yama, does stimulate activity beneath it. In fact, when Miyakejima erupts, a minor eruption occurs on Mihara-yama. When Mihara-yama erupts, all volcanic activity on Miyakejima stops. This implies that strain is first released on Miyakejima, and then accumulates under Mihara-yama. This is a major contributing factor in causing Mihara-yama to enter the active stage. Miyakejima last erupted in 1962. Mihara-yama began its first maximum in 1970; it will probably end sometime in 1975 (Fig. 3).

During the past 200 yr, four large eruptions have occurred on Miyakejima, followed by large eruptions on Mihara-yama at intervals ranging from 2 to 17 yr after activity was first noted on Miyakejima. Large earthquakes followed the eruptions of Mihara-yama within 3–11 yr (ref. 4). Since Miyakejima erupted in 1962, and since Mihara-yama has almost completed its first maximum, we can safely assume

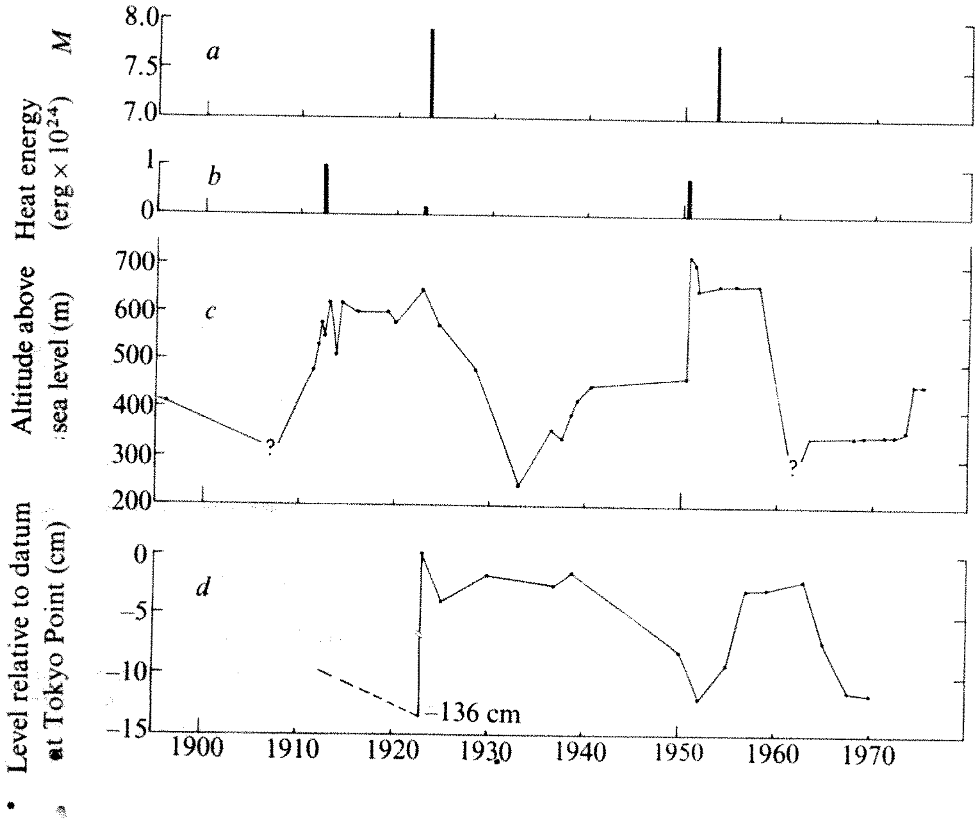

Fig. 2 Relationship between large eruptions, changes in level of floor of summit crater of Mihara-yama, and large earthquakes that have occurred along the Sagami Trough. *a*, Record of large earthquakes along the Sagami Trough (used magnitude data were officially determined by the Japan Meteorological Agency); *b*, heat energy discharged by large eruptions of Mihara-yama[1]; *c*, changes in levels of floor of the summit crater of Mihara-yama (ordinate shows the height above sea level; levelling data to 1958 from refs 7 and 8, after 1958, collected by author); *d*, changes in level at Aburatsubo (solid line measured with precise levelling relative to datum at Tokyo Point[9], and the broken line was deduced from tidal data[10]).

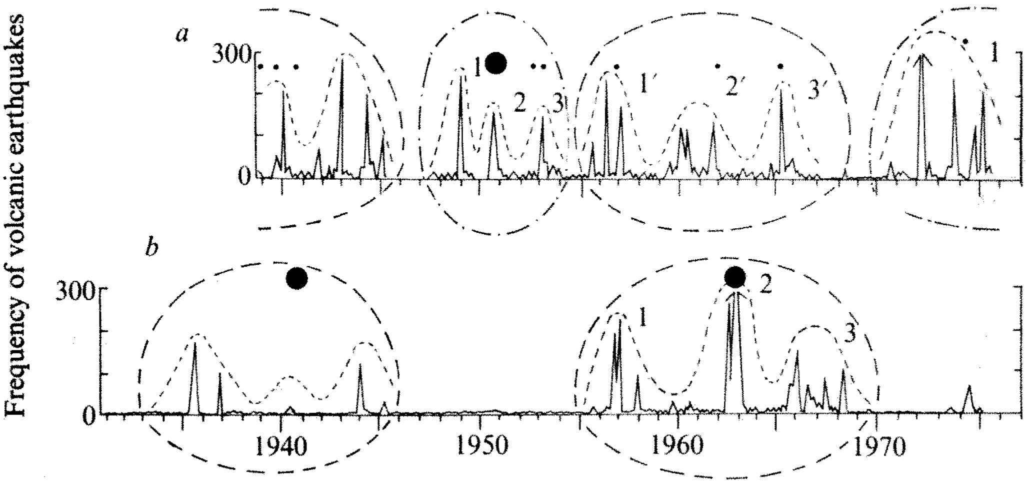

Fig. 3 Relationship between volcanic earthquakes and eruptions in Oshima (*a*) and Miyakejima (*b*) (data from the Japan Meteorological Agency). ●, Eruption points (large dots represent large eruptions; smaller dots represent smaller eruptions which ejected essential magmatic materials). that it will erupt sometime between 1975 and 1979. In fact, in 1974 I observed a 100-m elevation of the floor of Mihara-yama's summit crater (ref. 5 and Fig. 2*c*).

Thermoluminescence of magnesium oxide

MAGNESIUM oxide containing impurity levels of 130–1,400 p.p.m. Ni was investigated for use as a γ-radiation dosimeter, and compared with the widely used LiF (TLD-100). Other samples of MgO containing B, Cr, Fe and Co were also tried but none possesses the required characteristics. It has previously been shown[1] that MgO is suitable for neutron dosimetry when thermally stimulated exo-electrons (TSEE) are used.

The atomic number of MgO is relatively high by comparison with LiF, but this is useful since if the two materials were used in conjunction, it would provide a means of energy discrimination. MgO is also relatively cheap.

Samples of all the MgO types were first exposed to 1 kr. of ^{60}Co γ radiation, and the thermoluminescence (TL) colour observed by eye. A blue colour, suitable for matching the response of the photomultiplier tube in use, was only obtained from Ni-activated samples. Glow curves were then obtained after exposure to 100 r. of the same radiation[2]. The most marked difference between the glow curve of MgO containing Ni and that of pure MgO (ref. 3) and MgO containing other impurities[4], is the presence of a glow peak from 270 °C–320 °C; the peak tends towards the lower temperatures as the exposure is increased. The integrated TL from 75 to 325 °C was obtained for the complete range of nickel impurity concentration and indicated that 370 p.p.m. was the optimum value (Fig. 1). This material was found to have a linear response over the exposure range of 100 r.–100 kr. It was further found that the high temperature peak remained prominent after 14 d at 76 °C, when ~ 40% of the total TL still remained. The The fading of all MgO peaks was considerable (Fig. 2) where samples read out after intervals of 25 h, 9 d and 6 weeks are compared with a LiF TLD-100 extruded chip readout after 6 h. Nevertheless, the previously unreported

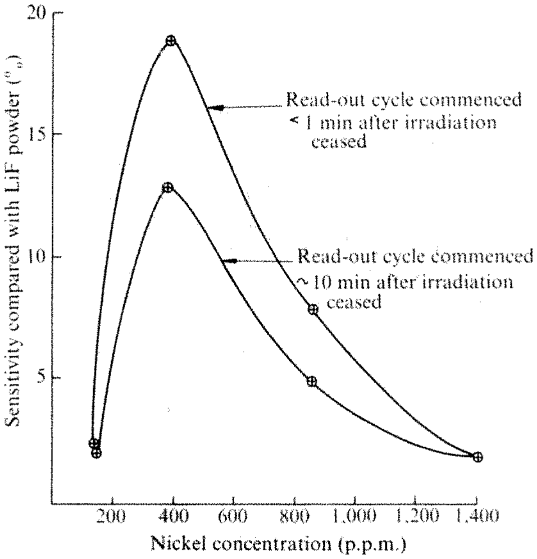

Fig. 1 Variation with concentration of Ni in TL sensitivity of MgO–Ni relative to LiF.

high temperature peak in MgO–Ni could be of use for high levels of radiation exposure measurement. The kinetics of the glow curves, energy level values and luminescence spectra are being investigated.

Influence of magnesium on nickel toxicity

THE influence of calcium in ameliorating heavy metal toxicity towards plants is well known. The possibility that magnesium might possess similar properties, if to a lesser extent, has been largely ignored by ecologists although there are indications in the literature that such is the case[1,2]. We here reaffirm the effect, and point out its ecological significance.

We investigated the growth of oats (*Avena sativa* L. var. Selma) over a wide range of nickel and magnesium concentrations in water culture. We here report in detail one of our experiments in which oats were grown at magnesium levels of 1.25, 2.5, 5.0 and 7.5 mM combined with nickel at 0 and 1.5 p.p.m. The oats were pregerminated and transferred as seedlings to containers filled with 1.6 l of culture solutions. The culture solutions contained, in addition to the experimentally varied levels of $MgSO_4$ and $Ni(NO_3)_2$, 1 mM $NH_4H_2PO_4$, 6 mM KNO_3, 0.5 mM $Ca(NO_3)_2$, 7 mM $NaNO_3$, 0.1 mM NaCl, and, as micronutrients, 90 µM NaFeEDTA, 46 µM HBO_3, 9.1 µM $MnSO_4$, 0.76 µM $ZnSO_4$, 0.32 µM $CuSO_4$, 9.1 µM $(NH_4)_6Mo_7O_{24}$. The *p*H was adjusted to 5.2 at each weekly change of culture solution.

The experimental layout was of a randomised block design; there were 64 containers in all, each with three oat plants, with 8 blocks for each treatment. The experiment was run for 35 d in a shaded glasshouse with 18 h d^{-1} supplementary light. Individuals were then scored for Ni toxicity symptoms and harvested. They were dried at 75 °C, weighed on a per pot basis, and the results (Table 1) subjected to an analysis of variance which indicated significant main effects of both Ni ($P < 0.001$), Mg ($P < 0.05$) and Ni–Mg interaction ($P < 0.025$).

Figure 1 shows that the characteristic Ni toxicity symptoms (described in detail by Vergnano and Hunter[3]) decreased in severity with increasing Mg concentrations. The dry weight measurements (Table 1) showed no significant difference between the oats grown at 0 p.p.m. Ni and 1.25, 2.5 and 5.0 mM Mg. The fall in yield at the 7.5 mM level is presumed to result from an excess of Mg. In contrast, there were marked increases in weight over the range 1.25–5.0 mM Mg at 1.5 p.p.m. Ni. This experiment, and a number of others not reported in detail here, show that Ni toxicity can be ameliorated by increasing Mg levels. (We have no evidence that sulphate anions influence Ni toxicity over the concentration ranges used.)

Table 1 Mean dry weight ± s.e. (g) of oat plants grown in culture solutions with differing magnesium and nickel levels. We have, for brevity, combined root and shoot data: their response is similar, although the Ni–Mg interaction is more marked for the roots

Mg (mM)	Ni (p.p.m.) 0	1.5
1.25	2.01±0.19*	0.83±0.17
2.50	1.99±0.17	1.21±0.17
5.00	2.02±0.17	1.62±0.17
7.50	1.38±0.17	1.35±0.17

*Mean of seven observations only.

A further aspect of the influence of Mg on Ni toxicity was shown in an experiment using very high levels of magnesium (25 and 40 mM) with high levels of nickel (5 and 10 p.p.m.). At 40 mM magnesium the plants were very badly stunted, but showed no symptoms of the toxicity of Ni, and were indistinguishable from plants subjected to the same high level of Mg with no Ni. At 25 mM Mg, the toxicity symptoms of Ni were completely suppressed at the 5 p.p.m. Ni level, but were visible to a small extent at the 10 p.p.m. level.

Further work is in progress to investigate the means by which Mg ameliorates Ni toxicity, but it seems worthwhile to comment on the ecological significance of these preliminary observations. Serpentine soils very often contain high levels of Mg and relatively large quantities of Ni, and many authors have used oats as a bioassay for the presence of toxic levels of Ni in these soils[4,5]. The failure to detect Ni toxicity in a number of such soils (ref. 4 and J.P., unpublished) in spite of evidence that appreciable quantities of Ni were present, may arise partly from the influence of high levels of Mg. The use of oats as a bioassay for Ni toxicity can now be seen to involve an oversimplification of the soil situation and assumes that the Ni–Mg interaction is similar for other species.

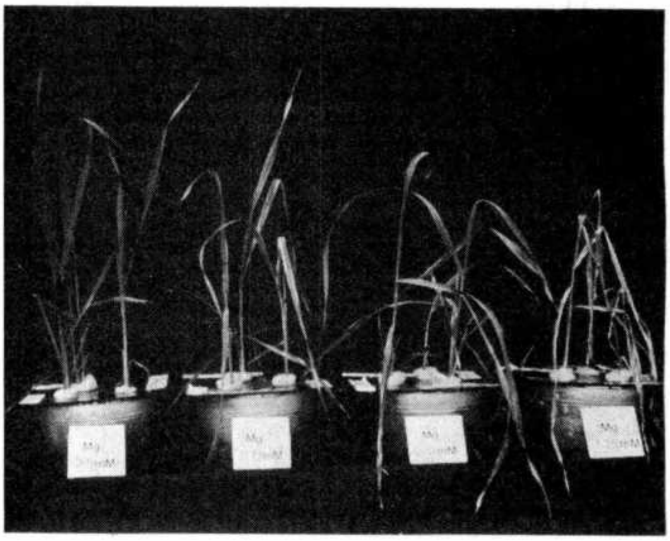

Fig. 1 Increasing symptoms of nickel toxicity in oats with decreasing levels of magnesium (from left to right: 7.5; 5.0; 2.5; and 1.25 mM).

The response to Mg of other Ni-sensitive species remains to be investigated, but we feel a consideration of Ni–Mg interactions must be involved in future studies on serpentine soils.

We thank Mr D. Machin for statistical help, and the staff at the glasshouses of the University of Stirling for their help in maintaining the water cultures.

Interoceanic differences in vulnerability of shelled prey to crab predation

SHELLED gastropods living on intertidal open rocky surfaces exhibit various shell features which can be interpreted as adaptations against such shell-breaking predators as fishes, spiny lobsters, and crabs. These anti-predatory devices include strong external shell sculpture, elongate or dentate apertures and low spires[1]. Not only are these characteristics more common among tropical species compared with ecologically similar cold-water forms, but within the tropics they are more prevalent and better developed in the Pacific and Indian Oceans than in the Atlantic[1,2]. Any or all of three conditions must obtain in areas with a high incidence and strong development of anti-predatory armour compared with areas where such armour is reduced: the prey are stronger, that is, the criteria needed by the prey to avoid being crushed are more stringent; the predators are stronger; and shell-breaking predators account for relatively greater mortality. Here I report data confirming the first two of these possibilities.

At the University of Guam Marine Laboratory (Pago Bay, Guam, Mariana Islands), various reef-flat crabs (Table 1) were found to feed readily on shelled gastropods and hermit crabs by crushing them in their massive master claw. Individual crabs were kept in aquaria with aerated or recirculating seawater. The critical size (maximum size of vulnerability) of prey was obtained for individual crabs by offering them a range of sizes of that prey species. The common occurrence in the field of snails whose shells show repair after presumed damage by a predator suggests that shell breakers often attack prey that are too large for them.

Direct comparisons between Guamanian and ecologically similar West Indian prey were made by allowing hermit crabs to inhabit Jamaican shells, which were then offered to the predatory crabs. Shells were collected alive near Discovery Bay, Jamaica; the soft parts were removed and the shells dried in air before being used in Guam 4–9 months later. Shells treated in this way seem to possess mechanical properties indistinguishable from those of living snails[3].

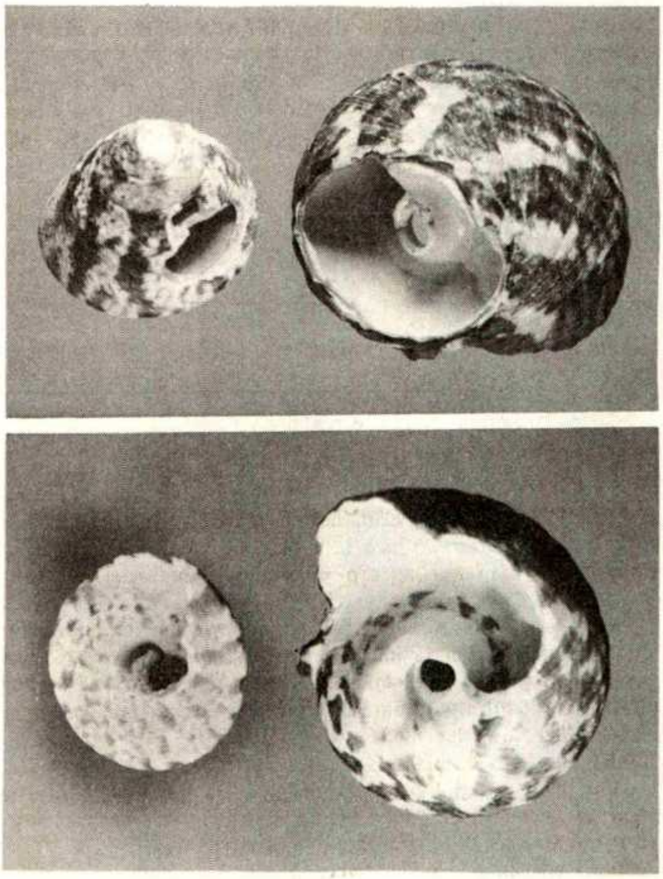

Fig. 1 Shells of the Jamaican *Cittarium pica* (left) and Guamanian *Trochus niloticus* (right) broken by the Pacific crab *Carpilius maculatus*. The two views of each species pertain to the same shell. Photograph by F. Dixon.

Although in most cases not enough shells were at hand to establish the critical size of Jamaican prey, it is evident from Table 1 and Fig. 1 that this critical size is greater than that of ecologically equivalent and taxonomically related Guamanian snails. Since the largest offered specimens of all West Indian species were extensively damaged, it is likely that the critical

sizes of these species are markedly larger than the maximum sizes available in my experiments. Even so, the largest successfully crushed *Cittarium pica* L. are about 1.5 times as large in body-whorl diameter as the Guamanian analogue, *Trochus niloticus* L. The superiority of *Trochus* over *Cittarium* stems in part from its relatively smaller umbilicus and proportionately smaller extent of outer shell wall not supported from within by earlier whorls (Fig. 1). *T. niloticus* also attains a larger adult size (150 mm compared with 110 mm in *C. pica*).

*All intrageneric differences are significant at the 0.01 level or better (Mann–Whitney *U* test) except that for manus thickness between *E. sebana* and *E. smithii*. *E. scrabricula* was not statistically compared with other species, and is included only for completeness.

The Jamaican *Conus mus* Hwass is thinner-walled (Table 1), higher-spired, and more broadly apertured than any Guamanian *Conus* normally found on hard substrata (*C. chaldaeus* Röding, *C. coronatus* Gmelin, *C. ebraeus* L., *C. flavidus* Lamarck, *C. lividus* Hwass, *C. miles* L., *C. sponsalis* Hwass). Among high intertidal species of *Nerita*, the West Indian *N. peloronta* L. and *N. versicolor* Gmelin are thinner-shelled and more vulnerable to predation by the intertidal crab *Eriphia sebana* than the Guamanian *N. plicata* L. (Table 1). The lower intertidal *N. tessellata* Gmelin from Jamaica is smaller and more vulnerable than, but comparable in shell thickness with, its Guamanian analogue *N. albicilla* L. (Table 1)

In other trials, individual crabs were offered hermited specimens of the cold-temperate snail *Nucella lapillus* L., whose North Atlantic crab predators (*Portunus puber* L., *Carnicus maenas* L. and *Cancer pagurus* L.) have been well studied in Ireland[4,5]. Thick-shelled high-spired specimens of *Nucella* were collected in August 1971, from sheltered sites near Boothbay Harbor, Maine. Table 2 suggests that Guamanian crabs can crush larger *Nucella* and are more powerful than similarly-sized Irish crabs.

Among the factors affecting the strength of a crab's master claw is the cross-sectional area of muscle in the manus (that part of the propodus behind the apposing fingers). Both components of cross-sectional area, manus height (dorsiventral dimension) and manus thickness (anteroposterior dimension), were measured on crabs in the US National Museum, Washington, DC. Within the genera *Eriphia* and *Carpilius*, both components of cross-sectional area relative to carapace width are greater among Indo–West-Pacific taxa than in their Caribbean counterparts (Table 3). No differences in manus height or manus thickness could be detected between males and females of either *Carpilius maculatus* or *C. convexus*, but in the other species (Table 3) the manus of the males is higher and thicker than that of the females. Differences between species are preserved even when only females or only males are compared. I found no differences in claw form between different populations of the same species, and there seems to be no allometry of either manus height or manus thickness with increasing carapace width.

In summary, the arms race between Indo–West-Pacific rocky-shore gastropods and their crab predators has progressed further or remains in a more escalated state than in other tropical or temperate regions. Presumably, this high degree of coadaptation is related in part to the great age and stability of the tropical Pacific and Indian Oceans. The applicability of this finding to gastropods in other habitats, and to shell-breaking predators other than the xanthid and parthenopid crabs considered here, remains to be determined.

I thank M. Yamaguchi for allowing me to use his laboratory during the summer of 1975, and E. Zipser and E. Dudley for assistance. Supported in part by the Oceanography Section, National Science Foundation, and by the John Simon Guggenheim Memorial Foundation.

Mechanism for digestion of detrital bacteria by the cichlid fish *Sarotherodon mossambicus* (Peters)

ALTHOUGH many species of fish ingest large amounts of detritus, its nutritional value has been questioned frequently[1,2]. Detritus in marine and freshwater habitats consists of a mixture of plant debris and amorphous organic matter together with associated heterotrophic and autotrophic microorganisms[3]. In detritus which does not contain large amounts of undegraded vascular plant matter, most of the protein is associated with heterotrophic microorganisms[5–8]. This is particularly true in fresh water[9]. Thus, the value of detritus as a food for fish depends to a large extent on their ability to digest heterotrophic microorganisms. It has been suggested that fish which consume detritus may have this ability[4]. Using ^{14}C-labelled bacteria in *in vitro* experiments I have now demonstrated it in *Sarotherodon mossambicus*.

Rapidly growing juvenile *S. mossambicus* (2.0–8.0 cm standard length) in Lake Sibaya (32°40′E, 27°25′S), KwaZulu, feed entirely on benthic detritus which contains large numbers of diatoms, bacteria and amorphous organic material (my unpublished work). Gastric *p*H in specimens examined immediately after capture was measured with test papers (Acilit, Merck) read to 0.25 *p*H units. In stomachs of actively feeding fish, *p*H was consistently below 2.5, with values of 1.5 and 1.25 most common, and occasionally a *p*H of 1.0 was measured. Intestinal *p*H ranges from 8.0 to 8.8 (ref. 10). Residence time of material in the stomach is estimated to be about 1 h. Although gastric *p*H values below 2.0 are very unusual in vertebrates, Moriarty[11] found that the cichlid fish *Tilapia nilotica* in Lake George, Uganda, uses gastric acid below *p*H 2.0 to lyse blue-green algae. Because of the chemical similarity between bacterial and blue-green algal cell walls, it seemed likely that the unusually low gastric *p*H found in *S. mossambicus* would cause lysis of bacteria.

The effect of different gastric *p*H values on the extent of subsequent intestinal digestion of bacteria was investigated in *in vitro* simulations of digestion in *S. mossambicus*. Pooled stomach and pooled intestinal contents of ten actively feeding *S. mossambicus* were centrifuged and the supernatants decanted and stored at −10 °C until required. Protease activity in stomach juice was determined with a sensitivity of 2 μg pepsin per ml by the method of Anson and Mirsky[12]. Detritus was collected from shallow sand terraces in Lake Sibaya, and bacteria in 20 ml of suspended detritus were labelled differentially with ^{14}C-glucose (271 mCi mmol^{-1}) for 1 h at a concentration of 32.4 μg glucose per l. It has been shown that concentrations of glucose below 500 μg l^{-1} are taken up by bacteria but are not high enough to be utilised by algae[13]. Unassimilated ^{14}C label was removed by repeated suspension of the detritus sample in sterile water followed by centrifugation. The detritus was then resuspended in 20 ml of sterile water, and 3 ml of suspended detritus was transferred to each of six centrifuge tubes.

To simulate stomach conditions, hydrochloric acid was added to the detritus in five of the six centrifuge tubes to produce a range of *p*H values from 1.3 to 2.5. To compare acid and enzymatic lysis, lysozyme (2 mg in 2 ml of phosphate buffer, *p*H 6.2, from egg white, Sigma) was added to detritus in the sixth centrifuge tube. The tubes were then stoppered and placed horizontally in a shaking water bath at 25 °C. After 1 h, the six suspensions were centrifuged and the levels of radioactivity in 0.1 ml of each of the supernatants was determined by liquid scintillation counting. The remaining supernatant was discarded.

To simulate intestinal digestion, each detrital pellet was resuspended in 3 ml of intestinal juice at *p*H 8.6. Boiled intestinal juice was used as a control. Release of ^{14}C from bacteria was monitored by centrifuging the suspensions periodically and determining radioactivity in 0.1 ml of each of the supernatants. After sampling, the pellets were resuspended quickly and the tubes were returned to the water bath.

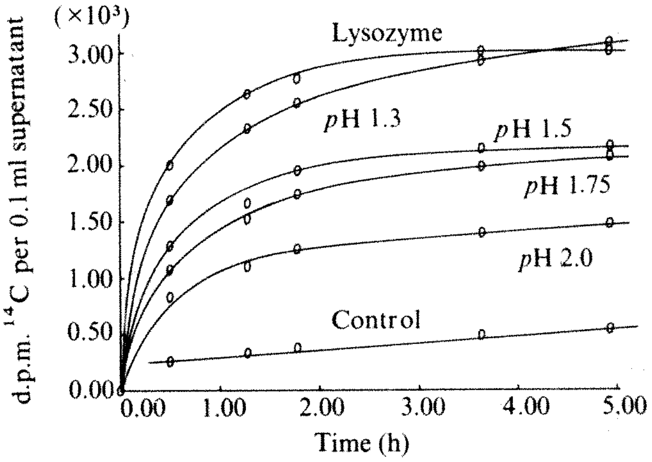

Fig. 1 Radioactivity released from bacteria during treatment with intestinal juice after acid treatment at *p*H values shown. Data given are experimental minus control with correction for volume reduction caused by sampling.

No label was released from bacteria during treatment with HCl, but after 30 min subsequent treatment with intestinal juice, large amounts of label were released relative to the control. Label continued to be released for up to 3.5 h, but no significant additional release was found thereafter. The total amount of label released was indirectly proportional to *p*H during treatment with HCl such that the activity released from bacteria treated at *p*H 1.3 was twice that released from bacteria treated at *p*H 2.0 (Fig. 1). The amount of label released from bacteria treated at *p*H 1.3 was similar to that released from bacteria treated with lysozyme. These results show that exposure to low *p*H lyses bacteria with an efficiency comparable with that of lysozyme and thus makes bacterial cell contents available to digestive enzymes in the intestine.

Gastric *p*H conditions required for bacterial lyses would be expected to be unfavourable for gastric enzymes. The normal *p*H of actively digesting vertebrate stomachs is approximately 2.0 and gastric enzymes usually show optimal activity at *p*H 2 or above. Fish[10] and Nagase[12] report *p*H optima of 2.2 and 2.8 respectively for protease from the gastric mucosa of *S. mossambicus*, with greatly reduced activity at lower *p*H. Pooled stomach juices from the ten *S. mossambicus* used in this experiment had a *p*H of 1.75 and no protease activity was detected. Moriarty[9] found a similar lack of enzyme activity in the stomach of *Tilapia nilotica* which use gastric acid to lyse blue-green algae. These results suggest that gastric enzymes are not secreted when gastric *p*H would result in enzyme activities well below optimum.

Of the four important groups of fish which feed on detritus; *Chanos chanos*, mullets, carps and tilapia (including *S. mossambicus*), only tilapia have true stomachs with gastric glands[14]. Thus, the mechanism for lysis of detrital bacteria reported here is probably unique to the tilapia, and other mechanisms may await discovery in the other groups.

I thank Professors B. R. Allanson, and J. C. van Hille, and Drs J. R. Moss and I. Railton for critically reviewing the manuscript and Mr S. Robertson for the protease assay.

Mescaline as a mitotic spindle inhibitor

COLCHICINE and its methyl derivative colcemid not only inhibit microtubule self-assembly[1] but also affect fast transport in nerve[2]. A report that mescaline likewise inhibits the rapid component of axoplasmic transport in nerve[3], led us to investigate the effects of this drug on mitosis, and on purified microtubule protein (tubulin[4]). The structure of mescaline does resemble an abbreviated version of colchicine (Fig. 1). We report here that mescaline can, like colcemid, be used as a mitotic spindle inhibitor and has certain advantages as a cytogenetic reagent.

We first investigated the effect of a range of concentrations of mescaline from just above to just below the limits at which concentrations of colcemid exert an inhibitory influence on mitosis. When human skin fibroblasts are cultured in small dishes, the dividing cells round up so that by mid-metaphase they stand out in marked contrast to the flat cells with a polygonal outline characteristic throughout interphase. If the rounded cells are examined using Nomarski interference optics[5], they can be seen to be in division as one can distinguish the chromosomes in the live cell (Fig. 2). By simply counting the number of rounded cells in a dish, under an ordinary dissecting microscope, one can score any compound for its effect as a mitotic inhibitor.

This first series of experiments (Fig. 3) showed that mescaline was similar to colcemid in its effectiveness. At the higher concentrations, cells treated with colcemid showed some signs of a toxic effect (detachment); those treated with mescaline did not.

A second series of experiments (Fig. 4) designed to study the time course of events up to 24 h after the inoculation of fibroblast cultures with mitotic inhibitors, showed that mescaline is metabolised rather readily, giving a peak of inhibition at 4 h followed by a plateau of moderate inhibition. The first breakdown product of mescaline in human brain is *N*-acetylmescaline[6]. We synthesised this compound, and found that it acts in our experimental system as a moderate inhibitor of mitosis. We therefore attribute this plateau effect to the metabolite *N*-acetylmescaline. Colcemid was also metabolised, but more slowly. It is likely that the first step in this process is the demethylation of a methoxy group in ring A of the molecule, as reported for colchicine in mammalian liver[7,8]. Results with 1,4-dichlorobenzene, which is known to be an effective inhibitor of mitosis in plants[9], gave no indication that this agent is metabolised at all.

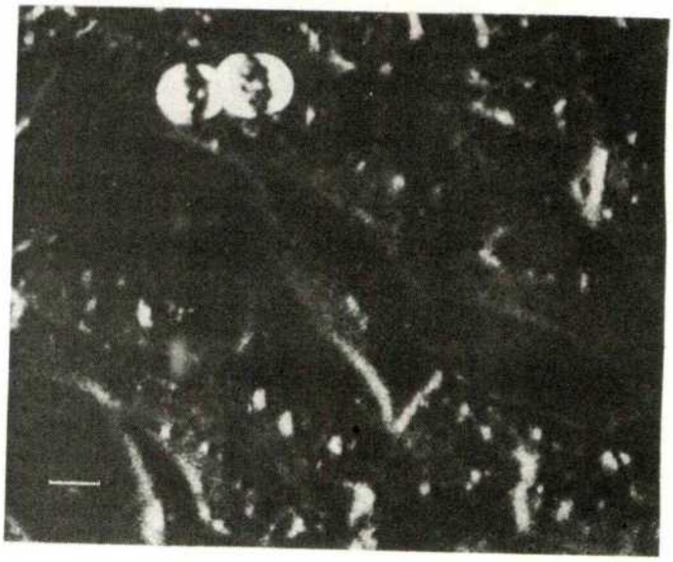

Fig. 2 Nomarski interference image of cells in division. Cells at the top left are in anaphase, with the chromosomes visible on the spindle. The rounded appearance of the dividing cells is in marked contrast with the polygonal interphase cells seen below. The micrograph shows the progress of division past metaphase in the absence of any drug treatment. Bar indicates 20 μm.

Our conclusion is that mescaline could be used as a mitotic inhibitor for use in cytogenetic work. Our observations with a variety of human and other mammalian cells show that this drug produces well-spread metaphases suitable for examination by banding techniques (Fig. 5). Mescaline has the advantage that it is 1,000 times less expensive to purchase than is colcemid; it has the disadvantage that its use is controlled by drug legislation.

Our experiments with radioactive mescaline demonstrated that it binds to purified microtubule protein. Like colchicine, it also inhibits the assembly of tubulin subunits to form microtubules. The implications of these findings should be of some general interest. Mescaline is a catecholamine-like neurotransmitter analogue. Its effects on tubulin raise the possibility that neurotransmitters or their

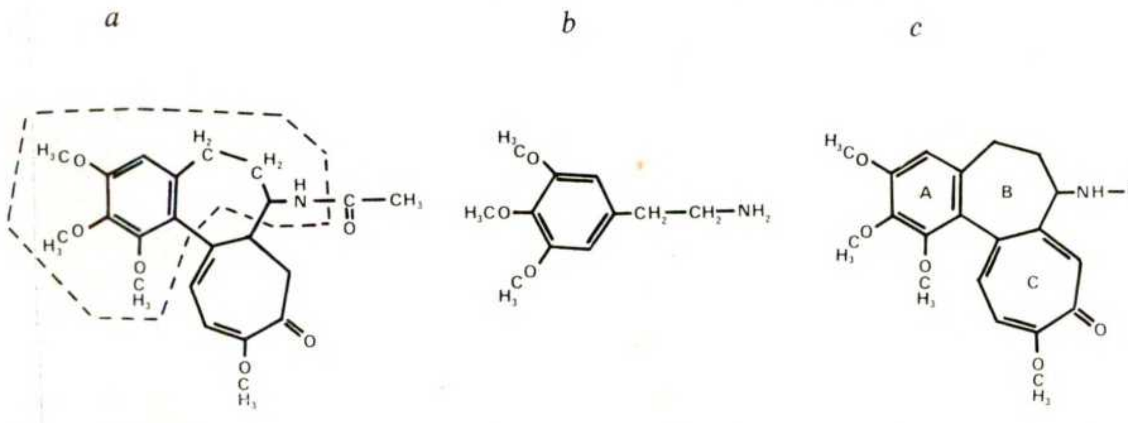

Fig. 1 Structure of spindle inhibitors. *a*, Colchicine; *b*, mescaline; *c*, colcemid. Dotted line indicates the portion of the colchicine molecule to which mescaline would seem to correspond.

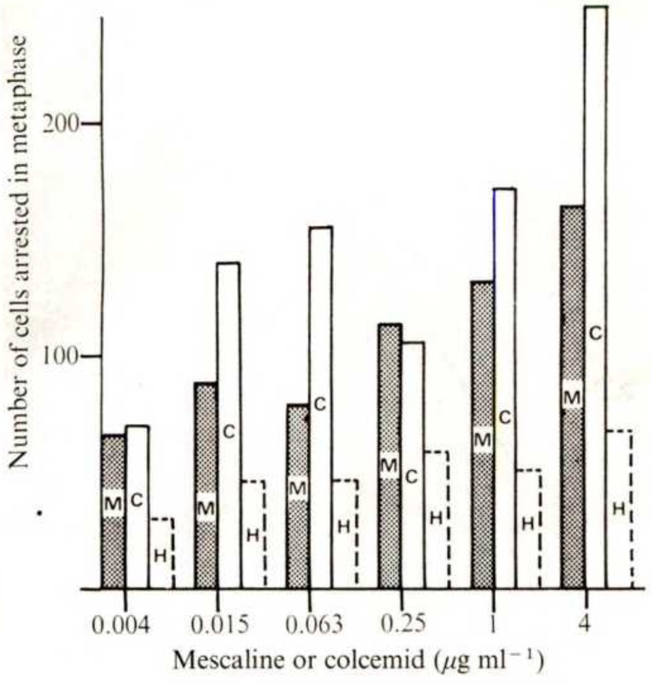

Fig. 3 Comparison of dose responses of human skin fibroblasts to mescaline and colcemid. Cells (2×10^4 per 3-cm Petri dish) were plated out, fed with fresh medium the following day, and exposed to the spindle inhibitors at the dosages indicated. Cell counts were begun 2 h after the start of the treatment and are expressed as the average of a forward and a backward count through the series of dishes. Slight effects of cooling and disturbance are reflected by minor increases in counts in the control dishes. Cells rounding up due to toxic effects at high dosage of colcemid may make some contribution to the count at 4 μg colcemid ml^{-1}. M, Dishes given mescaline in 0.1 ml Hanks' balanced saline; C, dishes given colcemid in 0.1 ml Hanks' balanced saline; H, control dishes given 0.1 ml Hanks' balanced saline.

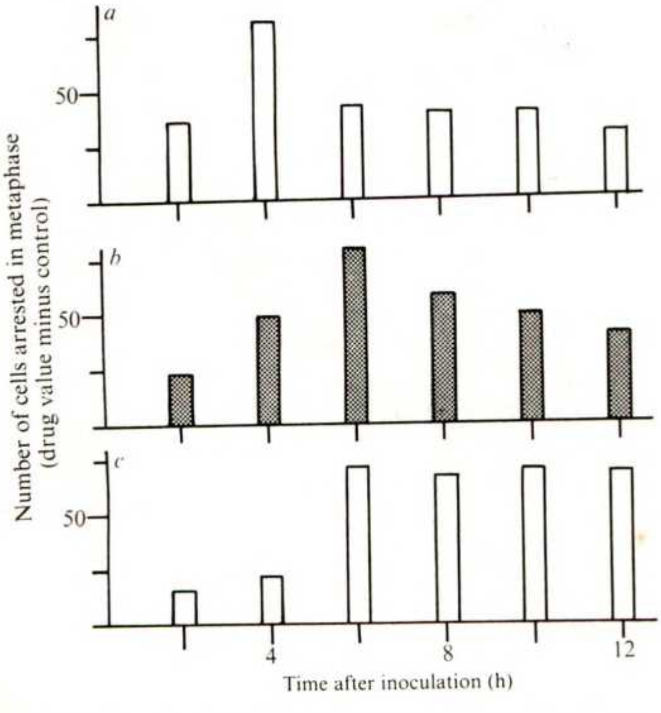

Fig. 4 Time course of effects of spindle inhibitors on human skin fibroblasts. Cells were plated out as in Fig. 3. Counts were made once on each of six sets of dishes at 2 h intervals, each set included a control inoculated with Hank's balanced saline, a dish with colcemid (*a*) at 4 μg ml^{-1}, a dish with mescaline (*b*) at 5 μg ml^{-1}, and a dish inoculated with 0.1 ml saturated solution (*c*) of 1,4–dichlorobenzene in Hanks' balanced saline.

metabolites may have a separate role additional to their effect at the cell membrane—regulation of the polymerisation state of fibrous proteins within the cell. The biochemical results of this work will be reported separately.

Antibodies to a cell-surface component coded by human chromosome 21 inhibit action of interferon

ANTICELLULAR sera able to block specific cell responses are important in the study of surface receptors. Particularly useful are antibodies against the human cellular antigens coded for by a specific chromosome, which can be prepared by immunising mice with mouse–human somatic cell hybrids containing defined human chromosomes[1]. We have applied this method to the study of the mechanism by which the presence of human chromosome 21 renders such hybrids sensitive to human interferon[2]. Interaction of an interferon with sensitive cells induces intracellular biochemical changes, including the formation of an inhibitor of protein synthesis, making the cell unable to support virus replication[3,4]. We have obtained antibodies to hybrid cells containing human chromosome 21, and these inhibit the response of live human cells to interferon. Our experiments indicate that chromosome 21 codes for a cell-surface component required as a specific receptor for human interferon.

For immunisation, C3H/FcJ mice were inoculated intraperitoneally once a week with 10^7 cells from clone WAVR4d (ref. 5) originating from the fusion of a mouse A9 cell and a human diploid fibroblast WI-38: this clone contains human chromosomes 4, 21 and 22 only. After 4 weeks, immune serum was collected and decomplemented at 56 °C for 30 min. The titre of antibodies was estimated by cytotoxicity tests[6] in the presence of rabbit complement. At a dilution of 1/128 the killing index was 70% on WAVR4d and 20% on mouse A9 cells. At 1/32, they were 90 and 70, respectively. The response to mouse cell was lowest for short periods of immunisation. Adsorption of the antiserum on A9 cells eliminated the mouse-specific reaction, while keeping intact the reaction against hybrid cells. No reaction was seen with hybrids whose human chromosomes do not include 4, 21 or 22. Reaction was observed with HeLa cells. Most important, no cytotoxicity was observed in the absence of complement, which is the condition used in the interferon assay. Human interferon (5×10^4 U ml^{-1}) was prepared in foreskin cells FS4 (given by Dr J. Vilcek) by induction with poly(rI)·poly(rC)[7].

Effects of anti-WAVR4d serum were first studied on the line of hybrid cells used for immunisation (Table 1). These cells contain human chromosome 21 and are therefore sensitive to human interferon (although they require at least 10 times more interferon than normal human cells). Hybrids lacking chromosome 21 do not respond to human interferon. Addition of the antiserum completely inhibits the effects of human interferon on vesicular stomatitis virus (VSV) replication in the sensitive hybrid cells. To establish that the inhibition of interferon's action is due to reaction with human immunodeterminants, we next examined the effect of the antihybrid serum on normal human diploid fibroblasts.

Pretreatment of human foreskin cells FS7, with anti-WAVR4d serum inhibited the antiviral effect of interferon (Fig. 1). At low interferon concentrations, the inhibition of VSV replication is completely abolished after exposure to the antibodies. Excess of interferon can overcome the effects of antiserum pretreatment. At intermediate interferon concentrations, more than 100 times more virus is produced in the cells exposed to the antiserum. The antiserum against hybrid cells containing only few human chromosomes is therefore active also against human diploid cells. Several independent immunisation experiments gave the same results.

The specificity of the anti-interferon effect was investigated after exhaustive adsorption of the antiserum on hybrid cells from lines either $4^+21^-22^+$ or $4^-21^+22^-$. Table 2 shows that the anti-interferon activity of the antiserum is lost only after adsorption on cells containing human chromosome 21. Furthermore, an antiserum prepared against mouse–human hybrid cells containing chromosome 6, 8 and X (but not 21) does not inhibit the antiviral effect of interferon even at high concentrations (experiment 2, Table 2).

Table 1 Effect of antiserum on action of interferon in hybrid cells

Additions	VSV yield in mouse–human hybrids WAVR4d (21$^+$) (log PFU ml^{-1})	JFA16a (21$^-$)
None	7.07	6.23
Interferon, 50 U	4.53	7.08
Anti-WAVR4d serum, 1:64	7.92	—
Antiserum + interferon	7.07	—

Interferon assays were carried out in microplates II (96 wells, Falcon) containing 2.5×10^4 cells per well in 0.1 ml Dulbecco's modified Eagle's medium—10% foetal calf serum (DVME). Incubations were at 37 °C. Antiserum adsorbed on mouse A9 cells (10^7 per ml serum) was added as indicated, followed after 1 h by human interferon. After 7 h, cells were washed and infected with 2.5×10^3 PFU VSV in Eagle's MEM–2% FCS. After 24 h, medium in each well was collected and the VSV titre was determined by the micromethod of Rosenthal and Shechmeister[14]. VSV titres are expressed in log PFU ml^{-1}. Karyotypes of the hybrid cells used were WAVR4d: 4,21,22; JFA 16a: 2,5,11,16,17,18 and 20.

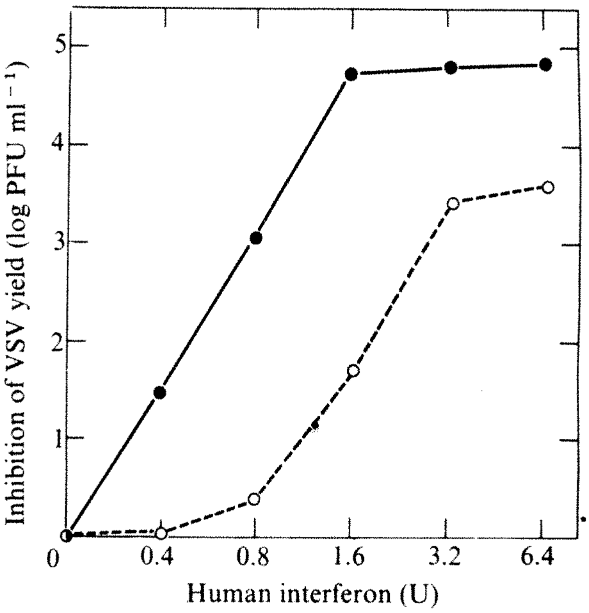

Fig. 1 Inhibition of the interferon effect by antihybrid serum applied to normal human diploid foreskin cells, FS7 (given by Dr J. Vilcek). Assay as in Table 1: to wells containing 2.5×10^4 cells in DVME–10% FCS, anti-WAVR4d serum (adsorbed on 10^7 mouse A9 cells per ml serum) was added at a dilution of 1/128. One hour later, the indicated amounts of interferon were added. After 7 h, cells were washed and VSV growth was measured as in Table 1. The virus yield in log PFU ml^{-1}, without interferon, was 7.28. The reduction in log PFU ml^{-1} VSV, caused by interferon, is plotted. ●, Control; ○, antiserum.

These data strongly implicate chromosome 21 as determining the antigen responsible for the serum's anti-interferon effect. We therefore compared the response of human fibroblasts either monosomic or trisomic for chromosome 21. The results

Table 2 Specificity of anti-interferon effect of antiserum for chromosome 21

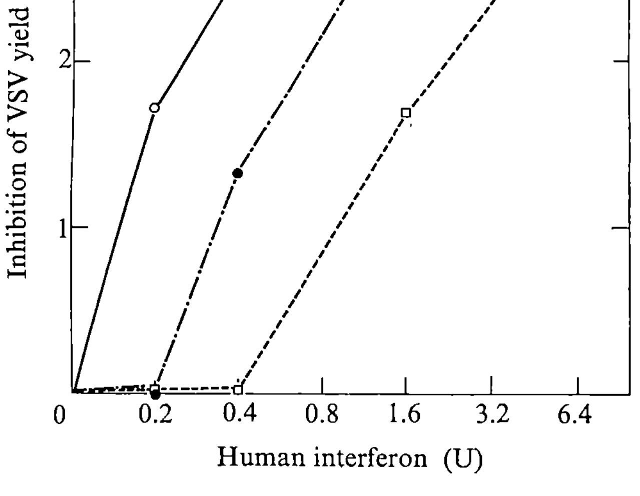
Antiserum used	VSV yield Inhibition by interferon (log PFU ml^{-1})	Antiserum effect
Experiment 1		
(1) No antiserum	3.6	—
(2) With anti-WAVR4d, 1:64 —adsorbed on mouse A9 cells	1.7	1.9
(3) —readsorbed on hybrid $4^+21^-22^+$ cells	1.7	1.9
(4) —readsorbed on hybrid $4^-21^+22^-$ cells	3.4	0.2
Experiment 2		
(5) No antiserum	1.9	—
(6) With anti-Hal-6 serum, 1:16	2.1	0.0
(7) With anti-WAVR4d serum, 1:16	0.0	1.9

Experiment 1: anti-WAVR4d serum was first adsorbed by incubation for 30 min at 25 °C with 10^7 mouse A9 cells per ml of serum diluted 1/32 in protein-free DVME. After centrifuging out the cells, antiserum was either used directly (line 2) or readsorbed at 2×10^7 cells per ml on mouse–human hybrid AIM3a (2,3,4,5,7,10,12,13,14, 17,19,22,X) (line 3) or AHA-16e (3,11,13,21,X) (line 4). Assay as in Fig. 1 with 1.6 U human interferon in 0.1 ml containing 2.5×10^4 human foreskin FS7 cells. Yield of VSV was 7.92 log PFU ml^{-1} without interferon. For experiment 2, mice were immunised with either mouse–human hybrids HAL (6,8,X) or WAVR4d (4,21,22) and the antisera obtained assayed as above. Yield of VSV was 7.08 log PFU ml^{-1} without interferon.

showed that the effect of the antiserum is stronger in monosomic 21 cells and decreases with increasing number of chromosomes 21 in the target cells. Because to produce the same inhibition in VSV replication, the monosomic line had to receive five times more interferon than the trisomic line[8] (Fig. 2), the antiserum effect is clearly determined by the cell and not by the interferon. Together with the fact that the hybrid cells WAVR4d, which served as immunogen, cannot produce human interferon (since they lack chromosomes 2 and 5) (ref. 9), these results enable us to conclude that the anti-interferon effect is due to antibodies directed against a cellular component different from interferon itself. This component, coded for by some gene(s) on chromosome 21, is required for the action of interferon.

Several observations indicate that the antiserum inhibits the action of interferon by combining with a component of the cell surface: (1) the effect is seen with living cells in which only the surface antigens are available for reaction with the antibodies[10]; (2) the inhibition is reversible: excess of interferon overcomes the inhibition caused by pretreatment of the cells with antibodies (Fig. 1); (3) immunofluorescence studies showed that the antiserum used in this work stains the surface of live human fibroblasts. We propose that this cell-surface component coded for by chromosome 21, serves as a receptor for human interferon. This interpretation is supported by the comparison of cells with different doses of chromosome 21. Figure 2 shows that chromosome 21 controls the amount of interferon needed to reach a given level of cell response, but not the final antiviral state achieved with saturating concentrations of interferon. This is expected if some gene on this chromosome codes for a receptor to human interferon; if, on the other hand, it would code for an intracellular antiviral protein (AVP) as suggested[8], the final antiviral state should be higher in trisomic than in monosomic 21 cells. In the mouse–human hybrids, the location of the gene for such an antiviral protein, made in response to interferon, remains undetermined; one possibility is that it needs not to be specifically human but may be a mouse gene.

Fig. 2 Comparison of human fibroblasts monosomic, disomic and trisomic for chromosome 21, in their response to human interferon. Lines GM 258 (trisomy 21) and GM 230 (monosomy 21) were obtained from the National Institute of General Medical Sciences genetic mutant cell repository (Camden). The diploid line was foreskin cells FS4. Interferon assay as in Fig. 1, except that treatment was for 24 h before VSV infection. The virus yield, after 29 h was in log PFU ml^{-1} 6.67 for FS4 and 5.38 for GM 258 and GM 230. ○, Trisomy 21; ●, diploid; □, monosomy 21



Human interferon binds rapidly to human cells[11]. Whether this first binding, which may involve gangliosides[12], triggers the antiviral state is still debatable[13]. We have found recently that even after 3 h of contact at 37 °C between interferon and human fibroblasts, the establishment of the antiviral state is still blocked by our antiserum. This indicates that a prolonged interaction of interferon with cell-surface receptors is necessary to induce the antiviral state. Our antiserum should prove useful for further study of cell–interferon interactions.

More generally, antisera against cell-surface determinants coded by given human chromosomes may select in a hybrid population against cells containing these determinants, and provide a selection method for the loss of specific human chromosomes.

Chromosome 21 and the cell growth inhibitory effect of human interferon preparations

INTERFERONS constitute a class of biologically active glycoproteins[1–3] which induce a spectrum of physiological changes in living cells, leading to the inhibition of virus replication[4], of cell growth *in vitro*—both normal and tumour cells[5,8]—and of tumour growth *in vivo*[9–15]. The mechanism(s) underlying these effects is unknown. Gressor *et al.* have suggested that the same molecule in an interferon preparation is responsible for both the antiviral (AV) and cell growth inhibitory (CGI) effect[5]. This suggestion was based on the observation of a consistent and direct correlation between the two effects in an interferon preparation purified more than a millionfold. Gressor also reported that tumour cells treated with interferon had a lower capacity to form colonies in Agarose and were less tumorigenic when innoculated[15], suggesting that the antitumour effect of interferon depended, in part, on the inhibition of tumour cell multiplication which can be demonstrated *in vivo*. I describe here a genetic approach to ascertain whether the CGI effect of human interferon preparations is mediated by chromosome 21-directed gene(s), known to govern the AV action of interferon[16–19]. Such an approach, should provide further insight into whether the different effects of interferon are governed by a cluster of genes on chromosome 21 or whether a single genetic locus on chromosome 21 codes for the pleiotropic effects of interferon.

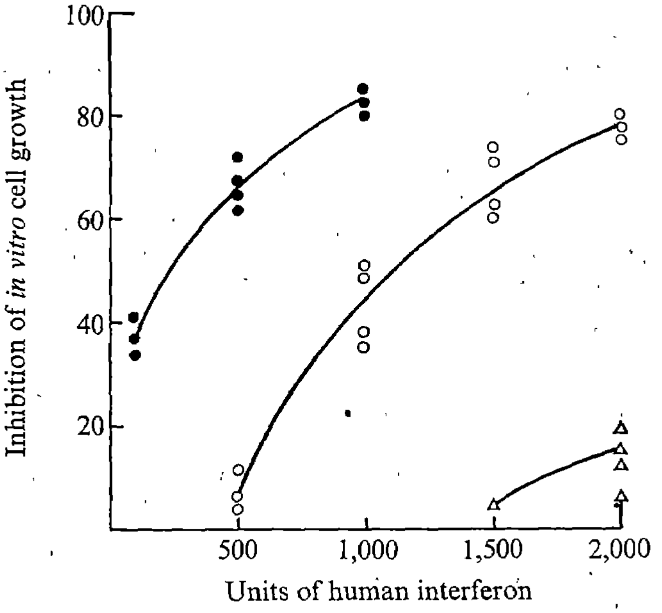

Fig. 1 Effect of human leukocyte interferon on the *in vitro* cell growth of trisomic 21 (●), disomic 21 (○) and monosomic 21 (△) human skin fibroblasts. Each point on the graph represents the results from one determination.

The CGI and AV effects of two human interferon (HIF) preparations were assayed on primary human skin fibroblasts containing different copies of chromosome 21. These cells are monosomic (M21), disomic (D21) and trisomic (T21) for chromosome 21. Primary human cells carrying chromosomal translocations were also used: (1) a diploid cell line (t4;21), in which one of the two chromosomes 21 is translocated to the short arm of chromosome 4, with the resultant loss of the proximal short arm of chromosome 21 (ref. 20); (2) a trisomic 21 cell line (t6;21), in which one of its three chromosomes 21 is translocated to chromosome 6, with the resultant loss of the centromere as well as the short arm of chromosome 21 (ref. 21), (3) another diploid cell line (t4;2), carrying a 2,4 chromosomal translocation, and (4) a trisomic 21 cell line (T21;t–17), carrying a 1–17 chromosomal translocation[22]. A primary human skin fibroblast trisomic for chromosome 18 is also used. The CGI and AV effects of interferon were assessed in these cells by assaying the amount of interferon required to inhibit the *in vitro* growth of cells and synthesis of vesicular somatitis virus, respectively, by 50%. Human cells which were less sensitive to the CGI effects of interferon were also less sensitive to its AV action (Table 1), confirming a similar observation in L1210 cells with differential sensitivity to mouse interferon[23]. Table 1 also shows that the sensitivity of human cells to both the CGI and AV actions of interferon varied inversely with the number of copies of human chromosome 21 present in the cell. Similarly, Fig. 1 shows that M21 cells were less sensitive than D21 cells, which in turn were less sensitive than T21 cells to the CGI effect of interferon. It is unlikely that these observations were due to a nonspecific increase in the number of human chromosomes because the T18 cells, which contain an extra copy of chromosome 18 but have the normal complement of chromosomes 21, behave like a D21 cell in terms of sensitivity to the CGI effect. These results suggest that chromosome 21 contains the gene(s) governing both the CGI effect and the AV action of interferon. Table 1 also shows a dose effect of translocated chromosome 21 on CGI activity. This translocated dose effect has been used to assign the gene(s) governing the AV action of interferon to the long arm of chromosome 21 (ref. 24). The translocated 21 chromosomes (the long arm portions) in both the t4;21 and t6;21 lines exert a dose effect on these cells such that t4;21 and t6;21 cells were as

Table 1 Response of cells to interferon

NIH-1F, Sendai-induced human leukocyte interferon reference reagent G023-901-S-27.

108-1F, poly(I)·poly(C)-induced human fibroblastoid interferon from a high producing cell line V-M15-clone 108.

For the cell growth inhibitory assay, 2×10^4 cells were seeded per 25 cm^2 flask and maintained in 5 ml of regular growth medium (MEM medium containing 10% of heat-inactivated foetal bovine serum, 2 mM glutamine and 1% chlorotetracycline) for 20–24 h. The test flasks were reincubated with different concentrations of human interferon in 5 ml of regular medium. The cultures were incubated at 37 °C for 6 d. On day 6 cultures were trypsinised and total cells were counted with a Coulter counter The CGI effect was assessed by the amount of HIF required to inhibit the total cell count by 50%. Control cultures were treated the same as the test cultures, except that interferon was omitted. Each figure represents average results obtained from one set of duplicate cultures.

sensitive as D21 and T21 cells, respectively, to the CGI activity of interferon (Table 1). It is unlikely that the effects observed with these translocations were due to a nonspecific chromosomal translocation, because two other translocations—the 4–2 translocation in the t4,2 line containing two copies of chromosome 21 and the 1–17 translocation in the T21 cells (T21,1–17) line containing three copies of chromosome 21—behaved like D21 and T21 cells, respectively, in terms of their sensitivity to the CGI effect. The results suggest that the CGI effect like the AV action of interferon is governed by gene(s) located on the long arm of chromosome 21.

Table 1 shows that for each unit of AV activity, human fibroblastoid interferon (108-1F) was more inhibitory to growth than human leukocyte interferon (NIH-1F) This is not surprising since the two interferons are biologically and antigenically different[25–27]. But whether this means that human fibroblastoid interferon is potentially more effective than leukocyte interferon as an antitumour agent is subject to further study.

Of the two interferons used in this study, 108-1F was a poly(I)·poly(C)-induced interferon from our high producing line of human aneuploid cells containing multiple copies of the chromosomes associated with interferon production[19,28]. To eliminate the possibility that the CGI effect observed with this preparation was due in part to residual poly(I)·poly(C), cells were grown in medium containing the concentrations of poly(I)·poly(C) indicated in Table 2. There was no inhibition of cell growth at these concentrations of poly(I)·poly(C), rather, at the lower concentrations, a small stimulation of cell growth was apparent.

Table 2 Effect of poly(I)·poly(C) on growth of primary human skin fibroblast cultures

poly(I)·poly(C) (μg ml^{-1})	Total cell count of cultures Treated	Not treated
0.09	1.1×10^5	1.3×10^6
0.05	1.3×10^5	$0\,9\times10^5$
0.009	1.4×10^6	1.1×10^5
0.001	1.2×10^5	$0\,8\times10^5$

Human cells trisomic for chromosome 21 (line 114) were seeded at 2×10^4 cells per 25 cm^2 flask and maintained in regular growth medium for 20–24 h. The medium was removed from each flask and reincubated with growth medium containing the above concentrations of poly(I)·poly(C) (P.L. Biochemicals) for 6 d. Poly(I)·poly(C) was omitted from controls. Each figure represents average counts from one set of duplicate cultures.

To interpret the significance of these findings, a model is presented to relate the role of chromosome 21 to the pleiotropic effect of interferon. According to this model, a single gene or a cluster of genes located on the long arm of chromosome 21, govern(s) the response of human cells to interferon. One of the first events after the treatment of cells with interferon is the interaction between interferon, or an inhibitory growth substance which has been coinduced and/or coreleased with interferon, with their respective receptor sites. These sites could also be specified by the chromosome 21-directed genes. (There is no direct evidence for the existence of these receptor sites, although they have been inferred from studies with interferon bound on Sepharose beads[29].) Then the chromosome 21 gene(s) is stimulated, presumably by the events at the cell surface[18,18,30], to transcribe gene product(s) which in turn are directly responsible for mediating the pleiotropic effects of interferon. Evidently, a newly induced second protein is implied here But unlike the induction of the AV state, there is no evidence that a second protein is required for the CGI effect. For this reason an alternative explanation is offered Presumably, again, interferon or the inhibitory growth factor interacts with a chromosome 21-directed gene product(s). This interaction produces chemical and/or conformational change(s) which interfere(s), with the replication of viruses and the normal rates of cell division. For this alternative, it is necessary to postulate that these gene product(s) are synthesised constantly and turned over rapidly. This assumption then explains the inhibition of the AV effect by actinomycin D (ref. 31) as well as the lack of the AV induction in enucleated cells[32]. Another alternative is that an interaction between interferon or inhibitory growth factor and chromosome 21 gene(s)-directed cell-surface component(s) is sufficient to cause cell-surface changes. These in turn inhibit the normal rates of cell division but not viral replication, which requires a second protein, the AV protein. To decide between these alternatives, it is essential to identify and isolate the gene product(s) in question. Until then, it would be worthwhile to consider these alternatives equally.

A natural sequel to this is to apply a similar approach to ascertain whether chromosome 21 also controls the antitumour effect of human interferon. As might be anticipated from the suggestion that the antitumour effect depends in part on the CGI effect, it will be feasible to design *in vitro* tests using this effect to predict the human tumour types that will be most responsive to interferon therapy.

Spermatogenic failure of translocation heterozygotes affected by *H-2*-linked gene in mouse

ACCORDING to Lifschytz and Lindsley[1,2], the basic control mechanism of spermatogenesis of all male heterogametic organisms consists of inactivation of the X chromosome during differentiation of germ cells The absence of this control mechanism in female meiosis, where both X chromosomes are active[3,4], could explain why only male gametogenesis is impaired in the carriers of some chromosomal aberrations.

Here, the first data are reported on a genetic factor located on the 17th murine chromosome which controls the range of spermatogenic impairment of mice heterozygous for T(14,15)6Ca translocation[10] (abbreviated, T6).

I have previously envisaged[5] a possible mechanism which would relate the male sterility of autosomal translocation carriers to the impairment of X-chromosome inactivation. The hypothesis of Lifschytz and Lindsley[1,2] fits well with the data on spermatogenic breakdown caused by X-autosomal translocations and certain X-chromosome deficiencies[1,2] but it apparently could not account for sterility caused by many autosomal reciprocal translocations[6-8]. Nevertheless, several characteristic features of both types of translocation indicate a possible common mechanism of male infertility: (1) the sterility is clearly chromosomal in both types of translocation heterozygotes; (2) only male carriers are sterile; and (3) infertility is caused by the breakdown of spermatogenesis.

My idea[5], outlined above and based on the observation of a non-random tight association of the X chromosome with translocation multivalent in primary spermatocytes, has been supported by an analogous cytological picture found in one tertiary trisomic male mouse[9] and in the other male-sterile translocation (J.F., unpublished). These data, however, give little information on the causal relationship between the X-autosomal attachment in meiosis and the subsequent spermatogenic failure Thus, another approach to the analysis of sterility of autosomal translocation carriers, might seem desirable.

The genic component of variation in the severity of spermatogenic failure of males heterozygous for T6 translocation is revealed when the particular types of F_1 hybrids from crosses of CBA–T6/T6 males with females of nine inbred strains are compared (Table 1). The symbol CBA–T6/T6 designates a homozygous T6 translocation carried on the genetic background of CBA inbred strain. By comparing the distributions of testes weight values, which are sensitive measures of spermatogenic impairment[11-13], the three phenotype classes of testes weight values (high, medium and low) are distinguished among the nine types of F_1 hybrids. The mean number of spermatozoa in epididymides, which is another criterion of spermatogenic failure[14], shows reasonable correlation with testes weight in spite of variations in individual scores (Fig. 1)

Table 1 shows further that spermatogenic failure displays several attributes of hybrid sterility[15]; the two homozygous parental forms, CBA/J and CBA–T6/T6, are normally fertile, the impairment of gametogenesis being limited only to T6 heterozygous male progeny of a CBA/J×CBA–T6/T6 cross. This combination is particularly interesting as the two parental strains, CBA/J and CBA–T6/T6 are genetically (quasi-)identical, except for a single reciprocal translocation between chromosomes 14 and 15. Thus, spermatogenic failure of the F_1 hybrids can be entirely ascribed to the heterozygosity for this chromosomal rearrangement.

Table 1 Testes weights and sperm counts in T6 heterozygous male progeny of (inbred strain×CBA–T6/T6) cross

Inbred strain*	Mean testes weight† (mg)	s.e.	Sample size‡ T/S	Number of spermatozoa§ $\times 10^{-4}$
C3H/Di	154 (H)	2.3	13/7	158

†Wet weight of paired testes of males aged 60±4 d; H, M, L, high, medium and low testes weight.

‡Number of F_1 hybrid males examined for testes weight (T) and those examined for sperm counts (S).

§Mean number of sperm heads in paired epididymides.

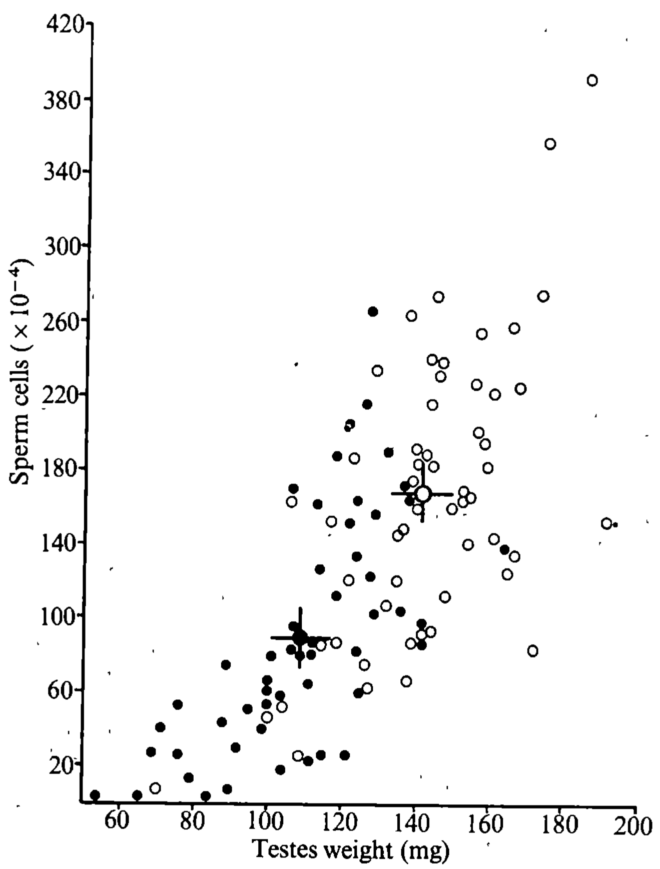

Fig. 1 Number of spermatozoa in paired epididymides plotted against testes weight in T6 heterozygous male progeny of CBA–T6/T6×(C57BL/10-*T*×C3H)*T*/+ cross. The tested males, 60±4-d-old, were genotyped as $H\text{–}2^b/H\text{–}2^k$ (●) or $H\text{–}2^k/H\text{–}2^k$ (○) by PVP haemagglutination[21] with specific anti-$H\text{–}2^b$ sera. The mean values of $H\text{–}2^b/H\text{–}2^k$ males (crossed ●), (109 mg, 90×10^4 sperm cells) and $H\text{–}2^k/H\text{–}2^k$ males (crossed ○), (141 mg, 164×10^4 sperm cells) differ significantly (Hotellings T^2 statistics=31.762; $P<0.01$) which indicates that a gene linked to $H\text{–}2^b$ on chromosome 17 from C57BL/10-*T* strain is the major genetic determinant responsible for low testes weights and low sperm counts. Fourteen recombinants between *T* and *H–2* were detected among 107 males tested; however, they do not provide sufficient information for location of the postulated gene with respect to *T* and *H–2* loci, partly because of a physiological component in variation of fertility parameters, and partly because of difficulties with classification of some *T*/+ compared with +/+ animals on this particular genetic background. Therefore, for the sake of clarity, only the *H–2* genotype is shown.

Chromosome 17 of the mouse carries at least two gene loci involved in a similar type of male-limited sterility, that is, the sterility factor of *t* alleles[16,17] and the *Hst-l* gene[13]. Using the *H-2* complex and *T* allele (*Brachyury*) as markers of chromosome 17, a distinct part of genetic variation in spermatogenic failure of T6 heterozygotes can be ascribed to a gene (or a gene cluster) linked to these markers on chromosome 17. The conclusion is drawn from an analysis of male progeny of CBA–T6/T6×(C57BL/10-*T* ×C3H)*T*/+ cross. Those males that received, from their F_1 parent, the $H\text{–}2^b$ haplotype and/or the *T* allele (the two markers of chromosome 17 of C57BL/10-*T* strain) had significantly lower testes weights and sperm counts than their brothers with H-2^k and $+^T$ markers of C3H origin (Fig. 1).

The relationship of the described gene to *T*/*t* and *H-2* complexes and to the *Hst-1* gene is not quite clear; it seems unlikely that the *T* allele itself would be involved since *T*/+ and +/+ male progeny of the CBA-T6/T6× C57BL/10-*T* cross does not differ in testes weights Furthermore, the strain distribution shown in Table 1 does not fit the assortment of alleles either of the *Hst-1* gene[13] or of the *H-2* complex; in this case, however, the possibility cannot be excluded that the genetic background in some strains can alter the expression of the described gene

Although the precise location of the described gene on chromosome 17 might have a bearing on the concept of the *T*/*t*–*H-2* supergene[18–20], two other questions that emerged from this preliminary genetic analysis are those concerning the effect of the described gene on further male-sterile translocations, and the role of this gene in the presumed mechanism[5] of translocation-associated male sterility.

I thank Dr P. Iványi for discussions, and Mrs J. Susová and Miss E. Kozlová for assistance.

Facilitation or attenuation of mixed leukocyte culture responsiveness by adherent cells

It is generally agreed that adherent cells, or macrophages, are required for maximum reactivity in mixed leukocyte culture (MLC). The system has been incompletely defined, for the mode of function of the adherent cell is unclear. There is evidence from human and animal systems that adherent cells have either a nonspecific helper role[1–4] or a more precise genetically defined stimulator role[5]. We report here that adherent cells which ingest latex particles seem to be capable of nonspecifically facilitating or attenuating human lymphocyte proliferation in MLC.

Heparinised venous blood was subjected to Ficoll–Hypaque flotation to obtain mononuclear cells. An aliquot of these cells was filtered through columns of Sephadex G-10 beads according to the method of Ly and Mishell[6], the principal modification being the use of medium containing 20% foetal calf serum for elution. This procedure selectively depletes the mononuclear cells of adherent latex-ingesting cells while leaving the relative proportion of T and B lymphocytes unchanged (Table 1). In these experiments, we accounted for 88–103% of the mononuclear cells using conventional cell marker techniques. The mean yield of lymphocytes from this column was 93%, and the viability was greater than 99% by Trypan blue exclusion. Thus, the only discernible effect of this procedure was selectively to remove adherent cells which ingest latex particles.

Using well defined methods[7], one-way MLCs involving 5×10^4 responding cells and 5×10^4 X-irradiated stimulating cells were planted in microtrays in 150 μl of RPMI-1640 containing 20% pooled normal human serum, HEPES buffer (25 mM), penicillin (100 U ml^{-1}), streptomycin (100 μg ml^{-1}), and fresh glutamine (2 mM). In all experiments, only fresh cells were used. MLCs were cultured for 132 h in a humidified atmosphere of 5% CO_2 and were labelled for the last 16 h of culture with 2.0 μCi of ^{3}H-thymidine. Cultures were collected on to glass-fibre filters with a semi-automated sample harvester, and ^{3}H-thymidine incorporation was determined by liquid scintillation spectroscopy The incorporation of isotope was expressed as the mean c.p.m of triplicate allogeneic cultures minus the mean c.p.m. of the isogeneic control.

Figure 1 clearly demonstrates that removal of adherent latex-ingesting cells either isogeneic to the stimulator or isogeneic to the responder has no significant effect on MLC reactivity ($P > 0.20$ by two-tailed *t* test). Removal of adherent cells from both the stimulating and responding cell populations, however, results in significantly decreased MLC reactivity ($P > 0.05$ by one-tailed *t* test), in spite of the fact that the relative proportions of T and B lymphoctyes in the column-filtered cells were virtually unchanged. It must be noted that these MLCs involved allogeneic combinations of HLA dissimilar individuals who were mutually strongly responsive in the routine MLC.

Abnormally low responsiveness in MLC can be quite

Fig. 1 *a–c*, The response of filtered cells of 14 normal individuals in MLC Each point represents the mean of 3 separate MLCs and is expressed as the percentage of the mean of the 3 companion unfiltered MLCs. Response of a single individual's filtered cells to 3 separate allogeneic stimuli is 81–124% of the unfiltered response (*a*). The mean response of 3 separate individuals' cells to a single filtered allogeneic stimulus is 88–121% of the unfiltered response (*b*). The mean response of a single filtered cell population to 3 separate filtered allogeneic stimuli is attenuated (*c*). The increased responsiveness of patients' filtered lymphocytes to 4 separate allogeneic stimuli relative to the unfiltered responses (*d*).

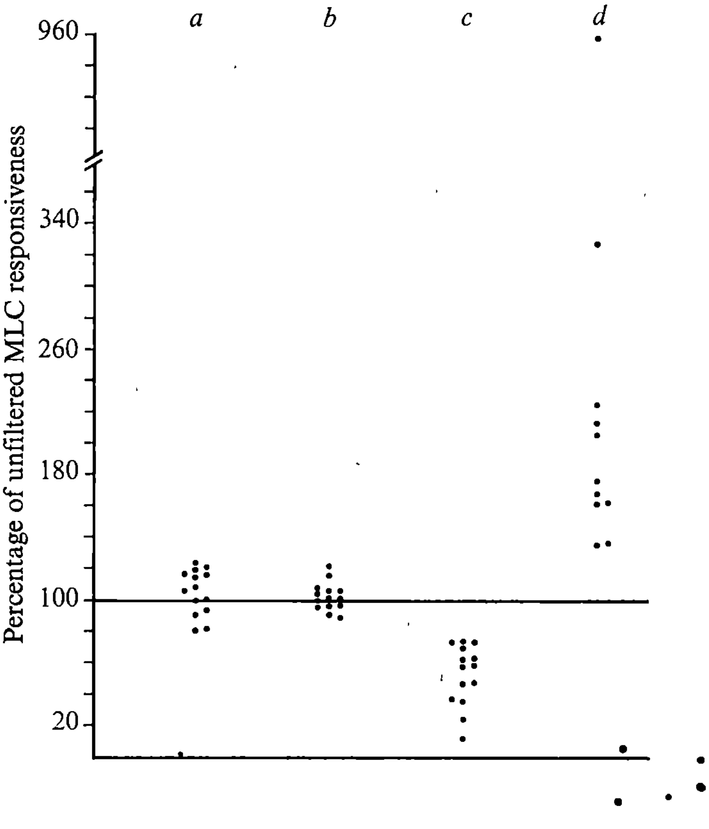

Table 1 Cell marker analysis of filtered and unfiltered cells

Subject	Lymphocytes identifiable as T cells (%)		Lymphocytes identifiable as B cells (%)		Mononuclear cells identifiable as macrophages (%)	
	Unfiltered	Filtered	Unfiltered	Filtered	Unfiltered	Filtered
1	68	75			8.0	0
2	70	74			4.5	0
3	80	74			5.5	0
4	66	73			5.5	0.25
5			6	4	6.0	0
6			16	18	5.5	0
7			15	11	16.5	0
8			14	12	11.0	0
9			10	9	13.0	0
10	72	78	20	14	6.5	0.5
11	83	82	18	13	3.7	0
12	88	88	9	6.6	11.5	0
13	77	75	15	15.5	9.0	0
14	85	80	11	8	7.0	0
15	87	80	12	10	8.5	0.7

All percentages represent a minimum of 300 cells counted. T lymphocytes were determined by their ability to rosette spontaneously with sheep red blood cells. B lymphocytes were enumerated with a rhodamine-conjugated polyvalent anti-human immunoglobulin antiserum. Macrophages were identified by their ability to phagocytose latex particles 0.801 μm in diameter.

reliably identified by calculating a relative response (RR)[8] for an individual being tested: This value expresses the responsiveness of an individual's cells to a panel of four separate allogeneic stimuli, relative to the responses of several normal individuals to the same allogeneic panel. We have determined an RR for each of 33 normal individuals. The range was 79–136% with a geometric mean RR of 101%. An abnormally low RR was considered to be one greater than two standard deviations (2σ) below this mean (μ), namely, less than 76%. These calculations involved logarithmic transformations of the data since expression of these values as relative changes, by definition, generated a log normal distribution.

Eleven individuals demonstrating abnormally low responses in MLC were selected from a group of patients with non-lymphoid malignancies. Six of these individuals demonstrated RRs $>3\sigma$ ($<66\%$) below μ, and the other five demonstrated RRs $\geqslant 5\sigma$ ($<50\%$) below μ. Figure 1 shows that filtered lymphocytes from these individuals, which were virtually devoid of adherent latex-ingesting cells, demonstrated significantly increased proliferative capacities in response to each of four normal allogeneic stimuli compared with the companion MLCs using unfiltered patient responding cells. When column-filtered lymphocytes were used, the RRs of eight of these individuals returned to values within the normal range as defined above, while the remaining three returned to near normal (data not shown). This markedly increased responsiveness was significantly different from that observed with 56 normal allogeneic combinations involving filtered responding cells ($P<0.005$ by one-tailed t test). In addition, four of these patients demonstrated a significantly decreased ability to stimulate normal allogeneic cells. When the patients' adherent cells were removed from the stimulating population by column filtration, the proliferative capacity of the four normal responders returned to normal values.

Our findings with mononuclear cells of HLA dissimilar normal individuals confirm the findings of others[2,9,10] that adherent cells are necessary for optimal MLC responsiveness whether the adherent cell is isogeneic or allogeneic to the responding cell population. Depletion of these cells from both the stimulating and responding cell populations results in significantly decreased MLC responsiveness. In addition, in the pathological situation, the adherent cell can be responsible for attenuated lymphocyte blastogenic activity, and when removed from culture, normal or near normal lymphocyte proliferation may be observed. Our experiments strongly suggest that such increased proliferation of patient lymphocytes is mediated by the allogeneic adherent cells in the normal irradiated stimulating cell population, giving further testimony to the nonspecific effects which mononuclear phagocytes may display in MLC.

In the light of the findings that macrophages can secrete discrete factors which are either stimulatory or inhibitory for cellular proliferation[11], it is appropriate to speculate that in human malignancy a perturbation of macrophage function occurs which involves a net increase of an inhibitory influence during the response to an allogeneic stimulus.

Isolation of a subpopulation of adherent peritoneal cells with anti-tumour activity

We have reported that adherent peritoneal cells from normal mice stimulated the growth of many lymphomas *in vitro*, while adherent peritoneal cells from mice injected with Bacille Calmette-Guerin (BCG) were far less stimulatory[1]. The latter were overtly cytostatic when tested on L929 cells[1], as well as on several other adherent fibroblastic malignant targets (unpublished). This leads us to speculate that adherent murine peritoneal cells consist of at least two subpopulations, one that tends to stimulate and one that tends to inhibit the proliferation of susceptible target cells. According to this view, infection of the mouse with BCG might lead to increased numbers or activity of the cytostatic subpopulation at the expense of the stimulatory subpopulation. We have now isolated an adherent, esterase-positive, poorly phagocytic mononuclear peritoneal cell with potent tumour-inhibitory capacity, which may represent the postulated cytostatic subpopulation.

Cells were washed from the unstimulated peritoneal cavities of DBA/2 or CDF1 mice or from age-matched mice 1–21 weeks after intraperitoneal injection of 10^7 viable BCG of the Phipps or Pasteur strains (Trudeau Nos 1029 or 1011). The cells were washed and allowed to adhere to plastic 35-mm dishes (Falcon) for 2–3 h in RPMI-1640 with 20% foetal calf serum. The dishes were then rinsed vigorously in beakers of saline, leaving cells which were essentially all esterase positive[1]. Starch granules prepared from the seeds of *Amaranthus caudatus*[2] were added to the monolayers in conditions leading to maximal phagocytic uptake, as defined for these cell preparations in preliminary experiments with ^{14}C-acetyl-labelled granules by methods described previously[3,4]. At the conclusion of the phagocytic period, the dishes were again washed vigorously in six beakers of saline.

In conditions of maximal uptake (15–20 mg of starch per dish for 3 h), microscopy revealed that $4.8\pm0.5\%$ of the adherent peritoneal cells in the monolayers from normal mice and $16.8\pm1.3\%$ of those from BCG mice were non-phagocytic for starch (mean ± s.e. for 14 and 17 experiments, respectively; "non-phagocytic" defined as 0–1 cell-associated granule). Cells were then dislodged from the monolayers by incubation in medium containing lidocaine[5] (Astra Pharmaceuticals) followed by exposure to jets of saline from a syringe. This procedure recovered nearly all cells from the normal monolayers but left behind a variable number of non-phagocytic cells in the dishes prepared from BCG-treated mice. The cells were washed, spun on Ficoll–Hypaque[6] at 240*g* for 12 min, and the non-sedimenting cells were washed again. Phagocytic cells and free starch pelleted, leaving at the interphase a preparation of non-phagocytic mononuclear cells with a viability of $92.4\pm1.9\%$ by Trypan blue exclusion, contaminated with $3.5\pm1.3\%$ of viable cells containing more than one starch granule, and with $0.009\pm0.0004\%$ of the initial free starch granules (mean ± s.e. from 14 to 17 preparations).

These non-phagocytic cells were plated in microtest wells (Falcon) in 0.2 ml with various tumour cells for 2 d, as indicated in Table 1. Uptake of ^{3}H-thymidine during the last 4 h of culture was measured as described before[1]. In each of five experiments, the isolated non-phagocytic adherent cells inhibited the uptake of ^{3}H-thymidine by the tumour targets to a greater degree than similar numbers of the total adherent peritoneal cell populations from which they were derived. The non-phagocytic adherent cells from BCG-treated mice appeared to differ from those from normal mice only in that there were nearly four times as many of them, and they were apparently more resistant to dislodgement by lidocaine. In dose–response experiments (not shown), there was no evidence that, per recovered cell, they were more potent. As few as 2.5×10^3–5×10^3 cells of the non-phagocytic subpopulation from either the BCG or the normal adherent populations markedly inhibited the uptake of ^{3}H-thymidine by 1×10^3 MCA-3 cells. Controls showed that the addition of starch and lidocaine to peritoneal cells in suspension with rapid centrifugation over Ficoll–Hypaque, before phagocytosis had proceeded very far, gave preparations which behaved like the parent populations (Experiment 2, Table 1). Likewise, when peritoneal cells were

* MCA-2 and MCA-3 are tissue culture lines derived from methylcholanthrene-induced sarcomas of the C57BL/6 mouse. L929 cells were obtained from Microbiological Associates.

† c.p.m. are corrected for the c.p.m. taken up by each group in the absence of tumour cells. Mean background values for each column from left to right above were: 33±5 (no cells: machine background); 291±109; 120±66; 45±10; 42±18.

‡ For total adherent cells, 5×10^4 peritoneal cells were added to each well for 3 h and non-adherent cells were removed before addition of tumour cells, leaving an average of 2×10^4 adherent peritoneal cells[1]. For the subpopulation, 2×10^4 cells were used in each well. Values are for triplicate cultures.

§ Peritoneal cells treated with lidocaine and starch in suspension before being processed over Ficoll–Hypaque.

¶ After phagocytosis, monolayers were treated with 36 mM lidocaine for 2 min (Experiments 1 and 2) or 12 mM lidocaine for 5 min (Experiments 3 and 5). The latter gave better yields.

allowed to adhere, collected with lidocaine and processed over Ficoll–Hypaque exactly like the experimental cells, except for the omission of starch, they interacted with tumour cells just like the parent peritoneal cell populations. These results suggest that the isolation procedure itself did not induce anti-tumour activity. In addition, anti-tumour activity could not be induced by addition of contaminating amounts of free starch to wells containing the tumour alone or tumour with either adherent peritoneal cells or the non-phagocytic subpopulation. There was no inhibition of uptake of ^{3}H-thymidine in MCA-3 cells added to cultures of non-phagocytic adherent cells which had been allowed to die by 4–5 d of preculture. Inhibition of uptake of ^{3}H-thymidine accurately reflected changes in viable tumour cell number as judged by haemocytometer counts.

Like the total adherent cell population from which they were derived[1], the isolated non-phagocytic adherent cells were esterase positive. Between 0.3 and 10% of non-phagocytic adherent cells from BCG-treated mice seemed to contain acid-fast organisms by Ziehl–Neelsen staining, compared with 3–10% of the total adherent peritoneal cells from such mice (cells from normal mice showed no positive staining). Because of the rare stainable intracellular mycobacteria and the fact that 10–50% of the "non-phagocytic" adherent cells (as operationally defined) seemed to contain one starch granule each, it may be preferable to regard these cells as "poorly phagocytic". When Wright's stain was used (Fig. 1), the active subpopulation comprised cells intermediate in size between small lymphocytes and macrophages, with scant to moderate, pale blue, sometimes vacuolated cytoplasm, a spiculated or ruffled cell margin, and an oval to reniform nucleus, occasionally with prominent nucleoli. Further work is in progress to characterise these cells; it is not clear whether they are macrophages.

Allison described non-phagocytic, adherent murine peritoneal exudate cells which he suggested might be effector cells in antibody-dependent cell-mediated cytotoxicity[7]. Cells with some similar characteristics were found in mouse spleen by Greenberg *et al.*[8]. Boyle and Ormerod isolated a subpopulation of phagocytic, adherent peritoneal cells from alloimmunised mice which seemed to bear all the cytotoxic potential for the specific tumour cell target[9]. Subpopulations of macrophages with different activities in endocytosis[10,11], immune RNA production[11], or antigen binding[12] have been obtained using density centrifugation in Ficoll[10,12] or albumin[11]. It is not yet known whether there is any relationship between the subpopulations described by these workers and the subpopulation described here.

Because of the metabolic perturbations induced by phagocytosis itself[13,14], the separation procedure used here precludes testing the residual, phagocytic cells in their basal state. Other techniques will be needed before the non-phagocytic adherent subpopulation can be compared directly with the remainder of adherent peritoneal cells in an anti-tumour assay.

Work is in progress to test the hypothesis that different classes of tumour cells differ in their susceptibility to the postulated inhibitory and stimulatory subpopulations of adherent peritoneal cells.

Thus, among adherent murine peritoneal cells, there are esterase-positive cells which can be isolated in nearly pure form on the basis of their deficient phagocytosis. These cells markedly inhibit the replication of various tumour cells *in vitro*, and seem to account quantitatively for the inhibition afforded by the total adherent peritoneal cell population from which they were derived. The tumour-inhibitory subpopulation can be isolated from untreated mice, although it can be identified in greater number among the adherent peritoneal cells from mice given BCG. The anti-tumour action of the subpopulation seems to be nonspecific. The existence of such a subpopulation may necessitate reassessment of the relationship of the numerous features of "macrophage activation", measured in a whole population, to its anti-tumour activity.

We thank Dr R. Hodes for helpful discussions, Drs S. A. Rosenberg and G. Parker for MCA-2 and MCA-3, and Astra Pharmaceuticals for lidocaine.

Inhibition and reversal of wheat germ agglutinin-induced caps by concanavalin A

ASSEMBLY of cell-surface components at one pole of the cell membrane, as a result of cross linkage with specific ligands, can be visualised by using labelled ligands. Such a demonstration of topographic changes on the cell surface is called capping. By using different labels for the different ligands it is possible to study the mutual relationship between various membrane components. Using the capping technique, it was possible to demonstrate the relationship between concanavalin A (con A) receptors and immunoglobulin (Ig) receptors on the lymphocyte surface[1], as well as other surface antigens such as H-2, HLA and θ antigens present on murine and human lymphocytes[2–4]. The present study was undertaken to demonstrate the relationship between the receptors of two plant lectins, con A with specificity for glucoside residues, and wheat germ agglutinin (WGA) with specificity for *N*-acetyl-glucosamine residues[5], that are both present on the surface of murine thymocytes.

Thymocytes of 4–6-week-old C57BL/6 mice were used in all experiments. Con A, WGA, con A labelled with rhodamine (Rh–con A) and WGA labelled with fluorescein (Fl–WGA) were obtained from Miles–Yeda. Succinyl–con A was prepared in our laboratory according to Gunther *et al.*[6].

Incubation of 5×10^6 thymocytes per ml with Fl–WGA, Rh–con A or with both lectins simultaneously, induced capping on the cells. Table 1 *a–d* shows the results of such experiments. It can be seen that Fl–WGA induced cap formation in 91% of the cells, while Rh–con A only in 7%. When cells were incubated with Fl–WGA and unlabelled con A or with Fl–WGA and Rh–con A, however, only 2% of the cells showed caps to WGA, whereas 89% of the cells showed a uniform distribution of the Fl–WGA around the cell surface. The presence of con A inhibited cap formation induced by Fl–WGA (Fig. 1*c*). Addition of succinyl–con A did not cause such an inhibitory effect (Table 1*e*). Pretreatment of the thymocytes with 10^{-4} M colchicine affected con A capping, as can be seen in Table 1*f–h*. This pretreatment elevated the percentage of cells with caps to Rh–con A from 7 to 22. Such pretreatment also elevated the percentage of caps to Fl–WGA from 2 to 19% in cells simultaneously incubated with con A. Moreover, the location on the cell surface of Fl–WGA caps was identical to the location of Rh–con A caps (Fig. 1*d*). The same phenomenon was also observed when Rh–con A treated cells were washed, incubated

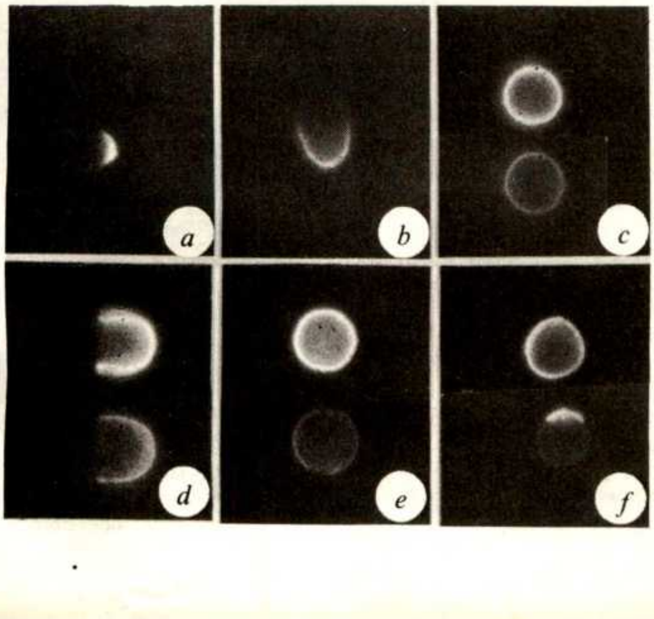
Washed C57BL/6 thymocytes (5×10^6 cells per ml) were incubated for 15 min at 37 °C, in the following conditions: *a*, 24 μg Fl–WGA; *b*, 50 μg Rh–con A; *c*, 24 μg Fl–WGA+50 μg con A; *d*, 24 μg Fl–WGA+50 μg Rh–con A; *e*, 24 μg Fl–WGA+50 μg succinyl–con A; *f*, as in *b* with pretreatment of cells with 10^{-4} M colchicine; *g*, as in *c* with pretreatment of cells with 10^{-4} M colchicine; *h*, as in *d* with pretreatment of cells with 10^{-4} M colchicine; *i*, as in *h* with incubation of cells in 10 mM NaN_3 before addition of Fl–WGA.

for 5 min in a solution containing sodium azide (non-capping conditions), and then Fl–WGA was added (Table 1*i*). These results resemble cocapping obtained with con A and anti-Ig on the surface of lymphocytes pretreated with colchicine[7]. In colchicine treated thymocytes the morphology of con A caps differs from that of WGA caps in that con A caps are elongated (Fig. 1*b*), whereas WGA caps are round (Fig. 1*a*). When cocapping occurs, however, Fl–WGA caps assume the morphology of con A caps. Addition of con A to thymocytes preincubated with Fl–WGA reversed WGA caps to a uniform distribution 30 min after the addition of con A (Table 2*b*) (Fig. 1*e*). This reversion of WGA caps was dependent on the con A concentration: addition of 50–12 μg con A ml^{-1} induced a complete reversal, while smaller amounts (6 μg and less) decreased the extent of reversal. This decrease was proportional to the amount of con A used. Such a reversion of Fl–WGA caps in thymocytes was also observed when con A was added at 4 °C, or when cells were treated with sodium azide (10 mM) before addition of con A (Table 2*d* and *e*). Thus, reversion of WGA caps by addition of con A occurs even in conditions in which cap formation is usually inhibited[8]. These results resemble the reversion of con A caps by cytochalasin B which is similarly unaffected by sodium azide[4]. Reversion of WGA caps was not observed when succinyl–con A was added 30 min after WGA-induced caps were already formed (Table 2*g*).

Fig. 1 Inhibition and reversion of caps induced by WGA. The photographs were taken using a Zeiss Universal microscope (barrier filters were used for observations of fluorescein fluorescence and rhodamine fluorescence). *a*, Cell stained with Fl–WGA at 37 °C for 15 min; *b*, cell stained with Rh–con A at 37 °C for 15 min in the presence of 10^{-4} M colchicine; *c*, cell stained with Rh–con A and Fl–WGA at 37 °C for 15 min. Both lectins were added simultaneously. Upper, Rh–con A; lower, Fl–WGA. *d*, Cocapping of Fl–WGA with Rh–con A in the presence of 10^{-4} colchicine. Upper, Rh–con A; lower, Fl–WGA. *e*, Reversion of WGA caps by con A. A cell stained with Fl–WGA, after 15 min Rh–con A was added for additional 30 min. Upper, Rh–con A; lower, Fl–WGA. *f*, Cell stained with Fl–WGA, after 15 min anti-WGA was added for 5 min, after which Rh–con A was added for additional 30 min. Upper, Rh–con A; lower, Fl–WGA.



Addition of α-methyl-D-glucoside (0.1 M) after reversion of WGA caps by con A resulted in the reappearance of WGA caps (Table 2*c*). Addition of antibodies to WGA after cap formation by this lectin, prevented the cap reversion caused by addition of con A (Table 2*f*). Moreover, when Rh–con A was added to thymocytes which had been incubated with WGA and subsequently with antibodies to WGA, it was possible to simultaneously demonstrate Fl–WGA caps and uniform distribution of Rh–con A (Table 2*f*), (Fig. 1*f*). Thus, addition of a specific cross linkage agent of WGA (anti-WGA) overcomes the antagonistic effect of con A.

The data in the present study demonstrates a mutual relationship between WGA and con A receptors on the cell surface of murine thymocytes. Receptors cross linked with con A control the topographic distribution of WGA receptors. In the presence of con A not only is WGA capping inhibited, but existing WGA caps are reversed to a uniform distribution. Such reversion is not affected by treatments involving sodium azide or 4 °C, indicating a process that does not require energy. Such a reversion in WGA caps can be overcome by addition of antibodies to

Table 2 Reversal of WGA caps by con A

Treatment of thymocytes	% WGA caps
a Fl–WGA	91
b Fl–WGA+con A	3
c Fl–WGA+con A+α-methyl-D-glucoside	91
d Fl–WGA+NaN_3+con A	2
e Fl–WGA+4 °C+con A	2
f Fl–WGA+anti-WGA+con A	89
g Fl–WGA+succinyl–con A	88

The cells were not washed after Fl–WGA treatment, but identical results were obtained when cells were washed after this primary incubation. In experiment 2*a* 5×10^6 thymocytes per ml were incubated at 37 °C for 15 min in the presence of 24 μg Fl–WGA. In experiment 2*b* 5×10^6 thymocytes per ml were preincubated at 37 °C for 15 min in the presence of 24 μg Fl–WGA and then incubated with 50 μg con A at 37 °C for 30 min. In experiment 2*c* 5×10^6 thymocytes per ml were preincubated at 37 °C for 15 min in the presence of 24 μg Fl–WGA, then incubated with 50 μg con A at 37 °C, after 30 min α-methyl-D-glucoside (0.1 M) was added at 37 °C for 15 min. In experiment 2*d–f*, 5×10^6 thymocytes per ml were preincubated at 37 °C for 15 min in the presence of 24 μg Fl–WGA. Then the first sample was incubated with NaN_3 (10 mM) at 37 °C. The second at 4 °C. The third—with anti-WGA (5 μg Ab ml)—at 37 °C. After 5 min 50 μg con A was added to the 3 samples for 30 min at the above-mentioned temperatures. In experiment 2*g*, 5×10^6 thymocytes per ml were preincubated at 37 °C for 15 min in the presence of 24 μg Fl–WGA and then incubated with 50 μg of succinyl–con A for 30 min at 37 °C.

WGA, which probably increases the extent of cross linkage of WGA receptors.

Our results correlate with previously published studies dealing with the effect of con A on the capping of mouse lymphocyte surface immunoglobulin and on the capping of mouse thymocyte antigens[1,4]. Our results could be interpreted by assuming that the surface molecule carrying con A receptors also carries WGA receptors as suggested for the case of con A and Ig receptors[1]. This explanation is, however, not feasible for WGA and con A receptors since, in the presence of anti-WGA serum, WGA causes capping while con A does not. The WGA used in the present study is completely free of contaminating sugars, as assayed by the phenol–sulphuric acid test[9], which precludes the possibility that con A binds to contaminated sugar residues present in the WGA preparation. Our data suggest the following alternative explanation: it is known that con A receptors of thymocytes and lymphocytes are a heterogeneous population in valence, affinity and chemical composition[10] and are also known to be bound to microtubules which restrict their mobility[4]. In addition, the con A molecule is tetravalent[11] while WGA is divalent[12], thus enabling con A to form a firm lattice-network on the surface of the thymocytes. This con A receptor lattice may trap WGA receptors as well as other receptors such as Ig and θ antigens which also seem to be interspersed among con A receptors[4]. As a consequence the mobility of WGA receptors is governed by the lattice formed by con A, and therefore the WGA caps can be reversed by the denser lattice formed by con A when binding to its receptors.

Our explanation of the cap-reversion phenomenon is supported by the following two observations: (1) substitution of tetravalent con A with divalent succinyl–con A does not cause a reversion of previously formed WGA caps, and (2) addition of antibodies to WGA prevents con A reversion of WGA caps, apparently by increasing the extent of cross linkage of WGA receptors. Preliminary results in our laboratory have shown that the reversion phenomenon also occurs with Ig receptors by con A.

We thank Mrs O. Asher for technical assistance. This study was supported partly by a grant from Bar-Ilan University.

Evidence for a soluble lymphocyte factor in the transplacental transmission of T-lymphocyte responses to *Mycobacterium leprae*

ANTIGENS introduced to the human foetus have been considered as "self" and thus not to provoke an immune response[1]. But, no sudden changes in the immune mechanisms seem to coincide with birth, and the development of adult immune responses is gradual. Moreover, in sheep, antigens can give rise to more or less mature immune responses in the foetus[2,3], dependent on the stage of gestation. The nature of transmission of these immune responses from mother to foetus remains unclear. Brody *et al.*[4] demonstrated in humans that T-lymphocyte sensitisation could be transmitted from mother to foetus and considered this was due to transplacental passage of antigen. Field and Caspary[5] showed that cell-mediated responses can be induced in the foetus, but thought that either maternal lymphocytes or some subcellular lymphocyte factor crossed the placenta to sensitise the foetal lymphocytes. We have tested ten randomly selected normal mothers and their babies at parturition for evidence of sensitisation to antigens of *Mycobacterium leprae*. We found that when the mothers showed sensitisation their babies did too: the children of unsensitised mothers were not sensitised. We consider the likeliest explanation for our findings is the transplacental passage of a soluble lymphocyte factor.

Lymphocyte transformation tests (LTT) were carried out by a micromethod[6] on both maternal and neonatal cord blood; whole washed *M. leprae* were used as antigen, and in each case the responses to BCG and PPD were also determined. Of the ten mothers tested, five showed a positive LTT response with *M. leprae* as antigen and five did not (Fig. 1). It was considered that a positive response existed when the LTT response with the antigen was more than

Fig. 1 LTT responses to whole *M. leprae* in mothers and neonates, comparing the five mothers with positive responses and the five mothers with negative responses (unstimulated control values are subtracted). ^{3}H-TdR, Tritiated thymidine uptake.

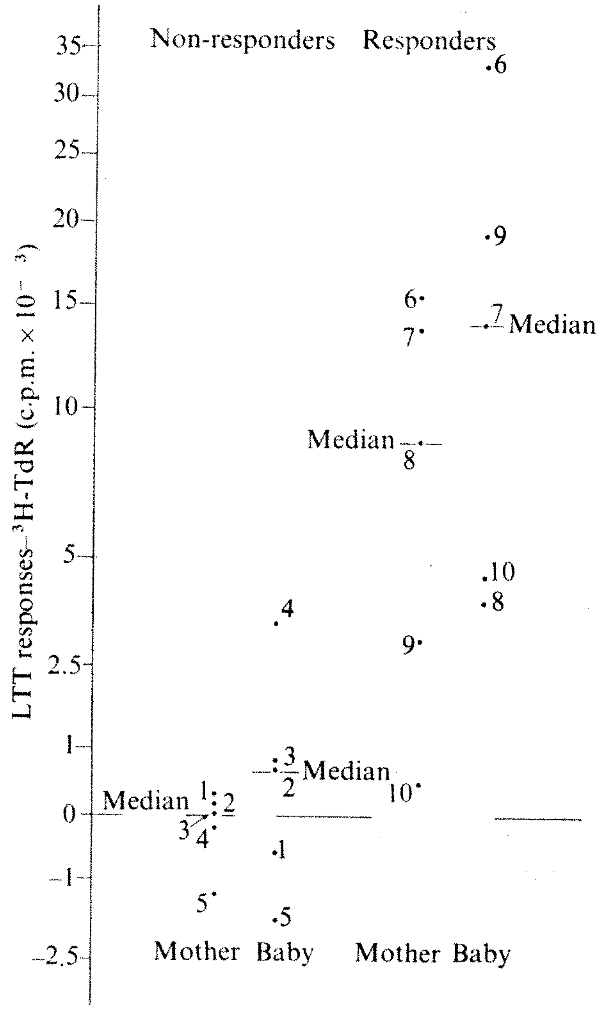

Table 1 Median responses to antigens

	M. leprae		BCG		PPD	
Mothers with positive responses to *M. leprae*	8,600	$P<0.005$	267	$P>0.1$	4,316	$P<0.02$
Mothers with negative responses to *M. leprae*	−11		21		−36	
Babies of mothers with positive responses to *M. leprae*	13,658	$P<0.005$	995	$P>0.1$	3,654	$P>0.1$
Babies of mothers with negative responses to *M. leprae*	602		−17		1,140	

Figures are c.p.m.

Median responses to antigens in the two maternal and the two neonatal groups. P, Probability of distribution between the two groups occurring by chance, calculated by Mann–Whitney U test.

twice the value of unstimulated control cultures. The values for these control cultures were much higher in the neonates (median: 13,171) than in the mothers (median: 532). In the five mothers with positive lymphocyte blastogenic responses, the response of the neonate reflected the maternal response, though the former were much greater. In the five unresponsive mothers, the neonatal response was much lower than in the neonates born of responders. The difference between the two neonatal groups is highly significant ($P<0.005$), using the Mann–Whitney U test for statistical analysis. There was also a statistically significant difference in responses to PPD (but not BCG) between the maternal responders and non-responders to *M. leprae* (Table 1), possibly due to some cross reactivity. There was, however, no significant difference of responses to PPD and BCG between the two neonatal groups.

Five out of ten may seem a high proportion of mothers to show evidence of sensitisation to *M. leprae;* but it is in accord with our experience that up to 90% of contacts with known cases of leprosy show evidence of previous subclinical infection[7]. Moreover, in Sao Paulo, Brazil, where the leprosy endemicity is similar to that of Addis Ababa, more than 50% of the normal population show positive lepromin (Fernandez) skin tests[8].

This study provides evidence that when mothers are sensitised to *M. leprae* this sensitisation is transmitted to the foetus. The sensitisation seems to be specific, as there was no significant difference between the responses of the two neonatal groups when BCG or PPD were used as antigens.

For transmission of this sensitisation, there are three main possibilities. The first is transplacental passage of antigen. In our study, this seems unlikely as the mothers showed no signs of leprosy, or other mycobacterial disease. The second possibility is transplacental passage of maternal lymphocytes. It is still debatable whether maternal lymphocytes enter the foetal circulation[9–12], so if they do cross the placenta it must be in very small numbers. In view of the high neonatal LTT responses, recruitment of neonatal lymphocytes by maternal lymphocytes would again seem improbable. Third, there could be transplacental passage of a soluble lymphocyte factor. It seems most likely that such a factor was responsible for the foetal lymphocyte sensitisation we have demonstrated.

The nature of this lymphocyte factor remains unclear. Some immunoglobulins are known to cross the placenta, but none has been shown to raise antigen-specific T-lymphocyte responses in unsensitised individuals. Several soluble factors for specific T-cell stimulation however, have now been described. One possibility in this context is transfer factor[13] which can transfer delayed type hypersensitivity and, having a molecular weight of less than 10,000, could cross the placenta passively. The nature of the factor suggested by our study clearly needs further investigation.

Cytoplasmic exclusion as a basis for asymmetric nucleocytoplasmic solute distributions

THE nuclear and cytoplasmic concentrations of solutes in cells are often unequal. This has been observed for ions[1,2], small molecules[3–5], and for macromolecules[6–10]. The role of maintaining these concentration differentials is commonly assigned to the nuclear envelope, but this practice is predicated on a questionable analogy with the plasma membrane. Most of the information derived from tracer kinetics[4,8,9] and electrical resistance[10–13] indicates that the nuclear envelope is too permeable to distinguish or differentially transport small solutes. Thus, we must look to other, presumably equilibrium, mechanisms to account for many nucleocytoplasmic solute asymmetries. One useful step in the analysis of solute distributions between two phases is to establish a reference phase to which the concentrations of substances in the other two phases can be compared. A suitable reference phase for cytoplasm and nucleus cannot, of course, be separated from them by the cell membrane, which itself has complex, asymmetric transport properties. Thus, the reference phase must be intracellular. We have carried out experiments in which a defined aqueous reference phase (a gelatin gel) was introduced into the cytoplasm, and the partition of solutes between this phase, cytoplasm, and nucleus was determined. We deal here with the intracellular distribution of ^{3}H-sucrose—a small, non-metabolised substance which reaches a greater concentration in the nucleus than in the cytoplasm[4].

The experimental design was as follows: a solution of 11% fluorescein isothiocyanate-labelled gelatin was microinjected into the vegetal hemispheres of grown *Rana pipiens* oocytes at 34 °C. The oocytes were immediately cooled in ice-cold Ringer's to gel the gelatin, and then brought to 15 °C. The gelatin remained gelled at this temperature and provided the intracellular reference phase. Shortly before or after gelatin injections (the sequence did not influence the results). ^{3}H-sucrose was microinjected into the oocyte cytoplasm. The oocytes were incubated for at least 3 h (adequate time for ^{3}H-sucrose to achieve diffusional equilibrium[4]), quenched to liquid nitrogen temperature, sectioned at −50 °C, and the intracellular distribution of tracer determined quantitatively by ultra-low temperature autoradiography[14]. Figure 1 is a diagram of a typical autoradiographic section showing the nucleus and the gelatin within the cytoplasm, with the local grain densities superimposed.

Silver grains were uniformly distributed under the cytoplasm, confirming that the injected ^{3}H-sucrose had reached diffusional equilibrium. Grain densities under the nucleus and gelatin were also uniform but were higher than under the cytoplasm—2.66 and 2.67 times greater, respectively. When the nucleus–cytoplasm (N–C) grain density ratio is corrected for the different water content of the two compartments (N–C = 1.88, ref. 1), a ^{3}H-sucrose partition coefficient of 1.41 is obtained for nucleus–cytoplasm. The water content of the intracellular gelatin gel phase is assumed to be that of the gelatin sol injected (89%), and the corrected ^{3}H-sucrose partition coefficient for gelatin–cytoplasm is 1.35. (It is possible that the water content of the gelatin changed subsequent to injection. Even total replacement of the gelatin by water, however, would yield a coefficient no less than 1.20). Table 1 summarises our results.

Control data include nucleocytoplasmic partition coefficients in oocytes injected only with ^{3}H-sucrose, and the dialysis partition coefficient between 11% gelatin and buffer. These controls show that intracellular gelatin does not affect the nucleocytoplasmic partition of ^{3}H-sucrose. Furthermore, the ^{3}H-sucrose asymmetries cannot be attributed to affinities of either gelatin or nucleus for ^{3}H-sucrose, since the gelatin–buffer concentration ratio is essentially unity, as is that of nucleus–gelatin. We conclude that there must be an exclusion of ^{3}H-sucrose from some of the cytoplasmic water—that is, cytoplasmic water is less available as a solvent than the water of gelatin, the nucleus, or buffer. The data may be explained if 4% of the nuclear water and 32% of the cytoplasmic water are unavailable as solvent for ^{3}H-sucrose.

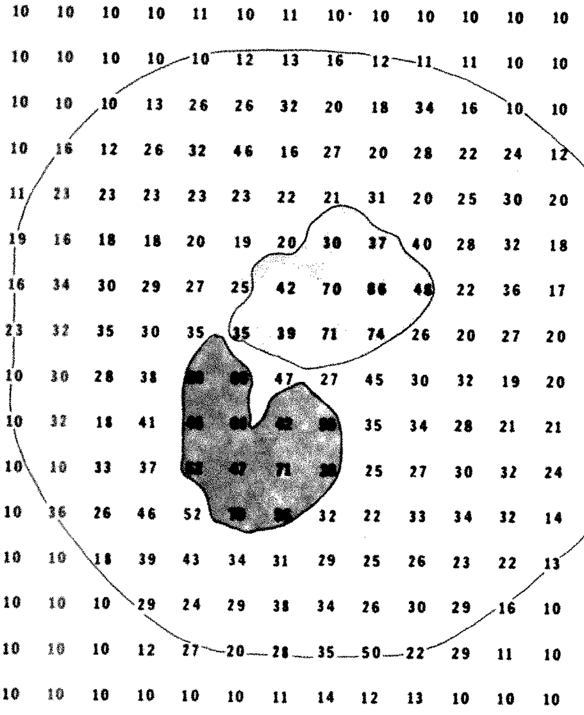

Fig. 1 Diagram of an ultra-low temperature autoradiographic section through the oocyte nucleus (light shading) and gelatin (dark shading). A volume of 11% fluorescein isothiocyanate-labelled gelatin about equal to that of the nucleus was microinjected as a sol (at 34 °C) in buffer (15 mM NaCl and 130 mM K phosphate, *p*H 7.1). After gelation (at 0 °C) of the gelatin, 0.2 μCi ^{3}H-sucrose (New England Nuclear) in 5×10^{-5} ml water was microinjected and the oocyte incubated at 15 °C for a time sufficient for the ^{3}H-sucrose to reach diffusional equilibrium (3–4 h). The oocyte was then rapidly embedded in OCT and quenched to −190 °C in liquid nitrogen, with sectioning and autoradiographic exposure carried out at ultra-low temperatures to prevent ^{3}H-sucrose redistribution[14]. The nucleus was identified by its size, location in the animal hemisphere, absence of yolk platelets and pigment granules, and the presence of chromatin and nucleolar clumps. The gelatin appeared as an inclusion-free area which was positively identified by its fluorescence in blue light illumination. Superimposed on the section are relative local grain densities, determined photometrically with a Leitz MPV-1 microscope photometer using Ploem incident light illumination[22]. The grain density values shown are absolute photometer readings, and have not been corrected for the different water contents of the cytoplasmic, nuclear and gelatin compartments. The data summarised in Table 1 were derived from 18 similar two-dimensional grain-density plots from sections taken from five cells.

Table 1 Equilibrium partition of ^{3}H-sucrose between aqueous phases at 15 °C

Phases	K*
Gelatin-injected cells	
Nucleus–cytoplasm	1.41 ± 0.03
11% Gelatin–cytoplasm	1.35 ± 0.03
Nucleus–11% gelatin	1.04
Controls	
Nucleus–cytoplasm (no gelatin injected)	1.34 ± 0.08
11% Gelatin–buffer (dialysis chamber)	0.98

* Ratio of ^{3}H-sucrose concentrations in the water of the respective phases at diffusional equilibrium (± s.e.m.).

Nucleocytoplasmic concentration asymmetries in oocytes have been previously reported for glycerol[3], unbound Na$^+$ (ref. 2), α-aminoisobutyric acid[5], inulin[8], three molecular sizes of dextran[9], and exogenous proteins[7,15]. Also, endogenous oocyte proteins exhibit nucleocytoplasmic distributions greater than unity[15,16], although their distributions may be caused in part by mechanisms other than cytoplasmic exclusion (for example, specific binding to nuclear components or asymmetric nuclear envelope transport).

Many other types of cells show asymmetric nucleocytoplasmic distributions of solutes, but without experimental analysis of the type described here, cases of cytoplasmic exclusion cannot be distinguished from asymmetries caused by other mechanisms. Nevertheless, because of the nature of the solutes and the magnitudes of the asymmetries observed, we suggest that the intracellular distributions of colloidal gold in amoeba[18,19] and of fluorescein-labelled exogenous proteins in salivary gland cells[10] of *Chironomus* may reflect the operation of cytoplasmic exclusion. It is likely that the asymmetric nucleocytoplasmic equilibrium distribution of the shuttling proteins of amoeba[17] is also explicable by cytoplasmic exclusion processes. Data from these diverse cell types suggest that the concentration of soluble cellular components in the nucleus occurs by cytoplasmic exclusion in many cells.

Intracellular concentration differences are not restricted to the nucleus, and other organelle–cytoplasm solute distributions may reflect the operation of cytoplasmic exclusion. Specifically, cytoplasmic exclusion may have a previously unexpected role in determining solute distributions between the cytoplasm, vacuoles, and the cisternae of the endoplasmic reticulum and the Golgi apparatus.

Our observations demonstrate the existence of cytoplasmic exclusion: they do not specify the molecular mechanism(s) responsible. It is clear, however, that much less cytoplasmic water is available as solvent than is measurable by subtraction of dry from wet weights. The operative mechanisms may include changes in bulk solvent properties of water through electrostriction, hydrophobic interactions, and solvent–polymer H bonding, and/or restriction of the accessibility of the water to solute through solvent microcompartmentalisation or polymer–solute repulsive interactions. Analogues for the behaviour of the cytoplasm are found in other macromolecular systems, such as solutions of

441.6–400 nm, reaching a value of less than 0 02 at the vaccinia virus[20], hyaluronic acid[21], and the cross-linked dextrans used in chromatography.

Whether these or other mechanisms are responsible for the exclusion behaviour of cytoplasm, the process itself should not be overlooked in seeking the explanation for asymmetric distributions of solutes between the nucleus and cytoplasm.

Retinal sensitivity to damage from short wavelength light

A GROWING body of literature attests to the deleterious effects of long term exposure to light[1–8]. To define more critically the differences between thermal and photochemical effects, we have exposed the retinae of rhesus monkeys to eight monochromatic laser lines from 1,064–441.6 nm. Thermal damage to the retina is to be expected for the 1,064-nm line since the photopigments are not involved and energy absorption takes place predominantly in the melanin granules of the pigment epithelium and the choroid Although data on pathogenesis are not yet available, we found some interesting differences in retinal sensitivity in going from the near infrared to the blue wavelengths in the visible spectrum

In a recent paper[9] on solar retinitis in the rhesus monkey, we pointed out that a simulated solar exposure of 3 min duration produced a retinal lesion which could not be explained solely in terms of thermal injury, but which must cause some damage by a photochemical mechanism. We postulated some type of thermally enhanced photochemical effect similar to Noell's findings[1]. It now seems possible to account for solar retinitis almost entirely in terms of the photochemical effects of the short wavelength components in the Sun's spectrum Tso[10] has reported on some patients who gazed voluntarily at the Sun for an hour before submitting to enucleation for malignant melanoma. An estimate of the maximum temperature on the retina using White's[11] mathematical model for solar observation yields approximately 1.5 °C above ambient for a 2-mm pupil. Whereas these patients suffered minimal visual acuity effects and obviously did not sustain retinal burns, the pathology after enucleation indicated damage to the retina which must have resulted from photochemical processes aided perhaps by thermal enhancement.

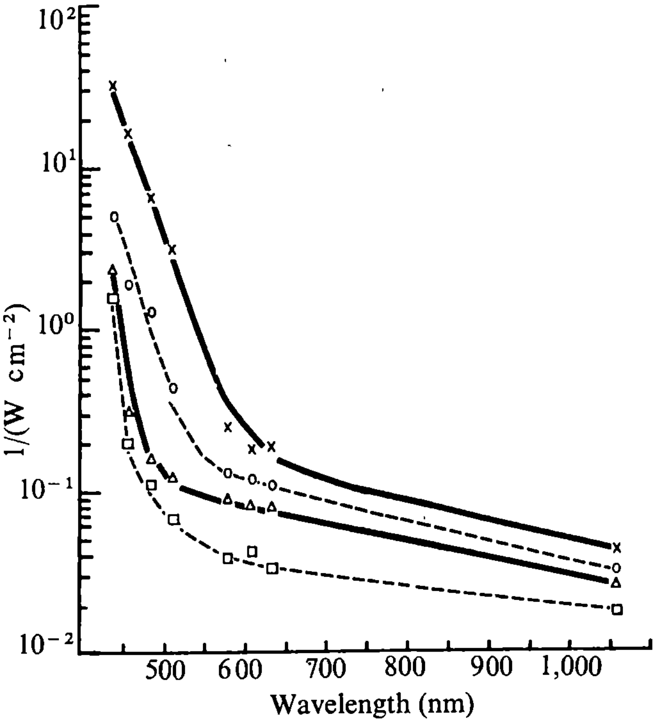

Fig. 1 Action spectrum of retinal sensitivity to threshold damage in the rhesus monkey. Reciprocal of retinal irradiance ($1/\text{W cm}^{-2}$) is plotted semi-logarithmically against wavelength (nm) for exposure durations of 1, 16, 100 and 1,000 s. Beam diameter on the retina was 500 µm to the $1/e^2$ points of the Gaussian distribution. □, 1s; △, 16 s; 0, 100 s; ×, 1,000 s.

Results of the present experiments are summarised in Table 1, in which maximum retinal irradiance (W cm^{-2}) and maximum temperature in the retina above ambient (°C) are given for each exposure duration and wavelength. Maximum irradiance H_0 is based on the Gaussian distribution of the laser beam

$$H = H_0 \exp(-r^2/2\sigma^2)$$

where H is the irradiance at radius r from the Gaussian peak and σ is calculated from the beam profile by measuring r at the $1/e^2$ points. H_0 on the retina is calculated from the formula

$$H_0 = P_c T / 2\pi\sigma^2$$

where P_c is the power (W) entering the cornea and T the transmittance through the ocular media of the rhesus monkey as measured in our laboratory on nine eyes from five animals. An irradiance of 24 W cm^{-2} at a temperature of approximately 23 °C above ambient produced a threshold lesion in 1,000 s with the Nd-YAG laser (1,064 nm) In contrast, the 441 6-nm line from the He:Cd laser required only 30 mW cm^{-2} with negligible temperature rise to produce a threshold lesion in a 1,000-s exposure. The ratio of the two irradiances on the retina is 800. The Nd–YAG lesion has the typical appearance of a burn lesion, whereas the He–Cd lesion has no central core but appears as a slight patch of yellowish-white on the fundus, often with irregular boundaries. We attribute the lesion produced by 1,064-nm radiation to thermal effects, whereas that produced by the 441.6-nm line must be caused by photochemical processes.

Figure 1 is an action spectrum obtained by plotting semi-logarithmically the reciprocal of retinal irradiance ($1/\text{W cm}^{-2}$) against wavelength (nm) for each exposure duration The increase in retinal sensitivity with decrease in wavelength is steep even on a semi-logarithmic plot and shows no tendency to peak at 441.6 nm. Transmittance through the ocular media falls rapidly for wavelengths 441 6–400 nm, reaching a value of less than 0.02 at the

Table 1 Retinal irradiance H_0 (W cm^{-2})±s.d. for threshold lesion as function of wavelength (nm) and exposure duration (s)

Maximum retinal temperature (°C) above ambient estimated from mathematical model of Clarke[12]. *T*, Transmittance through ocular media. Beam diameter on retina 500 μm to $1/e^2$ points. Entire laser beam, TEM$_{00}$ mode, enters eye of anaesthetised animal with pupil dilated to 8 mm. A beam splitter and fundus camera are used to view and direct beam on the retina. Criterion for a threshold lesion is the appearance 24 h after exposure of a funduscopically visible lesion. For details of method of determining thresholds, see ref. 9.

lower wavelength. This is caused primarily by absorption in the lens. Whereas the sensitivity of the retina may continue to increase in the wavelength band 441–400 nm, the number of photons reaching the retina is reduced drastically by absorption and scattering in the lens and the rest of the ocular media. In fact, the threshold for damage may shift from the retina to cataractogenesis in the lens. We are attempting to explore this region of the spectrum using narrow bandpass filters with a 2,500-W xenon arc lamp. Also, it is planned to expose the retina of the monkey after surgical removal of the lens.

These results help to explain the phenomenon of solar retinitis which cannot be interpreted solely in terms of thermal injury. Unattenuated sunlight peaks at 470 nm and a relatively large proportion of the solar energy is concentrated in the blue end of the spectrum. For example, the solar retinal irradiance at 440 nm for a 20-nm spectral band is approximately 0.20 W cm^{-2} at midday for an eye gazing directly at the Sun at sea level with a 2-mm pupil. In comparison, the threshold irradiance for a 100-s exposure to the 441-nm laser line of He–Cd is 0.20 W cm^{-2}. Thus, sungazing at bright midnoon for 100 s can produce a threshold lesion. It is our belief that solar retinitis is caused primarily by the short wavelengths in the visible spectrum of the Sun, with some thermal enhancement from the longer wavelengths in the visible and near infrared. The retinal pathology among military personnel on a Pacific island as reported by Smith[13] and the aetiology of foveomacular retinitis among military personnel as reported by Marlor[14] can be better understood in terms of these results. Those subject to exposure to bright sunlight over long periods should take precautions to shield their eyes from the short wavelengths of solar radiation. This has implications in the design of sunglasses and welders' goggles. The sensitivity of the retina to short wavelengths of light may also have clinical significance for certain retinal pathologies such as senile macular degeneration and retinitis pigmentosa.

The sensitivity of the retina to blue light may have more profound effects for man-made optical sources than for sunlight. The trend towards ever brighter sources in the blue end of the spectrum—high pressure Hg and xenon arc lamps, and the 'natural' lighting sources in current use—are examples. The ocular hazards associated with lasers may require re-evaluation. Arc welding is another example where the eyes may need special protection from blue light. Children undergoing phototherapy for bilirubinemia should have their eyes protected and the growing population of elderly people with aphakic eyes will need protection from the short wavelengths in the visible and near ultraviolet spectrum.

The basic photochemical mechanisms underlying the sensitivity of the retina to short wavelengths of visible light are unknown. Our preliminary results indicate that the lesion is located in the outer segment of the photoreceptor and perhaps in the pigment epithelium. We have not as yet been able to distinguish between rod and cone damage and do not know to what extent the photopigments are involved. Most previously reported long term photic damage results from exposure to bright environmental lighting over periods of days or weeks, whereas our exposures extend from 1–1,000 s and are confined to an extremely small and finite portion of the retina. Anderson *et al.*[15] have reported similar sensitivity to blue light in albino rats in environmental lighting conditions. A number of mechanisms to explain long term photic damage to the retina have been proposed. These include photo-oxidative membrane damage, toxic products in the outer retina, metabolic disorders from extended overbleach, and so on. In our opinion the continued increase in sensitivity with decreasing wavelength indicates that additional molecular systems become vulnerable to electronic excitation and photic damage as the energy per photon increases. This is to be expected and we believe that several photochemical mechanisms are probably responsible for the observed damage. We do not expect the action spectrum to peak as the near ultraviolet is approached.

Drs R. Peterson and R. James, Laser Section, Division of Electronic Products, Bureau of Radiological Health, provided exposures in their laboratory to the Nd–YAG 1,064-nm laser radiation. Supported jointly by the Bureau of Radiological Health, the Food and Drug Administration, the US Army Medical Research and Development Command, and the General Electric Foundation. In conducting the research described in this report, the investigators adhered to the *Guide for Laboratory Animals Facilities and Care* of the Committee on the Guide for Laboratory Animal Resources, National Academy of Sciences–National Research Council.

Visual adaptation produced by gratings with no brightness contrast

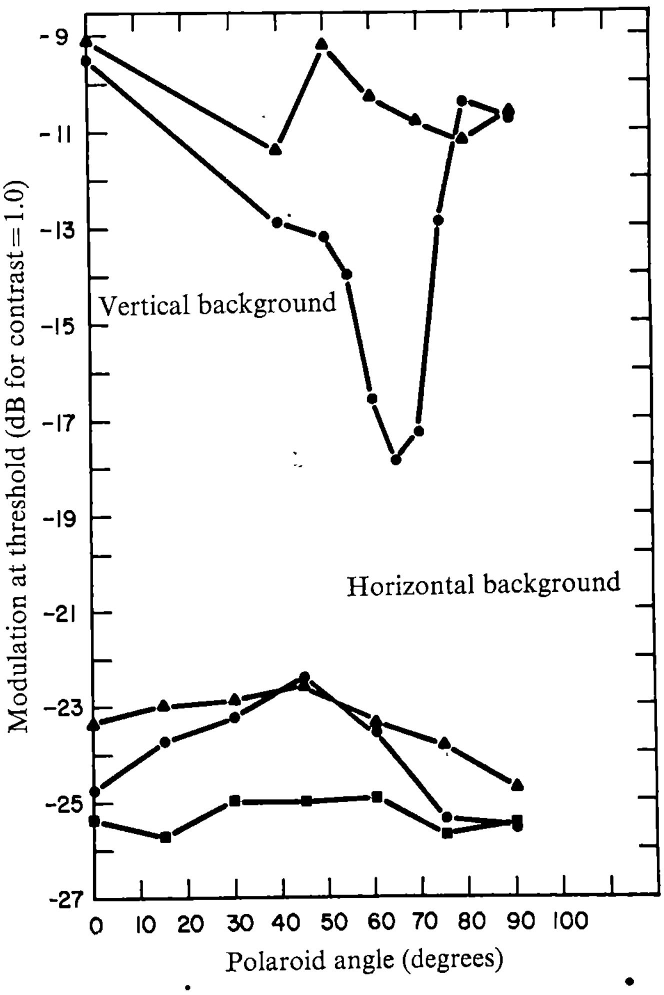
A STRIPED grating is more difficult to see after prolonged viewing of a similar grating[1,2]. Similarly, the contrast threshold is elevated when a test grating is briefly presented superimposed on a continuously viewed grating[3,4]. Here we show that the threshold is raised by gratings that have no brightness difference between alternate stripes, but only a hue difference. We measured luminance modulation thresholds for seeing a yellow grating superimposed on a background of interdigitated red and green stripes. We varied the relative luminances of the red and green stripes while holding the sum of their luminances constant. Thus we could be certain that for some luminance ratio, the red and green stripes must have had the same subjective or effective brightness for the observer. Nevertheless, we found that for all ratios of red-to-green luminance the contrast threshold for the test grating was higher than that obtained in several control conditions (including backgrounds with the same colours and configuration but perpendicular to the test grating, and uniform backgrounds with the same mean spectral composition).

Yellow test gratings were produced by conventional techniques on an oscilloscope with P31 phosphor, viewed at a distance of 3 m through an Ilford 201 filter. The test field was a 13 cycles per degree sine grating, 2° square. The background gratings, also 13 cycles per degree, were produced by two projectors whose beams fell on a ground glass screen after being merged by a half-reflecting pellicle. Each projector cast an image of a square-wave grating on the screen. An Ilford 624 (bright spectrum green) filter was placed in the beam of one projector, and an Ilford 205 (narrow cut tricolour red) filter in the beam of the other. Polaroid filters oriented perpendicularly with respect to each other were also interposed in the separate beams. The relative intensities of the red and green components could then be varied by rotating a Polaroid interposed in the common beam. The positions of the red and green gratings could be adjusted so as to superimpose the red and green stripes or to interdigitate them. When red and green were superimposed, the grating varied in appearance from red-and-black through yellow-and-black to green-and-black as the Polaroid in the common path was rotated. When red and green were interdigitated, the appearance varied from red–black through red–green to black–green. The screen was viewed from the side opposite the projectors at a distance of 3 m, and was seen through a pellicle that merged its image with that of the test grating. A dove prism close to this pellicle, but only in the path to the background screen, controlled the orientation of the background grating. Various adjustments allowed for the precise control of orientation, phase, and magnification of test and background gratings. The mean luminances over the area at the observer's eye were 6.2 and 3.9 cd m^{-2} for the red and green components at their respective maximum settings and 6.2 cd m^{-2} for the test field.

Contrast thresholds were measured by a two-staircase up-and-down procedure. When the observer pressed a key the test screen was changed from homogeneous to striped for 100 ms. If he saw the test grating, its contrast was reduced by 1 dB (about 12%) on the next trial on that staircase. If he did not see it, it was raised by 1 dB. Random selection of the staircase operative on each trial reduced the observer's ability to predict the changes in contrast from trial to trial. All of the results are contrast thresholds for detection of a yellow vertical sine grating; therefore any differences in thresholds are due to the differences in the backgrounds on which the test grating was presented.

Figure 1 plots the contrast thresholds for the test grating on various backgrounds. The x axis represents the relative luminances of the red and the green background stripes, as determined by the setting of the variable Polaroid. Thresholds were nearly independent of Polaroid angle for all background conditions except vertical interdigitated red–green gratings. With interdigitated vertical gratings, however, the threshold was found to vary with relative luminance of the red and green stripes, reaching a minimum at a Polaroid angle of about 65°. Even at this point, though, the threshold was elevated substantially—5 dB higher than in any of the three control

Fig. 1 Contrast thresholds for a vertical yellow test grating (13 cycles per degree) presented briefly against various backgrounds: interdigitated red and green stripes, superimposed red and green stripes, uniform yellow field. Relative luminance of red and green components was varied by rotating a Polaroid filter in the dual optical system. For interdigitated backgrounds Polaroid settings of 0° produced red–black and 90° black–green gratings respectively. All data are from the same observer. Mean s d. of observations, 0.94 dB. ●, Interdigitated stripes; ▲, superimposed stripes; ■, uniform background.



conditions (horizontal interdigitated, horizontal superimposed stripes, or uniform backgrounds of the same mean luminance and mean spectral composition as the striped fields). Essentially the same result has been obtained in several repetitions of this experiment using other grating frequencies (3 and 6 cycles per degree) and a second observer. We have always found some threshold elevation (at least 5 dB) with any luminance ratio of the red–green stripes. Thus it seems reasonable to conclude that threshold elevation can occur without luminous contrast in the adapting stimulus.

In this experiment the more intense stripes of the yellow test grating were aligned with the green stripes of the interdigitated backgrounds. An auxiliary experiment tested whether the relative position of background and test gratings had any effect on the contrast thresholds. Phase was varied in 30° steps from the condition where the more intense yellow steps were superimposed on the green background stripes to that where they were superimposed on the red background stripes. There was no systematic effect of phase. Threshold was 6 dB higher than the control condition with a maximum deviation of any point of 1 dB from the mean. Thus the variation of contrast thresholds with Polaroid angle (Fig. 1) cannot be attributed to phase effects.

Although thresholds are never as low on red–green vertical backgrounds as they are on the various control backgrounds, they do reach a minimum for an intermediate setting of the Polaroid, that is, when the luminance contrast is small or nonexistent. As shown in Fig. 1, this does not happen when the red and green stripes are in phase.

Two interpretations of the minimum in the curve with red–green interdigitated stripes are plausible. On the one hand, adopting a form of opponent-colour theory, it may be supposed that pattern information is carried by both luminance and chromatic channels. When the Polaroids were set at their extreme positions, producing red–black or green–black gratings, both classes of channels were activated, but in the middle range only the chromatic channels received inputs, thus resulting in less elevation of the threshold. Alternatively, it might be held that the sum of the contrasts in the primary cone mechanisms determines the degree of threshold elevation. Since the red light used stimulates the green cone mechanism (π_4) as well as the red cone mechanism (π_5) and the green light π_5 as well as π_4, the sum of the contrast in these mechanisms is greatest at the extreme settings of the Polaroid and reaches a minimum for some intermediate setting. It is not possible with the available data to choose between these alternative hypotheses.

From a simple, subjective point of view, it is perhaps not surprising that equally bright red and green stripes elevate the threshold for seeing gratings, since they are visible as gratings. Perhaps the threshold elevation is simply related to the visibility of the adapting pattern.

We thank F. W. Campbell in whose laboratory these experiments were conducted and C. Hood for assistance. J.K. was a Visiting Scholar at St John's College, Cambridge University, and held a US Public Health Services Special Postdoctoral Fellowship.

Dissociation of response to injected gonadotropin between the Graafian follicle and oocyte in pigs

THE process of ovulation in mammals is induced by a surge of gonadotropic hormone(s) that precipitates a series of changes in the cellular layers of the Graafian follicle. The changes in the somatic cells are extensive, ranging from enzymatic transformation in the biosynthetic pathway for steroid hormones[1,2] to morphological alterations in the membrana granulosa. In contrast, the only conspicuous modification in the germ cell is completion of the first meiotic division with extrusion of a polar body and formation of the second metaphase plate. The meiotic steps from diakinesis to first polar body formation are known to be programmed with considerable accuracy[3,4] by the endogenous surge of luteinising hormone (LH), but a similar sequence of nuclear changes can also be initiated by injection of a preparation rich in LH activity, such as human chorionic gonadotropin (HCG)[5–7]. Although the changes in the somatic cells and oocyte within the mature follicle usually occur in concert, we describe here circumstances in which the process of ovulation is dissociated from nuclear maturation of the germ cell, resulting in the shedding of a primary oocyte.

Mature Large White gilts with 20- or 21-d oestrous cycles were assigned to one of four groups and given a single intramuscular injection of 500 or 1,000 IU of HCG (Organon) in saline on day 17, 18, 19 or 20 of the cycle. Ovulation occurs 40–42 h after such an injection given during prooestrus[8,9]. Animals were tested immediately before injection with a mature boar to ensure that they were not in oestrus, a procedure continued twice daily until slaughter. Between 24 and 30 h after injection of HCG, laparotomy was performed under Nembutal–halothane anaesthesia and 5 ml of semen containing $1.99–2.74 \times 10^8$ spermatozoa per ml was instilled into each uterine horn. Animals were slaughtered 44–72 h after receiving HCG, and ova were flushed from the Fallopian tubes with Eagle's medium. These were fixed in acetic alcohol, stained with orcein and examined by phase contrast microscopy.

In 15 control animals, the steroid hormone environment of the oocyte was estimated in mid-follicular phase and shortly before ovulation. Follicular fluid was obtained at laparotomy during occlusion of the ovarian blood supply or immediately on ovariectomy, by aspiration into 1-ml plastic syringes through a 26-gauge needle Follicular fluid was stored at −20 °C until it could be analysed for oestradiol by radioimmunoassay; the method was essentially that of Hotchkiss *et al.*[10] but used an antiserum raised in sheep against 6-oxoestradiol coupled through a carboxymethyloxime bridge to bovine serum albumin. Progesterone was estimated by radioimmunoassay[11] using an antiserum raised in sheep against 11α-hydroxyprogesterone coupled through a succinate bridge to bovine serum albumin. Follicular fluids from animals injected with HCG were also examined by radioimmunoassay for LH activity.

Table 1 summarises the number of animals injected; the responses can be considered in terms of the maturation of several systems Display of behavioural oestrus was exceptional after HCG injection on day 17 or 18, but it was a predictable sequel to treatment in the later part of the follicular phase Likewise, after injection on day 17, the ovarian response to HCG was usually superovulation, whereas the mean ovulation rates after an injection on day 18, 19 or 20 did not differ significantly from those arising spontaneously in comparable animals.

The nuclear maturity of oocytes recovered from the Fallopian tubes was also related to the time of HCG injec-

Table 1 Responses to HCG

	System under consideration	Behavioural oestrus		Ovarian response		Maturity of oocyte nucleus	Block to polyspermy	Availability of vitelline factors (MPGF)†
Day of oestrous cycle* when HCG injected	No. of animals injected	Animals showing oestrus No.	(%)	Recent ovulations Total no.	Mean per animal	Primary oocytes (%)	Polyspermic eggs (%)	Eggs containing transformed sperm heads (%)
17	7	0	0	130	18.6	18.2	91.7	<10
18	9	1	11.1	112	12.4	17.4	38.0

Figures show results obtained from 88 post-puberal pigs illustrating five aspects of the response to a single intramuscular injection of HCG given at various stages of the follicular phase of the oestrous cycle. These results can be considered in terms of a series of biological systems which undergo maturation during the latter part of the oestrous cycle.

*Only animals with oestrous cycles lasting 20 or 21 d were assigned to this experiment.

†MPGF, Male pronucleus growth factor[14].

tion: most oocytes recovered after day 17 treatment possessed a dictyate nucleus in which the chromatin was condensed around a single large nucleolus. Such primary oocytes were tightly encompassed by cumulus cells. By contrast, after HCG injection on day 199 or 20, recovery of primary oocytes was rare, only 14 being observed among 785 ova examined from these groups.

Maturation of the mechanism underlying the block to polyspermy was also inferred to be taking place during the follicular phase, since 92% of the oocytes recovered after treatment on day 17 exhibited polyspermy compared with 2–3% after treatment on day 19 or 20 (Table 1). Moreover, the extent of the polyspermic condition in individual primary oocytes was frequently massive, with as many as 60–80 unswollen sperm heads in the egg cytoplasm and still more spermatozoa in the perivitelline space. Other systems in the egg cytoplasm were evidently undergoing maturation during the follicular phase, as judged by the failure of sperm heads within the vitellus of primary oocytes to decondense and form pronuclei. This metamorphosis is thought to be promoted by interaction between the sperm head and egg cytoplasm[12–14], and is an essential step in the formation of a spherical pronucleus.

Assay of samples of follicular fluid revealed a marked variation in the concentration of oestrogens between follicles from the same animal, ranging from 15–210 ng ml^{-1} on day 17 of the cycle to 108–750 ng ml^{-1} on day 20, shortly before the onset of behavioural oestrus. There was also considerable variation between animals in the oestrogen content of follicular fluid aspirated on the same day of the cycle. Nevertheless, an overall trend of an increasing concentration of oestrogens in follicular fluid could be plotted from day 17 (mean 75.3 ± 8.7 ng ml^{-1}) to day 20 (263.8 ± 54.5 ng ml^{-1}), these values decreasing only after the onset of oestrus or HCG injection. Twenty-four hours after the latter event(s), the concentration of follicular oestrogens was frequently reduced to 6–40 ng ml^{-1} (mean 20.7 ± 5.1 ng ml^{-1}), whereas progesterone titres were as high as 3,400–6,400 ng ml^{-1}. The corresponding values for the concentration of oestrogens in peripheral plasma increased from 42 pg ml^{-1} on day 17 to 190 pg ml^{-1} on day 20, decreasing to 25–30 pg ml^{-1} 24 h after the onset of oestrus.

These observations show that nuclear and cytoplasmic maturation of the oocyte are not essential concomitants of the final maturation of the Graafian follicle, at least when ovulation is induced by HCG in the mid-follicular phase of the oestrous cycle. The dissociation of the response of the somatic cells from that of the germ cell obtained in such a situation makes it reasonable to question any direct involvement of the oocyte in regulating the destiny of the follicle and its membrana granulosa[15], as suggested by studies of pigs and rabbits involving ovectomy[16,17]. and of rats involving cultured oocytes and granulosa cells[18].

The basic question arising from this work is the manner in which the oocyte normally responds to gonadotropic stimulation, and the nature of the failure to resume meiotic maturation in conditions of precocious ovulation induced by HCG. Previous work has demonstrated receptors for LH on porcine granulosa cells[19], and also that HCG can bind to these cells[16,20]. Accordingly, we propose that the increasing titres of intrafollicular oestrogens that arise during the latter part of the oestrous cycle mediate in the response of the oocyte to the gonadotropin stimulus, in part at least by increasing the binding sites available for LH or HCG on the granulosa cells; these sites have been reported to be similar[21]. Failure of the oocyte to respond after day 17 HCG injection is not due to a lack of gonadotropic hormone reaching the granulosa cells, since high levels of LH activity have been detected in follicular fluid within 4 h of injection of HCG (unpublished results of W. R. Carr and R.H.F.H.). In a broader biological context, the proposed involvement of oestrogens within the ripening follicle seems fundamental, since oocyte maturation would normally occur only in circumstances in which the animal was exhibiting behavioural oestrus, and where the reproductive tract was tonic and oedematous. In other words, an integrating gonadal hormone is needed during the late follicular phase to coordinate changes within the follicle, the reproductive tract and the hypothalamo-pituitary axis.

Bilateral electroencephalographic response and unilateral tolerance to unilateral intracerebral morphine injections

DRUG tolerance is characterised by a loss of sensitivity to the pharmacological properties of a drug as a result of repeated exposure. Because it can be produced by both intravenous and intracerebral injection of opiates or barbiturates[1–3], functional alteration of neural cells probably contributes to its development. The identification of mechanisms underlying the development of tolerance to morphine in the central nervous system is complicated by secondary drug-induced changes in bioelectrical and metabolic activity. This can be circumvented by the use of a mirror-focus preparation where comparison of the drug-treated region in one hemisphere can be made with the morphological homologue in the contralateral hemisphere. For example, Morrell[4] induced bilateral epilepsy after unilateral treatment with an irritant that causes the epileptic discharge pattern to be propagated, through the commissural projections, to the mirror-focus cells in the opposite hemisphere. Since the mirror-focus cells are never in direct contact with the epileptogenic agents, any alteration in their metabolism is due solely to epilepsy. Similarly, seizures generated by electrical stimulation of one amygdala propagate to the contralateral amygdala[4,5]. Since the anterior amygdala of the rat has a high concentration of opiate receptors[6], we have used it to investigate the effects of direct unilateral injection of morphine sulphate. We found that injections of opiates such as morphine and levorphanol produce seizures at the injection site that propagate to the mirror-focus in the contralateral hemisphere. Tolerance to opiates develops at the injection site but the mirror-focus retains normal sensitivity to opiates in spite of the shared epileptiform activity.

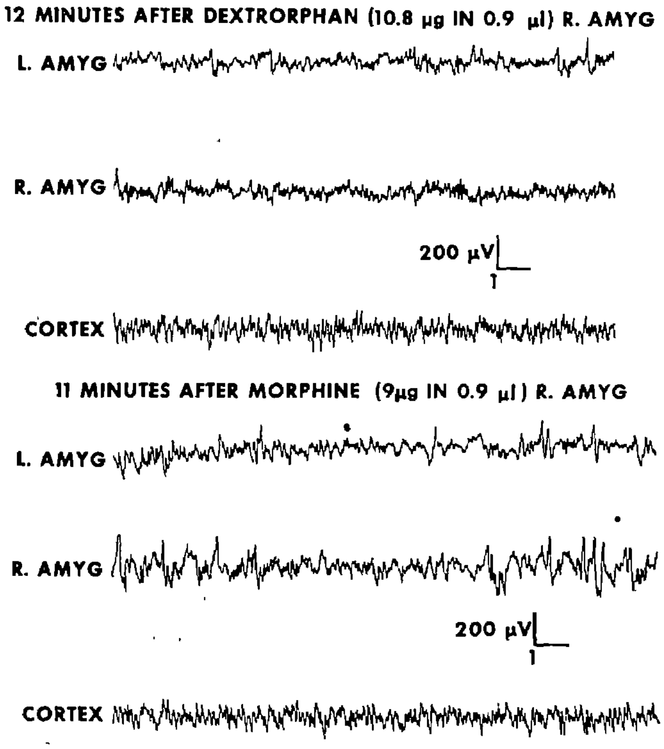

Fig. 2 Comparison of the effects of morphine and dextrorphan injected at the same site. Spike and wave pattern is evident after morphine. Dextrorphan has no effect. Cortical tracings are unaffected by amygdala injections.

Twenty-two Sprague–Dawley rats were anaesthetised with sodium pentobarbital and bilateral cannula-recording electrode assemblies were implanted in the anterior amygdala. The permanently implanted cannulae serve as a guide for smaller fluid delivery cannulae and as one pole of the bipolar recording assembly that monitors changes in electrical activity at the injection site. Injections of opiates

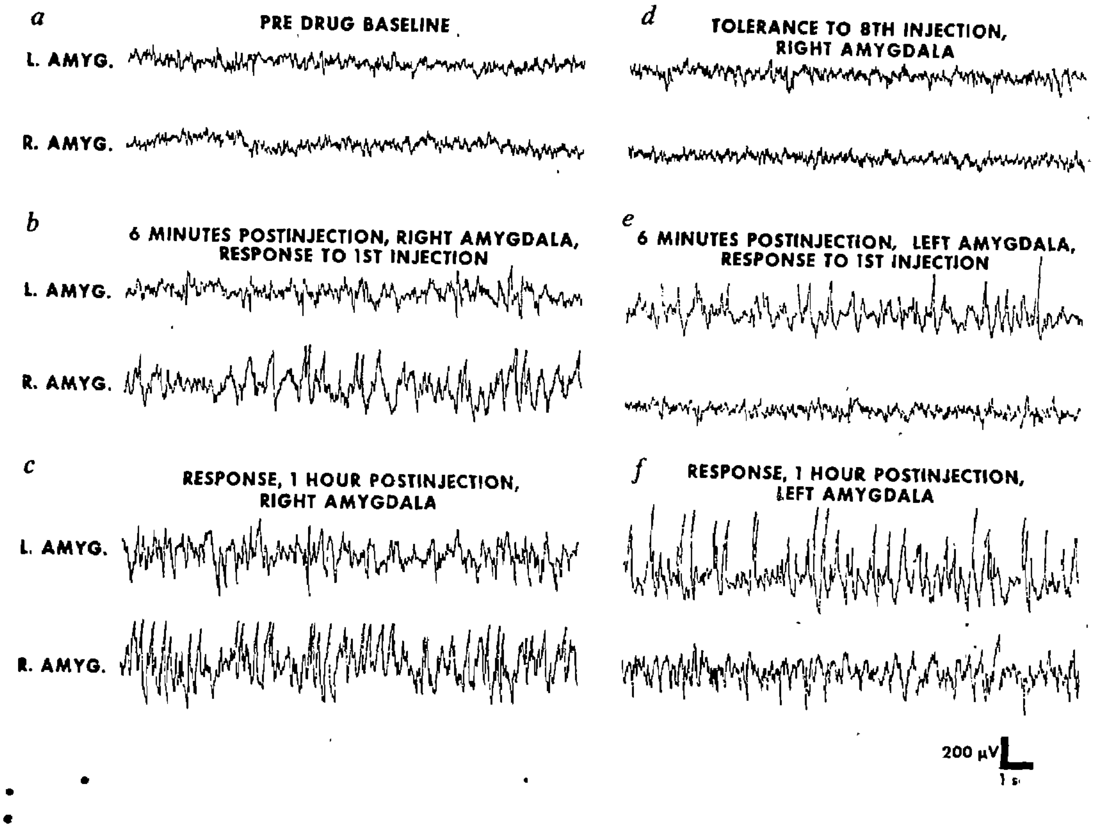

Fig. 1 Lateralisation of morphine tolerance to the right amygdala as a result of eight consecutive microinjections (2.7 μg in 0.9 μl) of morphine. In spite of the shared epileptiform activity of the mirror-focus in the left hemisphere, tolerance to morphine is restricted to the original injection site.

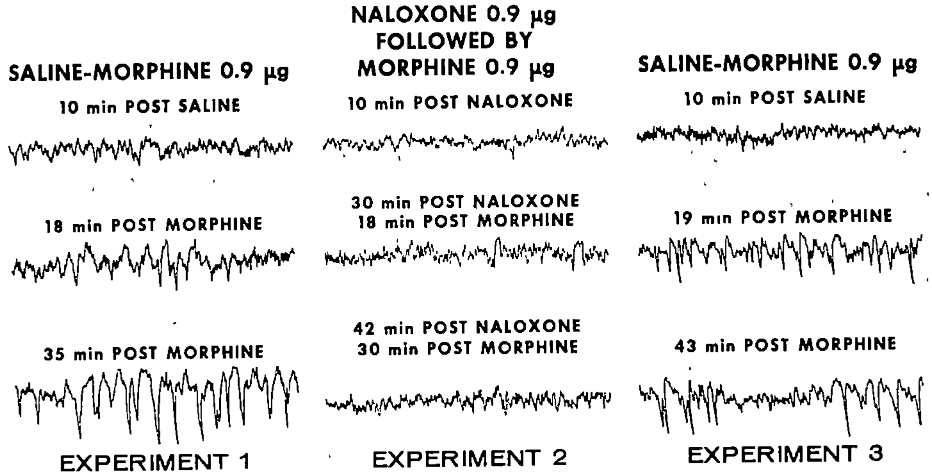

Fig. 3 Antagonism of morphine-induced changes in amygdala electroencephalographic activity by preinjection of an equal dose of naloxone. Experiments 1 and 3 were carried out 2 d before and after naloxone challenge.

and control injections of saline were delivered at a rate of 0.03 μl s^{-1} during 30 s.

After injecting morphine sulphate (2.7 or 9.0 μg) unilaterally into the anterior amygdala, we observed a spike and wave pattern at the injection site in 17 of 22 animals (Fig. 1*a* and *b*). The pattern appeared at the contralateral amygdala 15–30 min after injection and persisted for 3–4 h (Fig. 1*c*) each day. Injections of saline had no effect at either recording site. After repeated daily injections, tolerance manifested by a diminished bioelectric response developed at the injection site (Fig. 1*d*).

In spite of the daily appearance of sustained epileptiform patterns of the mirror-focus in the opposite hemisphere, tolerance was not transferred to the opposite hemisphere. When a similar dose of morphine was administered directly to the previously untreated amygdala, sensitivity to the drug was normal at the mirror-focus (Fig. 1*e*). Furthermore, kindled spike and wave patterns were seen at the original injection site (Fig. 1*f*). Levorphanol (3.0 μg) caused a similar response when injected into the amygdala. Furthermore, cross tolerance between the two opiates has been observed (our unpublished observations). Dextrorphan (10 8 μg), however, elicited no apparent electroencephalographic response (Fig. 2).

Several lines of evidence indicate that the electroencephalographic response of the amygdala elicited by acute morphine administration, and the eventual disappearance of this response with chronic morphine treatment is not a toxic or nonspecific effect

Cannula location is critical in the production of this response. Histological examination showed that cannulae placed bilaterally over the anterior amygdala gave bilateral opiate responses. If the tips of the cannulae were in the ventrolateral striatum or deep in the pyriform cortex, no morphine response was seen. The localisation of this response to the anterior amygdala is consistent with reports of high concentrations of opiate receptors in this region.

Although chronic morphine administration led to diminution of the response of the amygdala, an increase in the dose resulted in the reappearance of the response seen with acute doses. The loss of sensitivity seen after repeated injections of morphine could not have been the result of consequent tissue distortion, because a week of daily control injections of an equal volume of saline had no effect on morphine sensitivity of the amygdala ($N=3$). The response to the opiates is stereospecific—levorphanol but not dextrorphan mimics the action of morphine Naloxone has no apparent effect when administered by itself but blocks the effect of subsequent morphine administration. Pretreatment with an equal dose of naloxone (10 min before morphine) completely blocked the morphine response (Fig. 3) seen on control days before (experiment 1) and after (experiment 3) the naloxone test when sensitivity to morphine was normal ($N=4$).

Evoked potential thresholds (produced by electrical stimulation of the contralateral amygdala) were unchanged in spite of the appearance of drug-induced alterations in electroencephalogram patterns at the injection site. Recordings always returned to baseline after drug administration.

These findings show that unilateral tolerance can be produced by unilateral intracerebral microinjection of morphine sulphate into the amygdala Furthermore, the morphine-induced epileptiform patterns shared by both amygdala do not contribute to the development of drug tolerance

Although tolerance to direct intracerebral injections of opiates and barbiturates has already been demonstrated[1,3], this is the first demonstration of lateralisation of opiate tolerance. We plan to relate this unilateral alteration in drug sensitivity to an ipsilateral alteration in biochemical activity that is not seen at the contralateral site in the brain in spite of identical morphology and shared epileptiform experience.

We thank Endo Laboratories and Hoffman La Roche for naloxone, dextrorphan and levorphanol.

Changes in sensitivity of morphine-induced circling behaviour after chronic treatment and persistence after withdrawal in rats

BEHAVIOURAL effects of morphine may be mediated, at least in part, by functional changes in the dopaminergic nigrostriatal system[1]. Thus, for example, acute administration of morphine increases the rate of dopamine turnover in the striatum (for examples refs 2–4), and nigrostriatal lesions block symptoms of morphine withdrawal[5–7]. Spontaneous turning in circles after drug treatment in rats has been reported to be an index of an intrinsic asymmetry between left and right nigrostriatal pathways[8–12]. We now report that both acute morphine administration and cessation of chronic morphine administration induce this rotation, which persists for at least 2 months after withdrawal. The data suggest that morphine induces the synthesis of an endogenous morphine-like substance[13–15] which persists long after morphine is eliminated.

The subjects were naive female Sprague–Dawley rats weighing approximately 260 g. For measuring rotation, rats were placed individually in a completely automated rotometer[16] which differentiates between complete 360° rotations and incomplete oscillatory turns. After habituation for 15 min each rat was injected intraperitoneally with morphine sulphate or saline. Rotations were recorded on a printout counter during the 60 min after injection. Rotations to the left or right were totalled separately and the net positive rotational difference (that is rotations in the dominant direction minus rotations in the opposite direction) was determined for each rat.

In the preliminary acute dose–response studies, doses from 0.25 to 20.0 mg kg^{-1} were tested (12 rats per dose). Morphine induced significant ($P < 0.05$, t tests) rotation at 2.5, 5 and 10 mg kg^{-1}; with larger doses rats became increasingly catatonic. Mean net rotations per hour ± s.e. for 0 (saline), 0.25, 1.0, 2.5, 5.0, 10.0 and 20.0 mg kg^{-1} were, respectively: 2.2±0.6, 5.8±1.4; 5.7±1.6, 7.2±2.3, 12.7±3.9, 10.0±2.6 and 4.8±1.4. As with other drugs[8,11], the rotation induced by morphine was consistent in direction and magnitude; that is, when retested at weekly intervals with 5.0 mg kg^{-1}, some rats consistently rotated to the right and others to the left, and the numbers of net rotations were significantly correlated ($r = +0.55$ to 0.61, $P < 0.01$, t test) from week to week. The rotation cannot be attributed to hyperactivity. If an animal were only hyperactive there might be more turns, but there is no reason *per se* why such turns should be unevenly distributed, in any consistent way, to the left or right. It seems that net rotations are inversely correlated with locomotor activity[17].

In the experiments involving chronic administration, 16 rats were initially (day 1) tested for rotation following an injection of morphine (5.0 mg kg^{-1}). A day later, silicone reservoirs were implanted subcutaneously in all rats as described by Goode[18]. On the next day, chronic morphine administration was begun for 3 d (days 3, 4 and 5). Each morning the reservoirs were rinsed with physiological saline and refilled with 0.5 ml of morphine sulphate solution in a saline vehicle (50 mg ml^{-1}). On the withdrawal day (day 6), the reservoirs were rinsed and filled only with saline. Immediately after removal of morphine from the reservoirs, each rat was placed in a rotometer and, 15 min later, injected with either morphine (5.0 mg kg^{-1}; group 1, $N = 8$) or saline (group 2, $N = 8$). Each rat was tested again for rotation after receiving the same dose of morphine or saline 1, 3, 7, 15, 30 and 60 d after withdrawal of chronic morphine (days 7, 9, 13, 21, 36 and 66 in Table 1). The body weight of each rat was recorded before the first injection of morphine (day 1) and on every day thereafter that rats were handled.

The results are shown in Table 1. After withdrawal of morphine on day 6, the rats in group 1 were somewhat tolerant to the rotatory effect of morphine and the rats in group 2 did not rotate after receiving saline. Mean net rotations in group 2 were not significantly different ($P > 0.1$, t test) from an acute effect of saline in naive rats ($N = 12$) nor from an effect of saline in rats implanted with reservoirs filled only with saline ($N = 4$). By 3 d after withdrawal (day 9), the rats injected with morphine were obviously more sensitive to the rotatory effect of morphine and the rats injected with saline rotated as much as they had previously in response to their first (day 1) injections of morphine. Both of these latter effects were greater 7 d after withdrawal (day 16) and remained stable thereafter on all subsequent testing days. In contrast, body weight changes showed a typical early withdrawal pattern[7,19]—a decrease in body weight 1–3 d after withdrawal followed by a return to pre-withdrawal weights within 7–10 d. The small numbers of net rotations (approximately two per hour) induced by saline in naive rats were not consistent in direction and did not increase in magnitude when rats were retested at weekly intervals for up to 2 months. Since saline does not normally induce rotation, withdrawal-induced rotation seems to be a genuine manifestation of a protracted abstinence syndrome[20].

Correlations of day 1 morphine-induced rotation with withdrawal-induced rotation, as well as with morphine-induced rotation after withdrawal, suggest that chronic administration of morphine induces the synthesis of a morphine-like substance[13–15] responsible for the prolonged rotatory effects observed. That is, the direction of rotation of each rat was consistent across all tests, and saline and morphine data from 3 to 60 d after withdrawal were quantitatively correlated ($r = +0.64$ to 0.71, $P < 0.01$, t test) with day 1 data; the more a rat rotated in response to an acute injection of morphine, the more it also rotated during the withdrawal tests. In previous studies[21] with other drugs, we have generally found that although rotation is always consistent from week to week, when rats are retested with the same drug, there are no positive and quantitative correlations between drugs (for example, rats may rotate in opposite directions with (+)-amphetamine and apomorphine)—such differences probably reflect different ways in which drugs can effect the intrinsic cerebral asymmetry[21]. The correlation between acute morphine-induced rotation and withdrawal-induced rotation suggests, therefore, that long after morphine is eliminated an endogeneous substance persists which has at least one pharmacological action resem-

Table 1 Rotation and body weight after chronic morphine administration

Rotation and body weight are expressed as mean percentage of day 1±s.e.

*M alone refers to morphine sulphate, 5.0 mg kg^{+1}, intraperitoneal; chronic M or withdraw M refers to morphine administered through implanted (day 2) silicone reservoirs; S refers to saline, 0.1 ml, intraperitoneal.

†Mean net rotations per hour ± s.e. for all rats on day 1 were 11.2±4.8.

‡Mean body weight (g)±s.e for all rats on day 1 was 255.6±3.9.

§For all data points except this one, rotation was significantly different ($P < 0.05$–01, t tests) from day 1.

¶For all data points except these, body weight was significantly different ($P < 0.05$–01, t tests) from day 6 (pre-withdrawal).

bling that of morphine. This interpretation is consistent with the evidence that rotation is indicative of dopaminergic striatal function[8–12], that morphine is known to affect dopaminergic mechanisms in the striatum[1] and that the highest concentrations of opiate receptors[22] and endogenous morphine-like substances[13–15] are found in the striatum. Although there are other reports[23–25] of long term after effects of chronic morphine administration, the study reported here provides the first demonstration of an after effect resembling an acute effect of morphine.

This research was supported by a grant and a research scientist development award from the National Institute on Drug Abuse.

Lithium differentially antagonises self-stimulation facilitated by morphine and (+)-amphetamine

IN spite of widespread use of lithium (Li) in psychiatry, the mechanism underlying its antimanic action is poorly understood. Studies of the effects of Li on spontaneous and drug-induced behavioural activity have yielded conflicting results[1–8]. Electrical self-stimulation of the brain (SS) may be a promising alternative approach to such studies This behaviour is believed to be mediated by catecholamines (reviewed in ref. 9), which have also been implicated in the action of Li[10–14]. Investigations of the effects of Li on SS have been restricted to a small range of doses and to SS in lateral hypothalamus, and the results have not been consistent[15,16]. We have now used a wider range of doses to investigate the effects of acute and chronic Li on SS in the substantia nigra of rats

Electrodes were implanted stereotaxically in substantia nigra (2.2 mm anterior to lambda, 1.5 mm lateral to midline, 8 mm ventral to the skull surface) of 100–120-d-old male albino rats (Carworth Farms) as described before[17] One week after surgery, SS tests began in operant conditioning chambers which have been described before[17]. The brain was stimulated by sine wave a.c. current (0.2 s duration). Rats were required to exceed a criterion performance of 1,100 bar presses per 30 min when reinforced by optimal current intensities (typically 40–60 μA r.m.s.). Most rats performed at considerably higher rates. All screening and drug SS sessions lasted 30 min. After completion of drug treatments, rats were killed and electrode placements were verified as before[17] (Fig. 1)

Before treatment with Li, current intensity was adjusted to yield an average SS rate of between 1,200 and 1,800 bar presses per 30 min. After three consecutive test sessions in which responding remained within these limits, bacteriostatic saline or Li (1.5, 2.0 or 2.5 meq kg^{-1}) was administered as described in Fig. 2. Lithium chloride (Matheson, Coleman and Bell) was discovered in sterile distilled water and injected subcutaneously in a volume containing 2 ml kg^{-1}. The solution was halved and injected into different sites. Skin ulceration was never observed as a result of injection of Li.

The effects of Li on rats self-stimulating at a lower rate were also investigated. After current intensity had been reduced to yield baseline SS rates between 450 and 950 bar presses per session, Li (2.0 meq kg^{-1}) was administered and testing was conducted as in Fig. 2.

Neither saline nor Li at 1.5 meq kg^{-1} significantly changed SS from baseline responding rates (Fig 2). The small reduction of SS induced by Li at 2.0 meq kg^{-1}, was statistically significant on days 3 and 5 of treatment, but not on days 7 and 10, suggesting the development of partial tolerance to the initial depressant effect of Li on SS. Although Li at 2.5 meq kg^{-1} significantly reduced SS on days 3–10 of treatment, the large progressive reduction in SS was accompanied by an average weight loss of 9% in 10 d of treatment ($t=7.73$, $P<0.01$ for the comparison between body weight before Li and on day 10 of treatment). Concomitant lethargy was seen in some animals and it seemed possible that the effects of Li at 2.5 meq kg^{-1} on SS might have been confounded with nonspecific toxic effects of this dose. In contrast, Li at 2.0 meq kg^{-1} did not reduce body weight significantly. Gross observations failed to distinguish animals treated with Li at 2.0 meq kg^{-1} from controls except for polyuria in some animals. as described by Schou[18]. The animals self-stimulating at a lower baseline rate (Fig. 2) also reduced SS on day 5 of treatment and subsequent recovery was apparent. Thus, the effects of Li on SS did not seem to be rate specific. These results are compatible with the report that Li increased electrical current thresholds for SS 24 h after injection[16]

To evaluate the mechanism by which Li alters SS, its interactions with morphine and (+)-amphetamine were studied Both morphine and (+)-amphetamine facilitate SS[20–22] Although the mechanism by which these drugs enhance SS has yet to be fully elucidated. there is some evidence that their effects on behaviour involve different neuropharmacological mechanisms[23,24]

Before initiation of chronic treatment with morphine. current intensity was reduced to yield SS between 450 and 950 bar presses per 30 min. After three consecutive test sessions of responding within these limits, morphine (Mallinckrodt. 15 mg kg^{-1}, subcutaneously in saline) was administered daily After 9 d 19 of 24 rats had each increased SS to at least 50% above baseline responding These 19 rats were then matched for response rates on day 9 of chronic treatment with morphine and were injected subcutaneously with saline, Li at 1.5 meq kg^{-1}, or Li at 2.0 meq kg^{-1} The remaining five rats reduced SS during chronic treatment with morphine and were eliminated from the study.

Li significantly reduced morphine-facilitated SS throughout treatment (Fig. 3) At no time during combined Li (2.0 meq kg^{-1}) and morphine treatment did any animal regain the SS rate which had been attained on day 9 of treatment with morphine alone. After cessation of treatment with Li (2.0 meq kg^{-1}) on day 22, SS rates increased in five of six rats and on day 25 of continued treatment

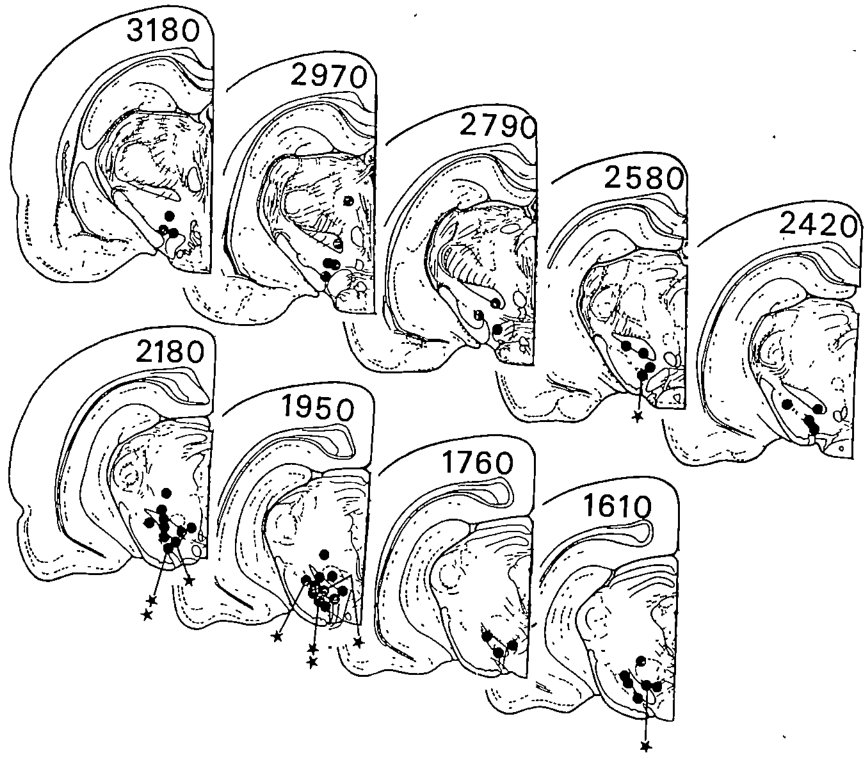

Fig. 1 Electrode placements of self-stimulating animals. Frontal sections are modified from Konig and Klippel[18]. Because of causes unrelated to the nature of the experimental treatment, histological results were unavailable for three rats. Some placements were slightly anterior to substantia nigra and others fell slightly dorsal to this structure, but there was no apparent relationship between electrode placement and experimental results. ★, Two overlapping electrode tip placements; ★★, three overlapping placements.

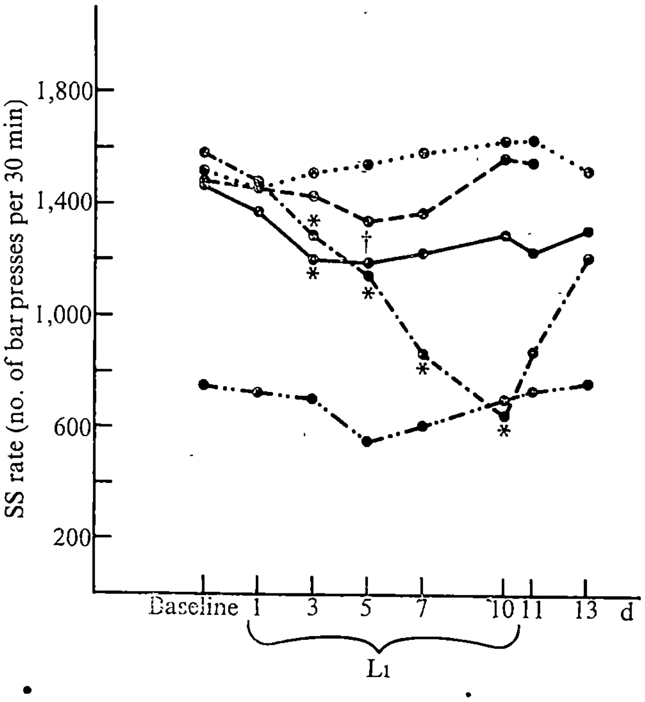
with morphine, SS did not differ significantly from those after morphine alone on day 9. Neither saline nor Li at 1.5 meq kg^{-1} significantly altered morphine-facilitated SS on any day of testing.

The observed antagonism of morphine-facilitated SS by Li agrees with the report[25] that Li reduces oral morphine consumption in morphine-dependent rats and that tolerance does not seem to develop to this effect. One possible explanation for the effects of Li on morphine-facilitated SS is that Li interferes selectively with the penetration or distribution of the narcotic. This does not seem to be the case, however, because Li has been reported to enhance morphine-induced analgesia[26].

Fig. 2 Effects of chronic Li treatment on SS. Test sessions for SS took place 2 h after injection of Li on days 1, 3, 5, 7, and 10 of treatment. The rats were retested for SS on the first and third days after cessation of Li treatment (days 11 and 13). · · · · ·, Saline (n = 8); – – –, Li, 1.5 meq kg^{-1} (n = 8); ——, Li, 2.0 meq kg^{-1} (n = 8); – · – ·, Li, 2.5 meq kg^{-1} (n = 6); – · –, Li, 2.0 meq kg^{-1}, low rate (n = 3) $*P < 0.05$ for comparison between the indicated data point and preceding baseline. $\dagger P < 0.01$.



Before treatment with (+)-amphetamine, current intensity was reduced in the same manner as for combined treatment with morphine and Li. After responding stabilised, (+)-amphetamine (Sigma, 0.5 mg kg^{-1}, free base) was administered subcutaneously 30 min before testing (days 1–17, Fig. 4). Li was administered daily from days 5 to 14 (Fig. 4). Chronic Li (2.0 meq kg^{-1}) did not alter SS significantly on any day of treatment with Li and (+)-amphetamine (Fig 4). Because the effects of (+)-amphetamine on SS in substantia nigra are not altered by repeated administration[17], it was not necessary to control for this possibility.

The lack of antagonism of (+)-amphetamine-facilitated SS by Li contrasts with the reported reduction of (+)-amphetamine-induced hyperactivity by Li[8] These results further support the suggestion that different neurochemical mechanisms mediate these behavioural activities[22].

Because both the nigro-neostriatal dopamine pathway[22,27,28] and the dorsal and ventral noradrenaline pathways[29,30] have been proposed as substrates for SS in substantia nigra, it is not possible to state which of these pathways are involved in the effects reported here. Regardless of the pathway involved, these results suggest that (+)-amphetamine- and morphine-induced facilitation of SS are mediated by different mechanisms of catecholamine neurotransmission. Enhancement of activity and SS by low doses of (+)-amphetamine is believed to result from facilitation of catecholamine release[20,24,31] from a newly synthesised pool[32,33]. In contrast, the effects of morphine on activity seem to depend on a reserpine-sensitive pool of stored catecholamines[34,36]. If, therefore, Li interferes with catecholamine storage as suggested[12], morphine- but not (+)-amphetamine-facilitated SS would be expected to be reduced by Li.

Regardless of the neurochemical mechanisms involved, the differential effects of Li on morphine- and (+)-amphetamine-induced facilitation of SS may have important clinical implications If the drug abuse potential of morphine and amphetamine is related to the activation of brain reward pathways, then the results obtained with

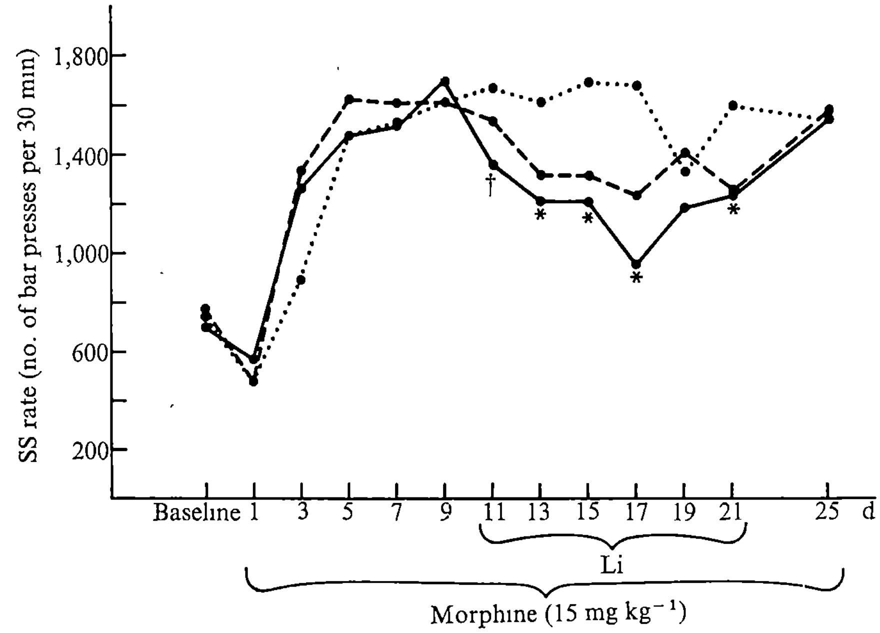


Fig. 3 Effects of chronic Li treatment on morphine-facilitated SS. Morphine was injected daily (days 1–25). Test sessions for SS took place on alternate days 3 h after injection of morphine. From days 11 to 21 Li was administered daily 1 h after morphine. The effects of Li on SS facilitated by morphine were assessed by comparison with responding on day 9. · · · · · , Saline+morphine ($n = 7$); – – –, Li, 1.5 meq kg^{-1}+morphine ($n = 6$); ——, Li, 2.0 meq kg^{-1}+morphine ($n = 6$). *$P < 0.05$ for the difference between the data point and the corresponding score on day 9. †$P < 0.01$.

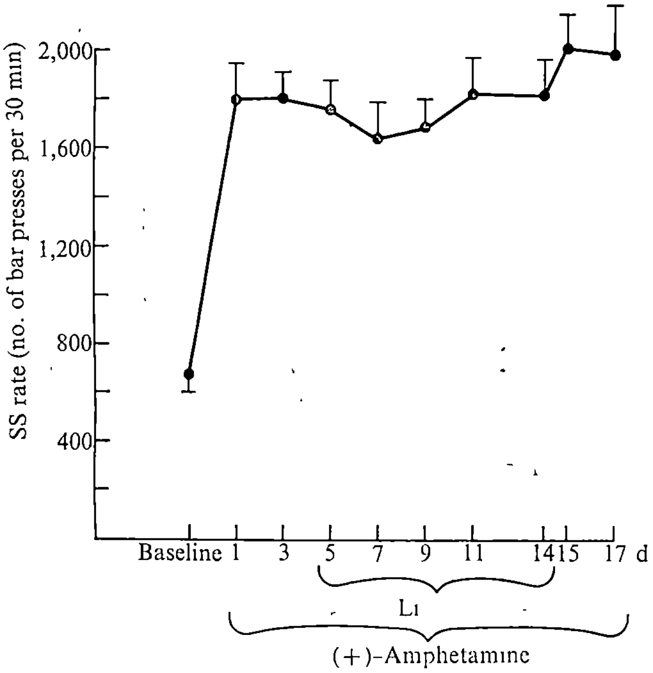

Fig. 4 Effects of chronic Li treatment on (+)-amphetamine-facilitated SS ($n = 8$). (+)-Amphetamine was administered 30 min before each test session on days 1–17. Li (2.0 meq kg^{-1}) was administered daily 2 h before testing on days 5–14. Self-stimulation during combined Li and (+)-amphetamine administration was compared with responding on day 3.

SS may have practical applications. Thus, for example, on the basis of our results it may be suggested that Li will be effective in the treatment of morphine, but not amphetamine, addiction.

Histamine-sensitive adenylate cyclase in mammalian brain

THERE is increasing interest in the possibility that histamine may be a neurotransmitter in the mammalian central nervous system (CNS). Electrophysiological evidence supports the existence of histamine receptors in nervous tissue through which neuronal excitability can be regulated. For example, the firing rate of certain neurones in the brain is depressed by histamine and this depression is specifically blocked by the H_2 antagonist, metiamide[1]. In addition, histamine influences the electrical excitability of neurones in the superior cervical ganglion[2]. Certain neurotransmitters may exert some of their effects in nervous tissue by stimulating the formation of cyclic AMP. It is therefore of interest that histamine raises cyclic AMP levels in brain slices[3–7], as do several other putative neurotransmitters, such as noradrenaline, dopamine and 5-hydroxytryptamine (5-HT). Furthermore, a dopamine-sensitive adenylate cyclase

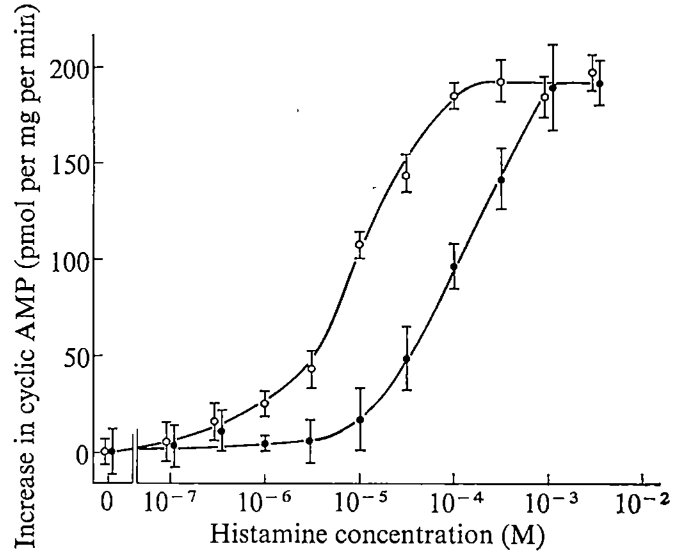

Fig. 1 Effect of various concentrations of histamine in the absence (○) or presence (●) of 10^{-5} M metiamide, on adenylate cyclase activity in homogenates of dorsal hippocampus from guinea pig brain. Adult female Hartley guinea pigs were killed by decapitation. The dorsal hippocampi were dissected, weighed, and manually homogenised in 150 volumes ice-cold 2 mM Tris maleate–2 mM EGTA, *p*H 7.8, using a glass homogeniser with a Teflon pestle. The adenylate cyclase reaction mixture contained the following final concentrations (mM): Tris maleate (*p*H 7.8), 100; EGTA, 0.6; 3-isobutyl-l-methylxanthine, 1; $MgCl_2$, 2; ATP, 1; GTP, 0.1; plus test substances as indicated, in a final volume of 500 μl. The enzyme reaction, initiated by the addition of 50 μl homogenate, was carried out for 6 min at 30 °C, and was terminated by placing the assay tubes in a boiling water bath for 2 min. Aliquots (50 μl) were assayed in duplicate for cyclic AMP by the method of Brown *et al.*[12]. Protein was determined by the method of Lowry *et al.*[13]. In the absence of added histamine or metiamide, 153±4 pmol cyclic AMP per min per mg protein were formed; in the presence of 10^{-5} M metiamide, 152±10 pmol cyclic AMP per min per mg protein were formed. The increase in cyclic AMP above basal level is plotted as a function of histamine concentration. Values represent the mean ± s.e.m. of nine replicate samples in the absence, and three replicate samples in the presence, of histamine.

has been found in homogenates of rat caudate nucleus and olfactory tubercle, with properties very similar to those of the dopamine receptor in mammalian brain[8–10]. We report here the occurrence of an adenylate cyclase which is activated by low concentrations of histamine in several regions of guinea pig brain. This histamine-sensitive adenylate cyclase has the pharmacological properties of an H_2 receptor. The results indicate that the actions of histamine on H_2 receptors in the CNS may be mediated through cyclic AMP.

In the present study, 100 μM histamine caused maximal stimulation of adenylate cyclase in homogenates of guinea pig dorsal hippocampus. In several experiments, the maximal increase in adenylate cyclase activity varied from 70–200%. Addition of GTP to the reaction mixture increased enzyme activity and markedly potentiated the stimulation of adenylate cyclase by histamine. There results are consistent with other studies indicating that GTP and its analogues can regulate the activity of adenylate cyclases[11].

Figure 1 illustrates the effects of various concentrations of histamine on adenylate cyclase activity in homogenates of dorsal hippocampus from guinea pig brain. The concentration of histamine required for half-maximal activation (K_a) of the enzyme was 8 μM. This agrees well with the K_a values of 7 and 9 μM reported, respectively, for histamine-induced cyclic AMP formation in brain slices[6] and in cultures of intact human astrocytoma cells[14].

Two types of histamine receptors have been characterised in mammalian tissues[15,16]. H_1 receptors are selectively blocked by classical anti-histaminic agents such as mepyramine and promethazine, whereas H_2 receptors are selectively blocked by recently developed H_2 antagonists such as metiamide, cimetidine and burimamide[17]. As shown in Fig. 1, metiamide acted as a competitive inhibitor of the activation by histamine of adenylate cyclase. In the presence of 10 μM metiamide, the apparent K_a for histamine was increased to 100 μM. From these data, the K_i value[18] of the enzyme for metiamide was calculated to be 0.87 μM, which is in excellent agreement with the K_i values for metiamide inhibition of H_2 receptors calculated from measurements of physiological responses using guinea pig atrium (0.92 μM) and rat uterus (0.75 μM)[17]. In contrast, the H_1 antagonist mepyramine, at 1 μM (a concentration which maximally inhibits the effects of 100 μM histamine on H_1 receptors[6]), had no effect either on the K_a for histamine or on the maximal stimulation of adenylate cyclase. Other agents which antagonise the actions of various neurotransmitters on their receptors were tested for possible effects on adenylate cyclase activity in the absence and presence of 100 μM histamine—propranolol, phentolamine, atropine, and fluphenazine, in concentrations of 10 μM, had no effect on basal or histamine-stimulated enzyme activity.

The ability of two substances known to act as agonists at histamine receptors were compared with histamine as activators of adenylate cyclase (Fig. 2). 4-Methyl-histamine increased adenylate cyclase activity with half-maximal stimulation occurring at 23 μM. This compound has been reported to have 25–43% of the potency of histamine in activating H_2 receptors, but negligible activity at H_1 receptors[16]. In contrast, 2-methyl-histamine primarily affects H_1 receptors. It weakly activates H_2 receptors as well, having 2–4% of the potency of histamine in this regard. In agreement with these properties, 2-methyl-histamine stimulated adenylate cyclase, but only at high concentrations (K_a=120 μM). Thus, the pharmacological properties of the histamine-sensitive adenylate cyclase seem to be those of an H_2 receptor.

The regional distribution of histamine-sensitive adenylate cyclase activity in rat and guinea pig brain is shown in Table 1. In guinea pig brain, histamine markedly stimulated adenylate cyclase in homogenates from hippocampus, neocortex, and corpus striatum, but did not significantly affect enzyme activity in other brain regions. This localisation of histamine-sensitive adenylate cyclase activity correlates well with the regional distribution of histamine-induced cyclic AMP accumulation in brain slices[7]. Of the various regions of rat brain examined, histamine-stimulated adenylate cyclase only in neocortex, where a small but statistically significant increase in activity was seen. An histaminergic pathway which projects to the cortex in rat brain has recently been described[19]. The histamine-sensitive adenylate cyclase present in rat neocortex may represent the postsynaptic receptor of neurones in this region receiving

Fig. 2 Effect of various concentrations of histamine (○), 4-methyl-histamine (△), and 2-methyl-histamine (×) on adenylate cyclase activity in homogenates of guinea pig dorsal hippocampus. Experimental procedures were as in Fig. 1. The maximal stimulation of adenylate cyclase activity by saturating concentrations of histamine, 4-methyl-histamine, and 2-methyl-histamine was the same within the limits of experimental error.

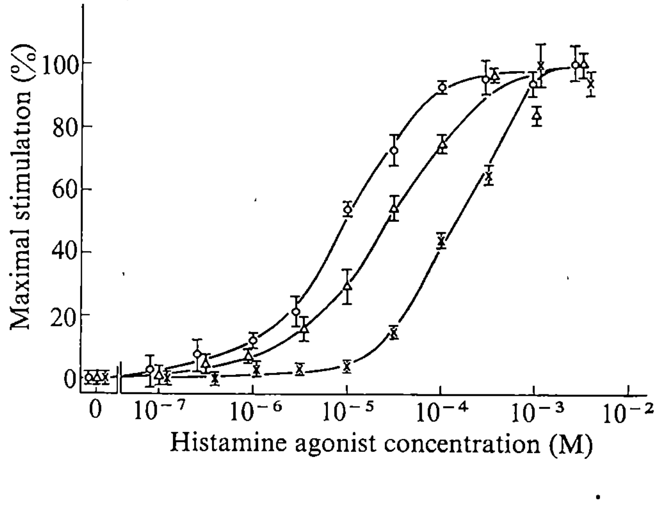

Table 1 Regional distribution of histamine-sensitive adenylate cyclase activity in guinea pig and rat brain

Brain region	Adenylate cyclase activity* (pmol per min per mg protein) −Histamine	+Histamine (100 μM)
Guinea pig		
Dorsal hippocampus	106±4	218±8†
Ventral hippocampus	111±6	199±6†
Neocortex	98±4	187±7†
Corpus striatum	101±5	165±3†
Cerebellum	33±3	35±2
Hypothalamus	157±4	158±6
Thalamus	65±5	71±3

Cerebellum	73±5	78±6

*Experimental procedures were as described in Fig. 1. Values represent mean ± s.e.m. of four replicate samples.

†Activity in the presence of histamine was significantly different ($P < 0.005$) from that in the absence of histamine.

histaminergic innervation. The localisation of histaminergic pathways in guinea pig brain has not yet been determined.

The non-uniform distribution of histamine-sensitive adenylate cyclase activity in brain is of particular interest, since histamine has been shown to increase cyclic AMP in cultured cells derived from glial elements[14] as well as to increase adenylate cyclase activity in brain capillaries[20]. If the enzyme we are studying were primarily glial or vascular in origin, one would expect a fairly uniform distribution of histamine-sensitive adenylate cyclase activity throughout the brain. The non-uniform distribution of activity actually observed (Table 1) is more consistent with the possibility that the enzyme is located primarily in selected neurones which receive histaminergic innervation.

In studies of guinea pig neocortical and hippocampal brain slices, activation of either H_1 or H_2 receptors led to the accumulation of cyclic AMP[6,7]. The present results indicate that the H_2 receptor in brain, like the dopamine receptor[8–10], is intimately associated with an adenylate cyclase. The idea of a direct connection between H_2 receptors and adenylate cyclase in nervous tissue is supported by studies of heart[21,22] and stomach[23,24], in which histamine, acting on H_2 receptors, caused an increase in formation of cyclic AMP in both intact preparations and homogenates.

We have been unable, using homogenates of guinea pig hippocampus, to identify a histamine-sensitive adenylate cyclase which possesses the pharmacological properties of an H_1 receptor. It is possible that such an adenylate cyclase does exist in brain, but that it was either labile or inactive in the experimental conditions used. Alternatively, histamine, acting on H_1 receptors, may cause cyclic AMP accumulation in brain slices by an indirect mechanism. For example, histamine might cause the release of other neurotransmitters which, acting on their own target cells, could then activate adenylate cyclases. Clearly, the relationship of H_1 receptors to cyclic AMP metabolism requires further investigation. Interestingly, in non-neuronal tissues, an increase in cyclic GMP in response to activation of H_1 receptors has been reported[25,26].

The present results indicate that the H_2 receptor in mammalian brain may be the histamine-binding portion of a histamine-sensitive adenylate cyclase. One corollary of this conclusion is that the physiological consequences of histamine acting at H_2 receptors in the brain, such as depression of the firing rate of certain neurones[1], may be mediated through cyclic AMP. Further studies on the biochemistry and pharmacology of this histamine-sensitive adenylate cyclase, and its relationship to physiological processes in neurones, may help to clarify the role of histamine in the mammalian nervous system.

We thank J. Paul of Smith, Kline and French for histamine agonists and antagonists, and F. Wilson for assistance.

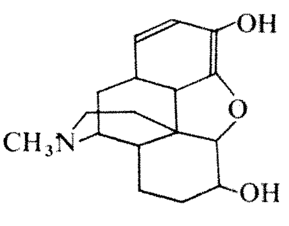
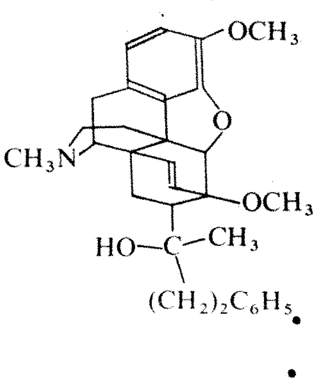
Biosynthetic origin and receptor conformation of methionine enkephalin

RECENT reports have shown that the brain contains an endogenous peptide with opiate-like activity[1–3] and similar peptides have been found in the pituitary[4,5,13]. One of the brain peptides, known as methionine enkephalin, was identified as a pentapeptide Tyr–Gly–Gly–Phe–Met[6], and evidence was presented that a minor component may have leucine in place of methionine. The principal sequence is identical to that at the NH_2-terminus of lipotropin C fragment, a peptide discovered in substantial quantity in porcine pituitary[7,8]. This suggests that methionine enkephalin is derived *in vio* by proteolytic cleavage of C fragment. Since enkephalin is thought to compete directly with opiates for the brain opiate receptor, while having no primary structure similarity to opiates, we have searched for and found a basis for the competition in a proposed secondary structure for the peptide.

Spatial models of morphine (I), oripavine (II), a potent derivative of morphine, and methionine enkephalin were





constructed. The conformation of morphine is essentially defined by the rigidity of its molecular structure and similar considerations apply to the assignment of conformation in oripavine. The pentapeptide, on the other hand, should be able to assume various conformations in aqueous solution but at the receptor a unique conformation would be expected. With methionine enkephalin a model could be constructed which presents structural elements in common with morphine; the proposed structure bears a striking resemblance to the spatial structure of oripavine (Fig. 1).

In the models, specific functional groups are held in the same orientation whether suspended from a peptide backbone or forming part of a rigid alkaloid structure. The tyrosine side chain and the amino group in enkephalin correspond exactly with the orientations of the phenolic ring in the phenanthrene nucleus and the tertiary amino group of oripavine. The two glycine residues occupy positions 2 and 3 in a β bend with a hydrogen bond between the carbonyl group of the tyrosine residue and the amino group of the phenylalanine, allowing the phenylalanine side chain to coincide with the positioning of the phenylethyl substituent at position 19 in the alkaloid. This lipophilic group, which is absent in morphine, could contribute to the stronger receptor binding of oripavine and enkephalin. The carboxyl terminal methionine residue lies between the aromatic side chains of tyrosine and phenylalanine; the methyl thioether chain then has the same orientation as the methyl ether substituent at position 6 in oripavine.

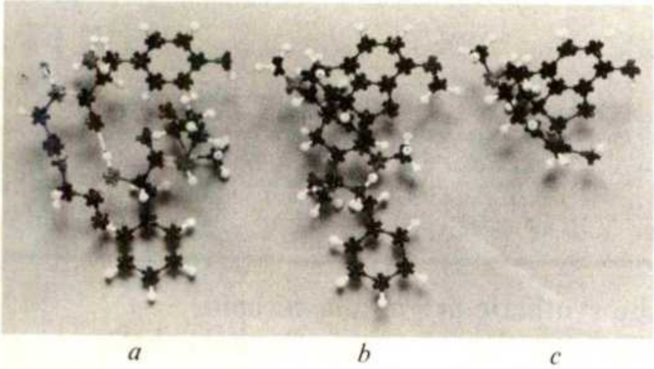


Fig. 1 Framework molecular models of tyrosylglycylglycylphenylalanylmethionine (methionine enkephalin) (*a*); oripavine (*b*), and morphine (*c*). The models were constructed from components described by Doré[12].

Evidence for the proposed conformation of the neuroactive pentapeptide emerged on application of empirical rules for predicting secondary structure from a knowledge of amino acid sequence. Both the Chou and Fasman rules[9,10] and the principles of Lewis, Momany and Scheraga[11] indicated a strong tendency for the NH$_2$-terminal region of the C fragment of lipotropin to form a β bend comprising the residues Tyr–Gly–Gly–Phe and this β bend is one of the structural elements in a model of lipotropin constructed in our laboratory (unpublished results). It is notable that the conformation proposed for the biologically active form of methionine enkephalin centres on a β bend involving the same four residues.

The molecular structures proposed for the opiate reactive peptide, morphine and oripavine provide an explanation for the fact that a characteristic biological activity is expressed by molecules entirely different in class and origin.

Gibberellic acid enhances the level of translatable mRNA for α-amylase in barley aleurone layers

α-AMYLASE is synthesised *de novo* in response to the plant hormone gibberellic acid (GA$_3$) in the aleurone layers of barley grains[1]. This enzyme induction depends on RNA and protein synthesis, as determined by the use of inhibitors[2–4], and it occurs after a temperature-dependent lag period[5]. The biochemical events of the lag period have been studied with respect to ionic requirements[5–7], early protein synthesis[8], RNA synthesis[9–12], polysome formation[13] and lipid synthesis and turnover[14–17]. It has been postulated that new mRNA for α-amylase synthesis might be produced in response to the hormone[2,3] and there is evidence that GA$_3$ enhances the incorporation of labelled ribonucleosides into poly(A)-containing RNA of barley aleurone layers[18–20]. Stimulation could be detected about 4 h after hormone treatment and although GA$_3$ probably stimulates synthesis of a limited number of proteins, there was stimulation of a wide size range of poly(A)-containing RNAs. Thus it was not possible to say that GA$_3$ had a selective effect on the synthesis of the mRNA for α-amylase.

In an attempt to relate GA$_3$-stimulated α-amylase production to the level of α-amylase mRNA, we have assayed for this mRNA by translating total and poly(A)-containing RNA isolated from aleurone layers in a cell-free system derived from wheat embryos[21]. This was followed by immunoprecipitation[22] and sodium dodecyl sulphate (SDS)–polyacrylamide gel electrophoresis[23] of the cell-free translation products. We found that the level of translatable mRNA for α-amylase increases in hormone-treated tissue in parallel with the increased rate of enzyme synthesis.

The template activity of total RNA from both control and hormone-treated tissue was low (fivefold stimulation) compared with tobacco mosaic virus (TMV) RNA[24] (50-fold stimulation). The aleurone RNA preparations, however, did not contain inhibitors of translation when assayed with TMV RNA-directed cell-free protein synthesis (unpublished). Total RNA isolated from aleurone layers incubated in the absence and presence of GA$_3$ for 8 h was used to program the wheat embryo cell-free system. The translation products were analysed by SDS–polyacrylamide gel electrophoresis followed by fluorography[26] of the dried gels and they varied in size from 8,000 to 70,000 daltons (Fig. 1*a* and *b*). In spite of the variety of proteins induced in aleurone cells by GA$_3$, there were relatively few detectable differences in the patterns of cell-free translation products when the system was programmed by RNA from GA$_3$-treated and untreated tissue. But cell-free synthesis of at least two polypeptides was increased by RNA from GA$_3$-treated tissue, one migrating as a broad band at about 35,000 daltons and one at 45,000 daltons. The former was not identified and may consist of several polypeptides. The 45,000-dalton polypeptide coelectrophoresed with α-amylase.

Poly(A)-RNA was fractionated from total RNA of 8-h treated aleurone layers by oligo(dT)–cellulose chromato-

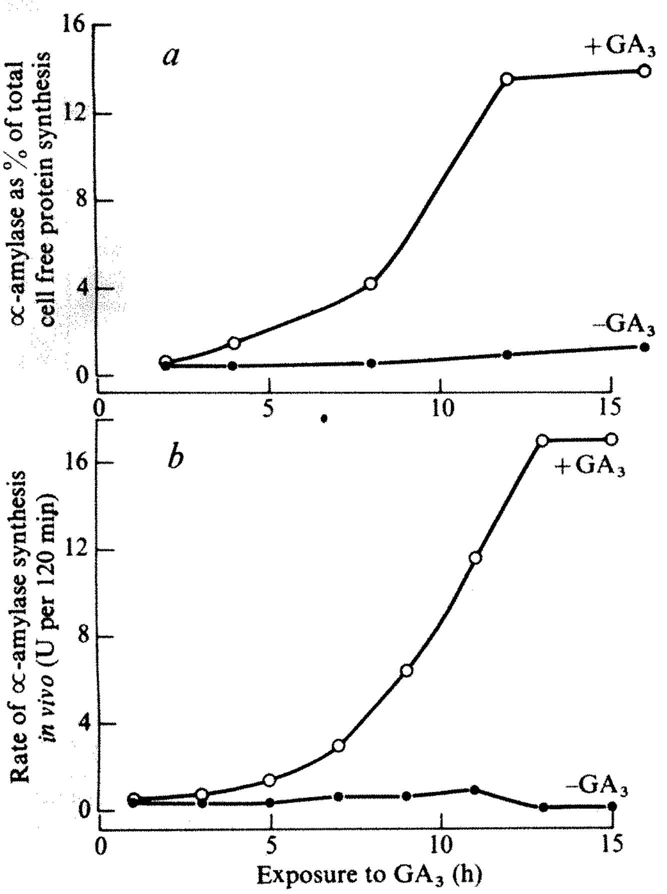

Fig. 1 Fluorographs of SDS–polyacrylamide gel electrophoresis of cell-free translation products of RNA isolated from aleurone layers 8 h after the beginning of hormone treatment. Aleurone layers were prepared from barley (var. Himalaya) half-seeds and incubated as before[4], at 25 °C in medium containing 10^{-2} M $CaCl_2$ and 10^{-6} M GA_3 where required. Total RNA was prepared by the following modification of the method of Click and Hackett[25]. The layers were ground in 10 ml of buffer containing 0.1 M sodium glycinate, *p*H 9.5, 0.01 M EDTA, 0.1 M sodium chloride and 1% SDS, with 1% insoluble polyvinylpyrrolidone (L. Taiz, personal communication). After centrifugation at 10,000*g* for 10 min an equal volume of phenol–chloroform (1 : 1) was added to the supernatant and the aqueous phase was extracted for 5 min while being shaken. The phases were separated, the phenol phase was shaken for a further 5 min with 5 ml of the same buffer and the combined aqueous phases were then extracted with 5 ml of phenol–chloroform. The RNA in the aqueous phase was precipitated by addition of 2.5 volumes of ethanol and stored overnight at −20 °C. It was then pelleted by centrifugation, redissolved in 3 ml of 0.5 M sodium acetate, *p*H 5.8 and reprecipitated with 0.4 ml of 1% acetyltrimethylammonium bromide[27]. The precipitate was recovered by centrifugation and washed with 0.1 M sodium acetate in 70% ethanol and finally with 3 M sodium acetate, 5 mM EDTA, *p*H 5.0. The RNA was then used directly or fractionated on oligo(dT)–cellulose as before[28] except that SDS (0.1%) was included in the buffer. After precipitation, the RNA was used to program the wheat embryo cell-free protein synthesising system[21] as modified[24]. ^{35}S-methionine (50 Ci mol^{-1}, Amersham) was the source of radioactive amino acid. The reaction was stopped after 90 min at 25 °C. The ribosomes were removed by centrifugation at 30,000 r.p.m. for 60 min and the soluble proteins were either analysed on SDS–polyacrylamide gels[23] (14%) in the presence of 2-mercaptoethanol with the modifications specified[24] or subjected to immunoprecipitation followed by SDS–polyacrylamide gel electrophoresis of the antibody precipitates. Sliced and stained gels were prepared for fluorography according to Bonner and Laskey[26]. The dried gels were exposed to Kodak X-OMAT X-ray film for 7 d at −80 °C. Immunoprecipitation was carried out on the proteins of the cell-free system from which the ribosomes had been removed. Antiserum (10 μl) produced in rabbits against purified α-amylase[31,32] was added to each reaction mixture and incubated at 25 °C for 60 min. Sufficient goat anti-rabbit gammaglobulin serum (provided by Dr David Kemp) was then added to precipitate all the rabbit antibodies and the mixture was incubated for 60 min at 25 °C and then overnight at 4 °C. The precipitates were collected by centrifugation through sucrose cushions and washed twice with saline–detergent as described[33] and modified[24]. The immunoprecipitates were then analysed on SDS–polyacrylamide gels and prepared as described above. Cell-free translation products of total RNA: *a*, $-GA_3$; *b*, $+GA_3$. Products of poly(A)-RNA: *c*, $-GA_3$; *d*, $+GA_3$. Specific anti-α-amylase immunoprecipitates of translation products of total RNA: *e*, $-GA_3$; *f*, $+GA_3$. The numbers refer to the molecular weights ($\times 10^{-3}$) of the markers, bovine serum albumin (molecular weight 68,000), ovalbumin (molecular weight 45,000), chymotrypsinogen (molecular weight 25,000) and cytochrome *c* (molecular weight 12,400). The arrow denotes the position to which authentic α-amylase migrated, and 0 refers to the origin.

graphy[28] and was used to program the cell-free system. This step resulted in a tenfold increase in template specific activity. The patterns of cell-free translation products were identical with those obtained with total RNA (Fig. 1*c* and *d* compared with Fig. 1*a* and *b*). Our observations thus provide further evidence[29,30], that the poly(A)-RNA of plants includes RNA with messenger activity.

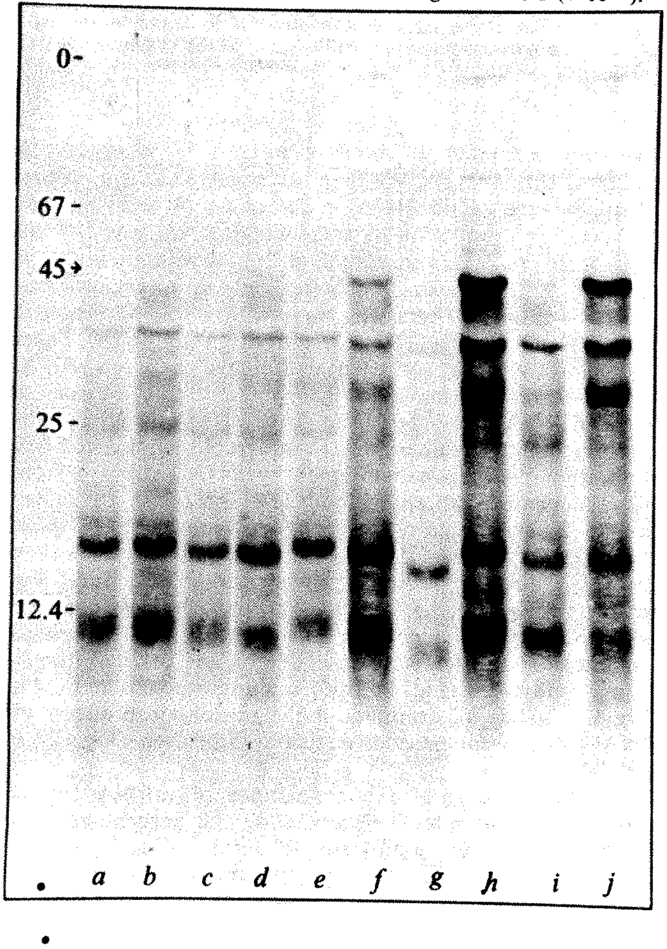
Evidence for the identification of the 45,000-dalton polypeptide synthesised *in vitro* was provided by immunoprecipitation with monospecific antibodies produced in rabbits against barley α-amylase[31,32]. The double antibody technique was used to precipitate the anti-α-amylase[22]. Although the unfractionated translation products of total RNA were complex (Fig. 1*a* and *b*) the immunoprecipitation step yielded a single polypeptide which coelectrophoresed with or was slightly larger than authentic α-amylase run on the same gel and stained with Coomassie blue (Fig. 1*f*). Sufficient material was not available for tryptic fingerprint analysis and it was therefore not certain whether the cell-free product was identical with the authentic protein or whether it contained some extra amino acids at either the NH_2– or –COOH terminals. A study of the cell-free synthesis of immunoglobulin light chain showed that the *in vitro* product was larger than the polypeptide found *in vivo*[34]. RNA isolated from aleurone layers incubated without hormone did not direct the cell-free synthesis of detectable α-amylase as determined by immunoprecipitation (Fig. 1*e*).

Based on the above evidence, we tentatively concluded that GA_3 increased the level of mRNA for α-amylase in barley aleurone layers. We then investigated the time course of appearance of the RNA in the tissue by assaying with the cell-free translation system. Total RNA was isolated from aleurone layers incubated with and without hormone for 2, 4, 8, 12 and 16 h and was used to direct cell-free protein synthesis. There was two- to threefold variation in template efficiency of RNA from batch to batch. There was, however, no consistent difference between RNAs isolated from hormone-treated and untreated tissue or between RNAs extracted from tissue after exposure to the hormone for different times. Fluorographs of the cell-free translation products programmed by RNA extracted from tissue incubated with and without GA_3 for 2–16 h are shown in Fig. 2. The range of polypeptides was similar to those shown in Fig. 1*a* and *b* and the major difference between the RNA-directed products of hormone-treated and untreated tissue were the 35,000-dalton polypeptide(s) and the polypeptide earlier identified as α-amylase. The increased amount of the latter was detectable on the original fluorographs within 2 h (Fig. 2*b*) and was quite apparent by 4 h (Fig. 2*d*) and in all examples of the translation products of RNA from hormone-treated tissue thereafter (Fig. 2*f*, *h* and *j*).

The time course of the appearance of mRNA for α-amylase was estimated by calculating the percentage contribution made by α-amylase to total cell-free protein synthesis. Autoradiographs were prepared by exposing X-ray film to the dried gels, similar to those in Fig. 2, for different times and the profiles were scanned by microdensitometry[35]. α-Amylase made an increasing contribution to protein synthesis when the *in vitro* system was programmed with RNA extracted from tissue incubated with hormone for increasing periods up to 12 h (Fig. 3*a*). GA$_3$ treatment for 16 h did not stimulate further the production of template RNA for α-amylase (Fig. 3*a*). The *in vivo* production of total α-amylase in response to the hormone is shown in Fig. 3*b* plotted as the rate of α-amylase synthesis rather than as total enzyme level. There is a positive correlation between the rate of α-amylase synthesis *in vivo* and the level of mRNA for α-amylase as assayed by the cell-free system. Investigation of the stimulation of ovalbumin synthesis in chick oviduct by oestrogen has shown that the level of mRNA for ovalbumin increases in response to the hormone[33,36,37], and that the rate of synthesis of the oviduct protein is controlled chiefly by the concentration of cellular mRNA[38].

Our data show that GA$_3$ increases the level of translatable mRNA for α-amylase, but we cannot distinguish between the following three mechanisms whereby the level might be increased: (1) a decreased rate of mRNA degradation; (2) enhancement of the translational capacity of mRNA for α-amylase through processing, activation or release of RNA from some inactive form (this possibility is relatively unlikely since total deproteinised RNA was used, eliminating the possibility that mRNP or other protein-masked forms of RNA were involved); and (3) synthesis of new mRNA molecules. Our results taken together with the fact that GA$_3$ stimulated poly(A)-RNA synthesis[18,20], although not eliminating an effect on degradation, provide correlative evidence that GA$_3$ promotes the synthesis of mRNA for α-amylase.

Fig. 2 Fluorographs of SDS–polyacrylamide gel electrophoresis of the cell-free translation products of RNA isolated from aleurone layers at various times after hormone treatment. Total RNA was extracted from aleurone layers (as described in the legend to Fig. 1) after 2, 4, 8, 12 and 16 h in buffer or buffer plus GA$_3$ and used to program the cell-free protein synthesising system. *a*, *c*, *e*, *g* and *i*, Translation products of total RNA from aleurone layers incubated without GA$_3$ for 2, 4, 8, 12 and 16 h respectively; *b*, *d*, *f*, *h* and *j*, translation products of total RNA from aleurone layers incubated with 10^{-6} M GA$_3$ for 2, 4, 8, 12 and 16 h respectively. The arrow denotes position of α-amylase and the numbers refer to molecular weight markers (×10^{-3}).



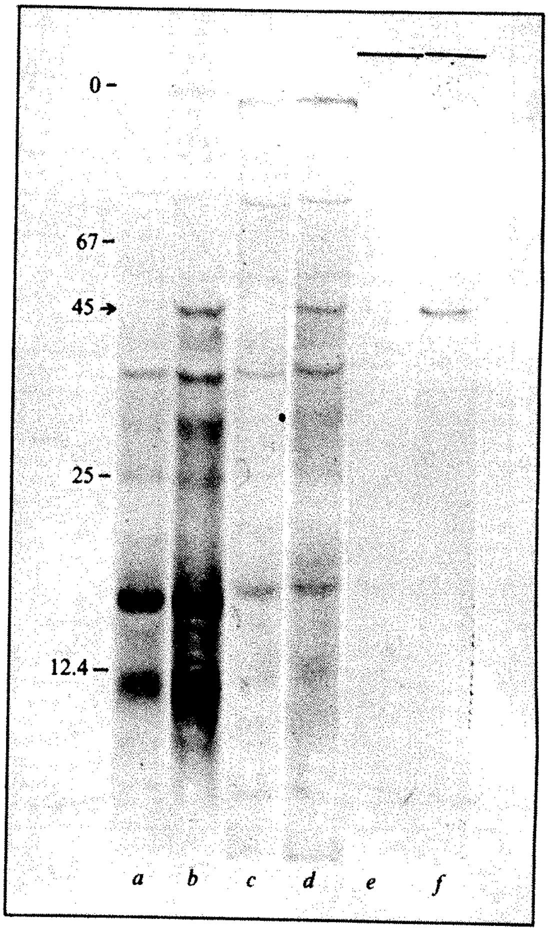


Fig. 3 The increase with time in the level of translatable mRNA for α-amylase and the increase in the rate of synthesis of the enzyme *in vivo* in response to GA$_3$ treatment. *a*, α-Amylase synthesised by the cell-free system was estimated from densitometric scans of autoradiographs of gels which had been in contact with X-ray film for different times. The gels were scanned using a Joyce–Loebl microdensitometer and the contribution made by the α-amylase peak to total protein synthesised was calculated by weight[35]. *b*, The rate of α-amylase synthesis *in vivo* was calculated as the increment in enzyme level (units of α-amylase) during successive 2-h intervals following hormone treatment. Total α-amylase activity was assayed using replicates of 10 aleurone layers as described[4]. U, Units of α-amylase.

Short-chain fatty acids as inhibitors of gibberellin-induced amylolysis in barley endosperm

ABSCISIC acid (ABA) is the only plant growth substance so far reported[1,2] to inhibit gibberellin(GA)-induced amylolyis in barley half seeds or α-amylase production in barley aleurone layers: the former physiological response has been used as a bioassay for ABA[3,4]. But the isolation procedures normally used to extract ABA from plant tissue also extract certain short-chain fatty acids[5]. We now present evidence that these naturally occurring short-chain acids[5] are powerful inhibitors of GA-induced amylolysis in barley endosperm.

Embryo-free half seeds were prepared[6] from husked barley (cultivar Ymer) and GA-induced starch hydrolysis was assayed by measuring[7,8] the amount of reducing sugar released into the medium (1.05 ml) by pairs of half endosperms incubated in the presence and absence of GA (80% GA_3 20% GA_1; 7.2×10^{-7} M) (B and G in Fig. 1). Buffering of the GA solution to *p*H 4.8 with citrate (10^{-3} M) did not alter the response to GA (C in Fig. 1). The effect of straight-chain carboxylic acids was assessed by replacing the citrate buffer with acetate (C_2), propionate (C_3), *n*-butanoate (C_4), *n*-pentanoate (C_5) . . . . . *n*-undecanoate (C_{11}) buffers[9] (10^{-3} M, *p*H 4.8) and the results are shown in Fig. 1. All these acids inhibit amylolysis to some extent; even acetate causes a 30% reduction in sugar release—a phenomenon first noted by Paleg[10]. The exceptional efficacy of pentanoic (C_5) and nonanoic (C_9) acids in overcoming the effect of GA is superimposed on a general increase in inhibition from C_1 to C_9 with a subsequent decrease at longer chain lengths.

Dose–response data for ABA and the four most inhibitory fatty acids (C_5, C_7, C_8 and C_9) are presented in Fig. 2. Clearly nonanoic aicd (C_9) is the most effective of the fatty acids but the most striking feature of Fig. 2 is the difference between the dose–response curves for ABA on the one hand and the fatty acids on the other. Inhibition by ABA is total at 10^{-4} M, virtually zero at 10^{-8} M and at intermediate concentrations the response is proportional to the logarithm of the concentration. On the other hand, inhibition by fatty acids (for example, C_5 and C_9 in Fig. 2) is total at 10^{-3} M but nonexistent at 10^{-5} M. Stated differently, inhibition by ABA is a finely graded phenomenon, infinitely variable over a 10,000-fold concentration range whereas inhibition by fatty acids is more akin to a threshold effect. We have detected nonanoic acid in ungerminated barley seed and if such fatty acids are true plant growth substances—and evidence is accumulating rapidly that they are—the threshold effect could be important in the regulation of "all or nothing" phenomena such as germination or release from dormancy.

In Glasgow and in our laboratories in Stirling, reports are being prepared of positive correlations between fatty

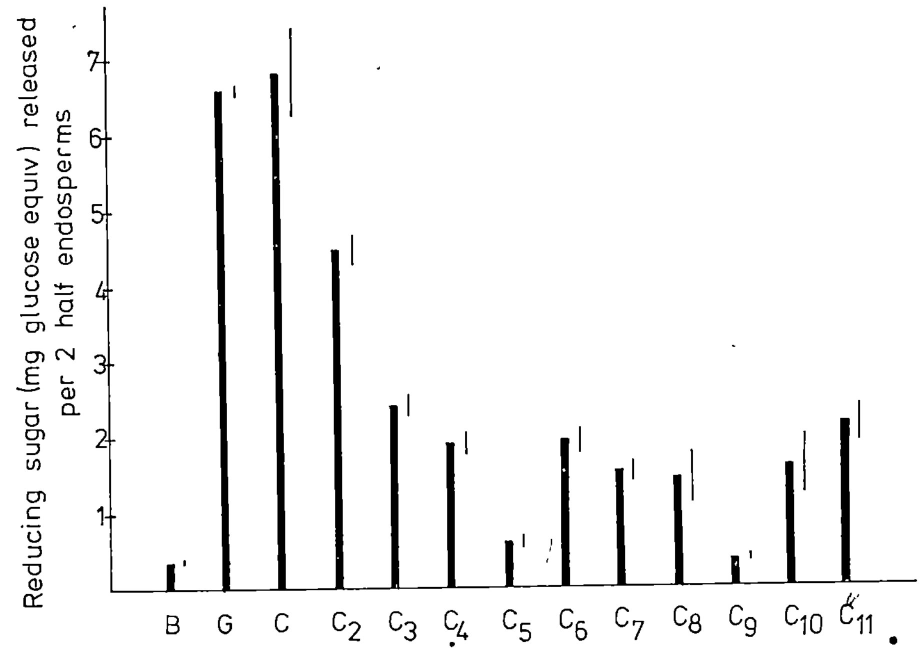

Fig. 1 Influence of normal, short-chain fatty acids on GA-induced amylolysis in barley endosperm. The vertical bars represent the amount (± s.e.m.) of reducing sugar released into the incubation medium by embryo-free half endosperms incubated in pairs (four replicates) for 42 h at 26 °C in the presence of water alone (B); 4.2×10^{-7} M gibberellin in water (G); 4.2×10^{-7} M gibberellin in 10^{-3} M citrate buffer *p*H 4.8 (C); 4.7×10^{-7} M gibberellin in 10^{-3} M acetate (C_2), propionate (C_3), butanoate (C_4) . . . undecanoate (C_{11}) buffers, all at *p*H 4.8.

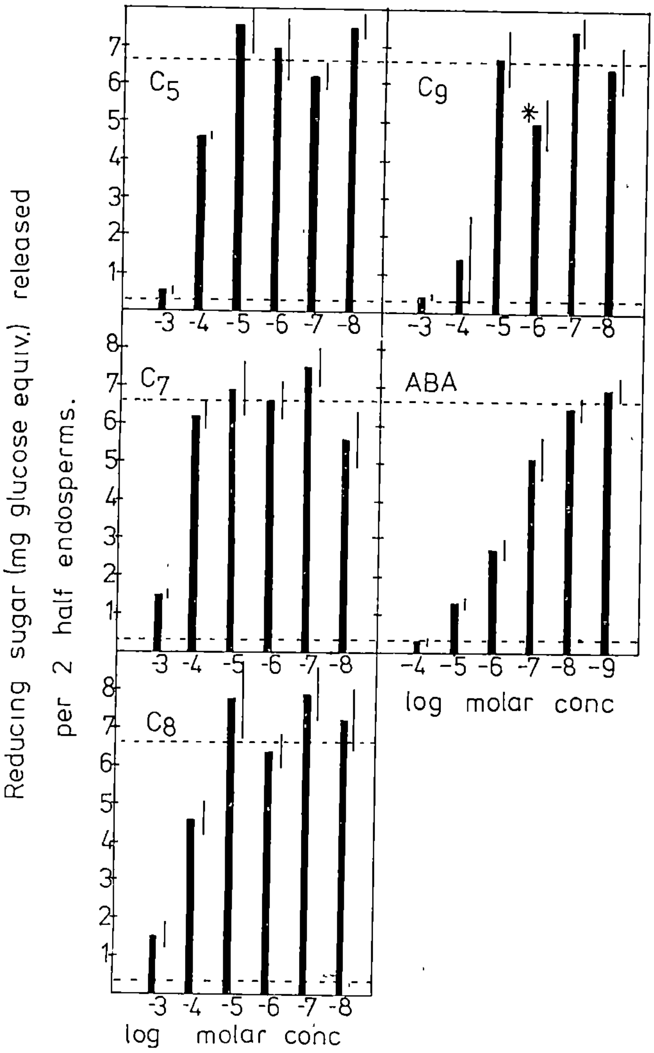

Fig. 2 Concentration dependence of fatty acid and ABA inhibition of GA-induced amylolysis in barley endosperm. Vertical bars represent reducing sugar released (see caption to Fig. 1) in presence of pentanoic (C_5), heptanoic (C_7), octanoic (C_8) and nonanoic (C_9) acids and ABA in the concentrations stated. All incubations were carried out at a constant GA concentration of 4.2×10^{-7} M, and *p*H 4.8. — — —, Mean blank value, that is, reducing sugar released in the absence of GA and inhibitors. - - - - - -, Mean control value, that is, reducing, sugar released in the presence of GA and absence of inhibitor. *Not significantly different from control value at $P<0.10$.

acid levels and depth of dormancy in oat; aleurone layer activity in fenugreek seed; the mechanism of stomatal functioning, and leaf abscission and ethylene production. The *in vitro* inhibition of amylolysis described here represents yet another phenomenon which may have considerable physiological relevance.

DNA related to the transforming gene(s) of avian sarcoma viruses is present in normal avian DNA

Infection of fibroblasts by avian sarcoma virus (ASV) leads to neoplastic transformation of the host cell. Genetic analyses have implicated specific viral genes in the transforming process[1-4], and recent results suggest that a single viral gene is responsible[4]. Normal chicken cells contain DNA homologous to part of the ASV genome[5-8]; moreover, embryonic fibroblasts from certain strains of chickens can produce low titres of infectious type C viruses either spontaneously[9] or in response to various inducing agents[10]. None of the viruses obtained from normal chicken cells, however, can transform fibroblasts, and results with molecular hybridisation indicate that the nucleotide sequences responsible for transformation by ASV are not part of the genetic complement of the normal cell[11]. We demonstrate here that the DNA of normal chicken cells contains nucleotide sequences closely related to at least a portion of the transforming gene(s) of ASV; in addition, we have found that similar sequences are widely distributed among DNA of avian species and that they have diverged roughly according to phylogenetic distances among the species. Our data are relevant to current hypotheses of the origin of the genomes of RNA tumour viruses[12] and the potential role of these genomes in oncogenesis[13].

We have prepared radioactive DNA ($\text{cDNA}_{\text{sarc}}$) complementary to nucleotide sequences which represent most or all of the viral gene(s) required for transformation of fibroblasts by ASV[14]. Our procedure to isolate $\text{cDNA}_{\text{sarc}}$ exploited the existence of deletion mutants of ASV which lack 10–20% of the viral genome (transformation defective, or td viruses)[11,15-17]; results of genetic analyses indicate that the deleted nucleotide sequences include part or all of the gene(s) responsible for oncogenesis and cellular transformation[4,14]. In our procedure the genome of the Prague-C strain (Pr-C) of ASV was transcribed into complementary DNA by endogenous RNA-directed DNA polymerase activity; we then used molecular hybridisation to select DNA specific for the region missing from the genome of the td deletion mutants. The preparation of $\text{cDNA}_{\text{sarc}}$ used was a virtually uniform transcript from about 16% of the Pr-C ASV genome[14], a region equivalent in size to the entire deletion in the strain of td virus used in our experiments[11,15-17]. Since the unit genome of ASV contains about 10,000 nucleotides[18,19], the genetic complexity of $\text{cDNA}_{\text{sarc}}$ is about 1,600 nucleotides, sufficient to represent an entire cistron. Nucleotide sequences homologous to $\text{cDNA}_{\text{sarc}}$ seem to be ubiquitous in the genomes of ASVs, but are not present in the genomes of avian leukosis viruses (including the endogenous chicken virus, RAV-0) or sarcoma-leukosis viruses from other species[14].

DNAs from several avian species (chicken, turkey, quail, duck and emu) contain nucleotide sequences which can anneal with $\text{cDNA}_{\text{sarc}}$ (Fig. 1 and Table 1). In contrast, we detected no homology between $\text{cDNA}_{\text{sarc}}$ and DNA from mammals (mouse and calf thymus; Table 1). The kinetics of the reactions between $\text{cDNA}_{\text{sarc}}$ and DNAs from chicken, quail and duck (Fig. 1*a*, *c* and *d*) were similar to the kinetics for the reassociation of unique nucleotide sequences in avian DNAs (C_0t about 1,000 mol s^{-1})[20]; thus, nucleotide sequences homologous to $\text{cDNA}_{\text{sarc}}$ are present as single (or a few) copies in each haploid complement of the avian DNAs tested. This conclusion was substantiated by measuring in a single reaction

Table 1 Homology between cDNA$_{\mathrm{sarc}}$ and normal DNAs

Assay	Hybridisation conditions [Na$^+$]	Temperature	Chicken	Quail	Turkey	Duck	Emu	Mouse	Calf
S1	0.9 M	68°	52%	46%	48%	45%	24%	<2%	<2%
HAP	0.9 M	68°					36%		<5%
HAP	1.5 M	59°					54%		

Extent of reaction between cDNA$_{\mathrm{sarc}}$ and DNA from: Chicken, Quail, Turkey, Duck, Emu, Mouse, Calf.

DNA was extracted from 10–11-d-old embryos of chickens, ducks and quails, 3-d-old mice (strain RIII), livers of adult turkeys, liver and heart of a 22-d-old emu, and calf thymus. Reaction mixtures contining denatured DNA (8 mg ml^{-1}) and ^{3}H-cDNA$_{\mathrm{sarc}}$ (0.32 ng ml^{-1}, 7,000 c.p.m. ml^{-1}) in a final volume of 0.3 ml were incubated at either 59 or 68 °C for 48 h. Samples incubated at 59 °C were in 1.5 M NaCl (final $C_0t = 40{,}000$), those incubated at 68 °C were in 0 9 M NaCl (final $C_0t = 32{,}000$); all reactions also continued 0.001 M EDTA–0.02 M Tris-HCl, *p*H 7.4. Duplex formation was measured by either hydrolysis with S1 nuclease[28] (in 0.3 M NaCl at 50 °C) or fractionation on hydroxyapatite (HAP) (samples adsorbed in 0.14 M sodium phosphate at 50 °C).

mixture the rates of reassociation between chicken DNA and both cDNA$_{\mathrm{sarc}}$ (labelled with ^{3}H) and unique nucleotide sequences purified from chicken DNA (labelled with ^{14}C) (Fig. 1*b*); the rates were similar for both labelled DNAs.

The extent of duplex formation with cDNA$_{\mathrm{sarc}}$ varied with the amount of chicken DNA used in the reactions (Fig. 1*a* and *b*), as expected in reactions where identical labelled and unlabelled DNA strands are competing for unlabelled complementary strands, and the reactions were incomplete (about 50%) at the highest value of C_0t (Fig. 1*a*, *c* and *d* and Table 1). Nevertheless, we believe that most or all of the nucleotide sequences of cDNA$_{\mathrm{sarc}}$ are present in the DNA of quail since cDNA$_{\mathrm{sarc}}$ anneals completely with RNA from certain quail cells (unpublished results of ourselves and C. Moscovici). Moreover, the rates and extents of annealing between cDNA$_{\mathrm{sarc}}$ and DNA from chicken, duck and turkey are approximately the same as the rate and extent of annealing between cDNA$_{\mathrm{sarc}}$ and quail DNA (Table 1 and Fig. 1). Thus, it is likely that most or all of the nucleotide sequences of cDNA$_{\mathrm{sarc}}$ are present in the DNA of all these birds.

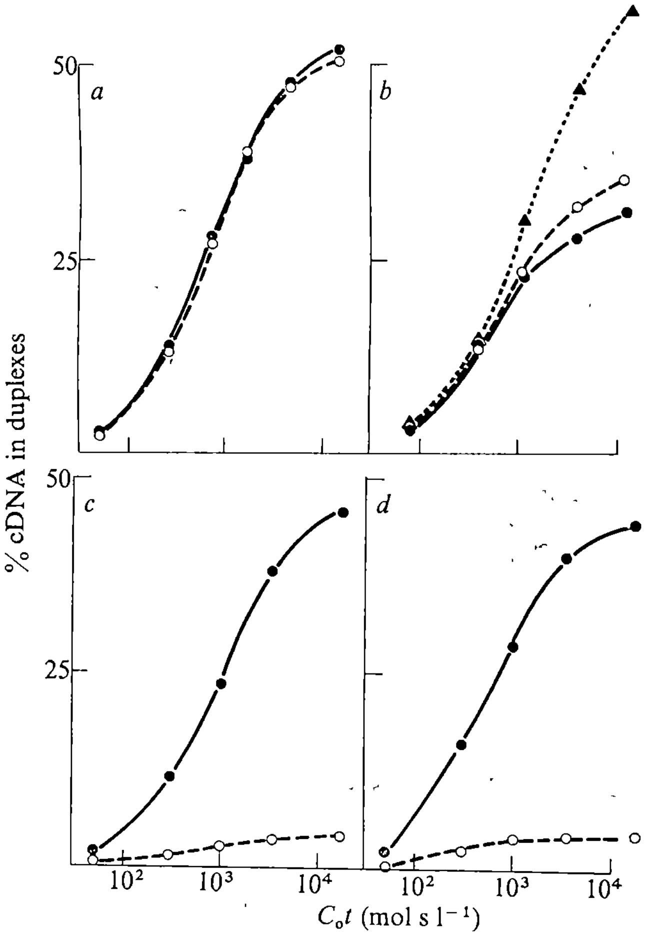

Fig. 1 Annealing of cDNA$_{\mathrm{sarc}}$ to normal avian DNAs. DNA was prepared from 10–11-d-old embryos[7], denatured and incubated with ^{3}H-cDNA$_{\mathrm{sarc}}$ and ^{32}P-cDNA$_{\mathrm{B77}}$ in 0.6 M NaCl-0.001 EDTA–0.02 M Tris-HCl, *p*H 7.4 at 68 °C for 0 1 to 32 h. Samples (0.1–0.2 ml) were withdrawn at different times and the extent of duplex formation with cDNA$_{\mathrm{sarc}}$ and cDNA$_{\mathrm{B77}}$ was measured by hydrolysis with the single-strand specific nuclease, S1 (ref. 28). The preparation of cDNA$_{\mathrm{sarc}}$ and cDNA$_{\mathrm{B77}}$ has been described elsewhere[14] and is outlined in the text. Unique sequence chicken DNA was prepared by reannealing denatured ^{14}C-chicken DNA to a C_0t of 500; unique sequence DNA was eluted from a hydroxyapatite column at 60 °C in 0 14 M phosphate buffer[20]. *a*, Chicken DNA (9 mg ml^{-1}) with ^{3}H-cDNA$_{\mathrm{sarc}}$ (0.5 ng ml^{-1}, 10,000 c.p.m. ml^{-1}) (●) and ^{32}P-cDNA$_{\mathrm{B77}}$ (0.3 ng ml^{-1}, 10,000 c.p.m. ml^{-1}) (○). *b*, Chicken DNA (5 mg ml^{-1}) with ^{3}H-cDNA$_{\mathrm{sarc}}$ (0.45 ng ml^{-1}, 9,000 cpm ml^{-1}) (●); ^{32}P-cDNA$_{\mathrm{B77}}$ (0.5 ng ml^{-1}, 6,000 c.p.m. ml^{-1}) (○), and ^{14}C-chicken unique sequence DNA (▲). *c*, Quail DNA (9 mg ml^{-1}) with ^{3}H-cDNA$_{\mathrm{sarc}}$ and ^{32}P-cDNA$_{\mathrm{B77}}$ as in *a*. *d*, Duck DNA (9 mg ml^{-1}) with ^{3}H-cDNA$_{\mathrm{sarc}}$ and ^{32}P-cDNA$_{\mathrm{B77}}$ as in *a*.

The extent of the reaction between cDNA$_{\mathrm{sarc}}$ and DNA from emu, a relatively primitive Australian bird, was limited (24%) when tested by hydrolysis with a single strand-specific nuclease (Table 1); the extent of the reaction was greater when analysed on hydroxyapatite, a less stringent procedure than the nuclease test (Table 1), and was further augmented when the annealings were performed in conditions which facilitate pairing of partially matched nucleotide sequences (1.5 M NaCl, 59 °C, ref. 21) (Table 1). These date indicate that the nucleotide sequences homologous to cDNA$_{\mathrm{sarc}}$ in emu DNA are substantially diverged from the homologous sequences in the other avian DNAs; we have obtained further data to sustain this conclusion by analysing the thermal stability of the duplexes formed between cDNA$_{\mathrm{sarc}}$ and various avian DNAs (see below, Table 2 and Fig. 2).

Avian DNAs were also tested with ^{32}P-labelled single-stranded DNA, complementary to the RNA genome of the B77 strain of ASV (cDNA$_{\mathrm{B77}}$), synthesised with detergent-disrupted virions, and purified as described previously[14] The virus used to prepare cDNA$_{\mathrm{B77}}$ consisted mainly of td variants (about 90% of the particles; unpublished observations). Consequently, DNA synthesised with the virus was deficient in nucleotide sequences homologous to cDNA$_{\mathrm{sarc}}$ and served principally to detect other portions of the ASV genome. A substantial fraction (about 50%) of cDNA$_{\mathrm{B77}}$ reacted with normal chicken DNA, but there was little or no reaction with quail, duck, turkey and emu DNAs (Fig. 1 and unpublished data); these results conform to previous reports[20,22,23]. We conclude that the DNAs from widely divergent avian species all contain nucleotide sequences which are at least partially related to transforming gene(s) of ASV, whereas only chicken DNA has appreciable homology with the remainder of the ASV genome.

The relatedness of DNA sequences homologous to cDNA$_{\mathrm{sarc}}$ in different avian species was analysed by denaturing duplexes formed between cDNA$_{\mathrm{sarc}}$ and normal avian DNAs (Fig. 2 and Table 2). In addition, we denatured duplexes between cDNA$_{\mathrm{sarc}}$ and DNA from XC cells (rat cells transformed by Pr-C ASV) to test completely matched duplexes containing cDNA$_{\mathrm{sarc}}$ sequences. The mammalian DNAs we have tested (calf and mouse) contain no nucleotide sequences homologous to cDNA$_{\mathrm{sarc}}$ before in-

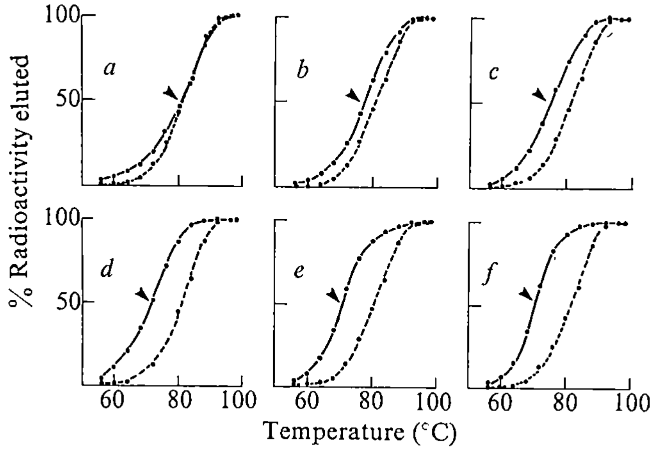

Fig. 2 Thermal denaturation of duplexes formed between cDNA$_{sarc}$ and cellular DNAs. DNA was extracted from XC cells grown in culture, from 10–11-d-old embryos of chickens, ducks and quails, from the livers of adult turkeys, and from liver and heart of a 22-d-old emu. Denatured DNAs (0.5 mg) were incubated with ^{3}H-cDNA$_{sarc}$ (0.25 ng, 5,000 c.p.m) in 0.1 ml of 0.9 M NaCl-0.001 M EDTA-0.02 M Tris-HCl, *p*H 7.4, for 100 h at 68 °C, final C_0t = 40,000. In a separate reaction, ^{32}P-cDNA$_{B77}$ (2.5 ng, 100,000 c.p.m.) was annealed with 7 mg of denatured chicken DNA (final C_0t = 80,000). Samples (0.4 mg of chicken DNA and 6,000 c.p.m. of cDNA$_{B77}$) of this reaction were added to the DNAs which had been annealed with cDNA$_{sarc}$. The mixtures were then passed through a column of hydroxyapatite (3 ml packed vol) in 0.12 M sodium phosphate, *p*H 6.8, at 56 °C; in these conditions, stable duplexes bind to the hydroxyapatite, whereas single-stranded DNA does not. The columns were then washed continuously with 0.12 M sodium phosphate (0.4 ml min^{-1}) while the temperature of the column was raised in increments of 4 °C every 10-min. Fractions (4 ml) were collected and analysed for acid-precipitable radioactivity. ●——●, Duplexes with cDNA$_{sarc}$; ●- - - -●, duplexes with cDNA$_{B77}$ and chicken DNA (internal standard). *a*, Provirus (XC); *b*, chicken; *c*, quail; *d*, turkey; *e*, duck; *f*, emu.

fection by ASV; consequently, the DNA homologous to cDNA$_{sarc}$ in rat cells after infection presumably represents nucleotide sequences contained entirely in recently integrated provirus for ASV rather than related sequences present in the DNA of uninfected cells. Denaturation was standardised internally by adding duplexes formed in a separate annealing reaction between normal chicken DNA and ^{32}P-labelled cDNA$_{B77}$; these duplexes denatured with a T_m of 81±1 °C.

Duplexes between cDNA$_{sarc}$ and DNA from XC cells had the highest T_m (81 °C; Table 2), as expected for completely matched complementary nucleotide sequences. Duplexes with chicken DNA were slightly less stable (T_m=77 °C); the nucleotide sequences of cDNA$_{sarc}$ in the ASV genome are apparently diverged from the homologous sequences in the avian host. The reduction in the T_m is consistent with about 3% mismatching of bases[24]. The stability of duplexes with other avian DNAs (T_m=70–74 °C) decreased roughly in accord with phylogenetic distances among the species tested (Table 2); the T_ms suggest 5–8% mismatching of base pairs[24]. We made no effort in these tests to obtain maximum duplex formation with cDNA$_{sarc}$, and the reactions with quail, turkey, duck and emu were relatively limited in extent (15–37%). In other experiments where at least 50% of cDNA$_{sarc}$ was annealed into duplexes with chicken, quail and duck DNAs, we observed T_ms similar to those given in Table 2. cDNA$_{sarc}$ seems to represent nucleotide sequences which arose and diverged during the course of avian speciation.

We have shown previously that the nucleotide sequences of cDNA$_{sarc}$ include genetic information required for transformation of fibroblasts by ASV[14]; the data reported here indicate that similar or partially related information is present in the genome of the normal chicken cell and widely distributed among the avian species. We suggest that part or all of the transforming gene(s) of ASV was derived from the chicken genome or a species closely related to chicken, either by a process akin to transduction[25] or by other events, including recombination, which are alleged to have generated type C viruses from normal cellular genes[12]. If the entire ASV genome originated from cellular genes[12], then nucleotide sequences in the transforming gene(s) have been conserved relative to other viral genes, because the nucleotide sequences of cDNA$_{sarc}$ are the only portion of the ASV genome which we can detect in DNA from birds other than chickens. We cannot exclude, however, the possibility that viral genes other than those represented by cDNA$_{sarc}$ have been introduced into the germ line of chickens after speciation. The sequences homologous to cDNA$_{sarc}$ in the genome of ASV are slightly diverged from the analogous sequences in chicken genome; this could be the consequence of either the process which generated viral genes from cellular genes[12] or mutations during the course of repeated viral propagation.

Others have reported evidence concerning the genetic divergence during possible spread of unidentified portions of type C viral genomes during evolution[26,27] and the apparent transduction of cellular nucleotide sequences by type C viruses[25], but our study provides the first data on the origins of a genetically identified set of viral nucleotide sequences. It should be possible to carry out similar studies for at least one other gene of ASV (the gene coding for the type-specific glycoprotein), using techniques similar to those reported here.

Neiman and his colleagues have reported that the hybridisation of ASV 70S RNA to normal chicken DNA was competed completely by RNA from non-transforming viruses[11]. They therefore concluded that the genes responsible for transformation by ASV were present in the avian genome only after viral infection. We cannot explain the discrepancy between their results and ours.

We anticipate that cellular DNA homologous to cDNA$_{sarc}$ serves some function which accounts for its conservation during avian speciation. The nucleotide sequences which anneal with cDNA$_{sarc}$ are part of the

Table 2 Thermal stabilities of duplexes between cDNA$_{sarc}$ and normal DNAs

DNA	%cDNA$_{sarc}$ in duplexes	T_m	ΔT_m	Phylogenetic distance from chicken (Myr)
Provirus (XC)	56	81	0	
Chicken	52	77	−4	0
Quail	37	74	−7	35–40
Turkey	30	72	−9	40
Duck	16	71	−10	80
Emu	15	70	−11	100

Denatured DNAs (0.5 mg) were annealed with ^{3}H-cDNA$_{sarc}$ (0.25 ng, 5,000 c.p.m.), adsorbed to hydroxyapatite in 0.12 M sodium phosphate at 56 °C, and denatured with a thermal gradient, all as described for Fig. 2. Duplexes between ^{32}P-cDNA$_{B77}$ and normal chicken DNA, included in each analysis as an internal standard, denatured with T_m = 81 ±1 °C. The estimates of phylogenetic distance, deduced from fossil records and antigenic relationships among proteins[29], were provided by Professor Allan Wilson (personal communication).

unique fraction of cellular DNA and could represent either structural or regulatory genes. But the function of those sequences is unknown. We are testing the possibilities that they are involved in the normal regulation of cell growth and development or in the transformation of cell behaviour by physical, chemical or viral agents.

We thank William E. Meeker of Sacramento Zoo for assistance in obtaining the emu, Karen Smith and Jean Jackson for technical assistance, and H. Temin and L. Levintow for editorial advice. Raman spectra of transfer RNAs with ultraviolet lasers

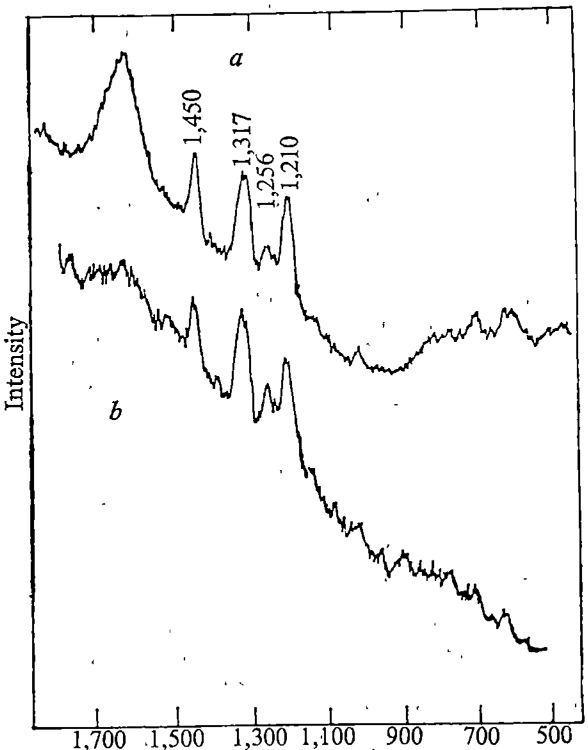
WE suggest here a new use for Raman spectroscopy in structural studies of nucleic acids. We demonstrate that an enhanced vibrational Raman spectrum of a certain limited portion of an amino acid transfer RNA (tRNA) macromolecule can be observed, if a proper ultraviolet laser beam is chosen for excitation.

Until now, Raman spectra of tRNAs have been observed with laser beams of visible light[1–6]. They all show a number of Raman lines characteristic of the four common bases, namely, adenine, uracil, guanine, and cytosine. For such observations concentrated solutions (usually about 5 %) or considerable amounts (10 mg) of tRNA are required. Some of the minor constituent nucleosides in tRNAs have strong absorption bands in the 300–350-nm region, whereas the common bases have them at 260 nm. Using the correct ultraviolet laser, therefore, one would expect to observe resonance Raman effects of minor nucleoside bases. Such effects would be valuable, first, because they would provide information on one particular base residue of the 70–80 bases in tRNA and second, because this could be done with much smaller amount samples of tRNA this usual.

We have observed a Raman spectrum of formylmethionine tRNA of *Escherichia coli* with the 363.8-nm beam of an argon ion laser (Coherent Radiation 52 GA). The power of the laser beam was 5 mW at the sample. The tRNA concentration of the sample solution was only 0.3%, in cacodylate buffer, *p*H 7.2. The total volume of the sample solution used was 0.2 ml, contained in a cylindrical cell of silica glass. A JRS-U1 Raman spectrophotometer (Japan Electron Optics) was used. The recorded curve is shown in Fig. 1*a*. The curve can be reproduced more than ten times from one sample solution. The aminoacylation activity of the tRNA remained undegraded after 5 h irradiation with the ultraviolet laser beam. When the wavelength of the laser beam was changed from 363.8 to 351.1 nm, almost the same Raman spectrum was observed.

All of the observed Raman lines are attributable to the 4-thiouridine residue (at position 8) subjected to photochemical modification (probably cross linking[7,8] with the cytidine residue at position 13 of the tRNA). This can be concluded because, first, at that concentration and with that laser power, on the basis of the available data, none of the Raman lines of the common base residues can be expected to appear. Moreover, none of the

Fig. 1 Raman spectra excited by the 3,638 Å beam of an argon ion laser. *a*, tRNA^{fMet} from *E. coli;* concentration, 0.3 %; solvent, 10^{-1} M NaCl+10^{-2} M Na-cacodylate (*p*H 7.2)+10^{-3} M MgCl$_2$. *b*, tRNA^{Gly} from *E. coli;* concentration, 0.3 %; solvent as in *a*.



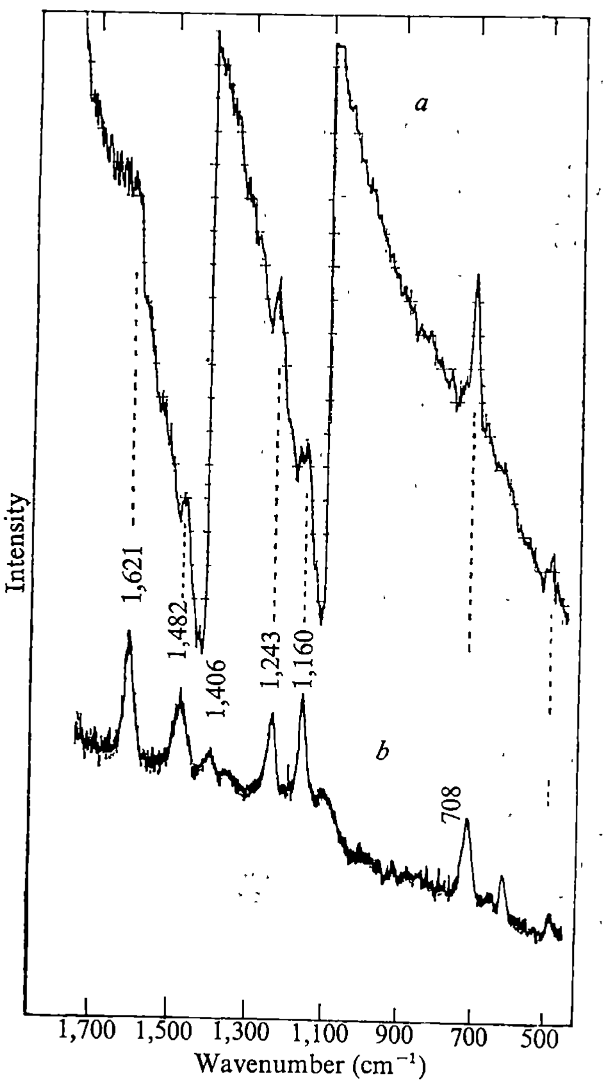


Fig. 2 Raman spectra excited by the 3,638 Å beam of an argon ion laser. *a*, tRNA^{Tyr} (2) from *E. coli*; concentration, 1 %; solvent, 10^{-1} M NaCl+10^{-2} M Na-cacodylate (*p*H 7.2),+10^{-3} M $MgCl_2$. *b*, 4-Thiouridine; concentration, 10^{-4} M; solvent, 10^{-2} M Na-cacodylate, *p*H 7.2; observed with a rotating cell.

observed lines has the same Raman frequency as the common base residues. Second, 4-thiouridine has a strong absorption band at 330 nm, and is the only base (in this tRNA) known to have an absorption band in the 300–350-nm region. Even when 4-thiouridine forms a cross linkage with cytidine, it shows an absorption band of nearly equal intensity at 330 nm (ref. 8).

Third, none of the Raman lines in question has the Raman frequencies (1,621, 1,482, 1,243, 1,160, and 708 cm^{-1}) of 4-thiouridine itself (see Fig. 2*b*). The 708 cm^{-1} line of 4-thiouridine can be assigned to the C=S stretching vibration. In the Raman spectrum now in question, on the other hand, no line assignable to the C=S stretching vibration is found. Thus, a structure lacking a C=S bond is suggested.

Fourth, *E. coli* tyrosine tRNA(2), which has 4-thiouridine residues (see, for example, ref. 9), (two at positions 8 and 9), but no cytidine residue[10] at position 13 shows the Raman lines of 4-thiouridine. The sample is fluorescent, but on the fluorescence background all of the five stronger Raman lines of 4-thiouridine can be identified (Fig. 2*a*).

Fifth, *E. coli* glutamic acid tRNA(2), which has no 4-thiouridine residue[11], has been found to give no Raman lines in these conditions. Sixth, when a bulk tRNA sample of *E. coli* is placed in a rotating cell[12] the Raman lines of 4-thiouridine do appear, but after a few runs of the spectrum with the ultraviolet laser they are gradually replaced by the Raman lines discussed.

The photochemical modification (probably the S^4U–C linking) is considered to be caused in this case by the laser beam itself. When the rotating cell is used, the chance of the laser photon hitting the intact tRNA molecule would increase, so that the Raman lines of 4-thiouridine free from the cross linkage appear.

Most of the *E. coli* tRNAs have one or two 4-thiouridine residues. Using a similar Raman spectroscopic examination we found that tRNA^{Gly} should have the 4-thiouridine residue, and that this must be involved in a similar photochemical modification (probably the 4-thiouridine-cytidine cross linkage) (see Fig. 1*b*). (Although no 4-thiouridine has been reported[13] in the primary sequences of tRNA^{Gly}, chemical analysis have shown[14] that this tRNA contains 1 mol of 4-thiouridine.) Also for tRNA^{fMet} (ref. 15) of *Thermus thermophilus*, an extremely thermophilic bacterium[16], a similar Raman spectrum attributable to the 4-thiouridine-cytidine cross linkage has been observed.

The ultraviolet laser would also be useful in obtaining information for other chromophore groups in tRNAs, for example, the Y base in yeast tRNA^{Phe} (ref. 17).

We thank Professor H. Hayatsu, University of Tokyo, for providing the sample of 4-thiouridine.

New Zealand archipelago

Malcolm Coe

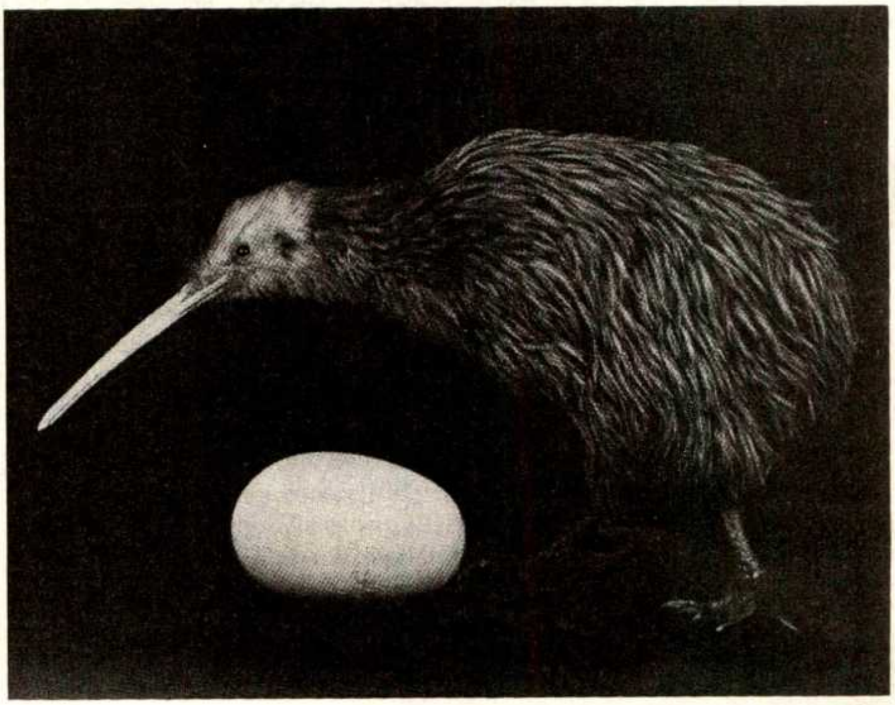

Photo: National Museum

North Island brown kiwi, Apteryx a. mantelli, *female (440 g, 125 × 78.5 mm) and egg (400 ml)*

At a time when the trend is towards publication of specialist volumes dealing with individual animal and plant groups, this broad approach* will be welcomed by the biologist who is anxious to obtain an overall assessment of an area's fauna. In using other volumes in this interesting series, I have always felt that much would have been gained by attempting to use the same format for each volume. One appreciates, however, the difficulty of persuading authors to write on anything other than their own particular specialist field. The comparative isolation of the New Zealand archipelago makes its study of particular interest to the biogeographer, for 80% of its flowering plants and 90% of its arthropods are endemic.

The first of 17 chapters sets out to describe the geological history of the archipelago as a background for the later account of the development and evolution of the main biota. In a concise account of an isolated flora and fauna, one is reminded of the drastic effect man has had on this environment when he first arrived there a 1,000 or so years ago and exterminated the moas, several species of Carinate birds and even a variety of previously prominent invertebrates. For those who still doubt the association of man with dramatic post-Pleistocene extinction it should make interesting reading. This account is followed by two chapters dealing with the climate and soils which form essential background reading on the description of vegetation which follows.

The story of man-induced changes in the biota is a continuing theme throughout the volume and considering how comparatively recent the changes are it is the more remarkable when we consider the influence that such features as the extermination of moas must have had on a vegetation for which they were the dominant large herbivore.

Although the terrestrial vertebrate fauna is only represented by 100 species, comprising 30 reptiles, 65 land birds and two mammals, this small number represents a fascinating illustration of adaptive radiation in isolation, of which probably the development of the terrestrial parrots is perhaps the most dramatic. Considering that a further 70 species of exotic birds and mammals have been introduced to New Zealand, it is surprising that even more elements of the endemic fauna have not become extinct. The fishes, in contrast to other vertebrate groups, comprise 8 families, none of which are endemic; and perhaps the greatest feature of interest is their ability to move between fresh and salt water, indicating no doubt the route by which freshwater habitats in New Zealand have been occupied. The kiwi and *Sphenodon* are justifiably given chapters of their own.

Aquatic environments are discussed in two chapters dealing with the marine benthic and freshwater biota, respectively. The greater degree of isolation experienced by the freshwater flora and fauna make them of somewhat greater biogeographical interest. Perhaps one of the greatest features of interest that emerges when we examine these 'early' groups is that comparatively few of them are represented by endemic forms, illustrating the comparative geological youth of New Zealand.

The land molluscs, arachnids, and terrestrial and freshwater insects all provide valuable examples of radiation and speciation.

The final two chapters deal with the adaptation and change in Maori culture and the influence of man on the biota. I found these two chapters disappointing, for having learned a great deal about the flora and fauna of New Zealand, the great gap in our knowledge lies in considering the ecology of the early colonists in relation to the landscape change, which has perhaps been more dramatic in New Zealand than almost any other part of the Earth's surface.

It is easy to criticise the features either included in or excluded from this volume but the resulting work will be an important source book for all students of the biogeography of Australasia. □

**Biogeography and Ecology in New Zealand.* (Monographiae Biological, Volume 27). Edited by G. Kuschel. Pp. xvi + 689. (Junk, Hague, 1975.) 200 Dutch guilders.

Plasma proteins

The Plasma Proteins: Structure, Function and Genetic Control, Volume 1. Edited by Frank W. Putnam. Second Edition. Pp. xvi+481. (Academic: New York and London, October 1975.) $37.50; £19.50.

THE appearance of volume 1 of the second edition of *The Plasma Proteins* is to be welcomed for several reasons. Most important is that it provides a survey of the multifarious developments which have occurred in the 15 years following the publication of the first edition. The mass of data now available finally decided the editor to subdivide the authorship so that a number of specialists are now responsible for particular chapters. As is stated in the introduction, however, this approach was adopted with some hesitation because of the danger that an integrated coverage might be lost. An initial attempt by the editor to write the whole of the second edition himself became impossible because "the rate of progress in plasma proteins outstripped my pen". Finally, in volume 1 only two chapters, constituting a general survey of the plasma proteins and a chapter on transferrin, have been written by the editor. The survey is valuable but, in view of the high price of the volume, a case can be made out that a wider readership would have been reached if this survey were to have appeared separately.

The second reason for welcoming this book is that it is well up to date. Probably because of the desirability for rapid publication, a few minor matters were not tidied up—for example, on p279 appears a warning which was already given on p272 that the iron-saturated and iron-free forms of transferrin can only be separated on starch gel if the starch is iron free. Also both Glx and Glu appear as abbreviations for glutamic acid. Table 1 of Chapter 2 represents a useful updating of the previous list of properties of plasma proteins. It is unfortunate, however, that reference to the original papers from which the data has been taken is indirect by way of another chapter in volumes 1, 2 or 3.

Since the appearance of the first edition, patient work in many laboratories has brought to light the complete sequences of a number of plasma proteins. Thus it may be appropriate to enquire as to the return which has resulted so far from this immense investment of time and energy. A positive answer in respect of the H and L immunoglobulin chains, albumin and the α_1 acid glycoprotein may be given with confidence. As is explained in chapter 3, the division of the albumin molecule into domains and the structures associated with the binding sites are now known. For α_1 acid glycoprotein the outcome is even more satisfactory since it is now apparent that this protein is the first single-chain plasma protein having some homology with two other plasma proteins: IgG and haptoglobin. These results suggest that the time points at which each of the currently existing plasma proteins branched off from their primitive precursors will become known.

A. H. Gordon

On-line computing

Laboratory On-Line Computing: An Introduction for Engineers and Physicists. By J. E. Brignell and G. M. Rhodes. Pp. x+297. (International Textbooks: Leighton Buzzard, September 1975.) £8.75.

THIS book sets out to introduce engineers and physicists to on-line computing. The authors wisely confine themselves mostly to generalities but at the same time there is sufficient depth of detail to make this book of real use to persons entering this complex and rapidly developing field.

Two early chapters introduce the reader to the basic elements of both hardware and software, assuming a level of knowledge usually gained in most courses in engineering or physics—a good starting point. But it is in getting to grips with the real problem—hardware–software interaction—that the authors excel, with their ability to delineate and explain the essential features of interfacing. Many complex design features of both hardware and software are explained with a lucidity which is both refreshing and instructive.

The authors devote a large section of their book to a much neglected subject—the consequences of interfacing the real continuous world to the discretised world of the digital computer. The reader is introduced very gently to theories of sampling and digital filtering.

There are, however, one or two surprising omissions. There is an absence of detailed comment on, for example, either the influence of operating systems on real-time response, or on modern programming techniques which are important for memory-starved minicomputers, such as subroutine re-entrancy. On the hardware side the ubiquitous asynchronous serial line unit is not mentioned.

On the whole, however, this is an excellent book and anyone planning to "go on-line" will certainly find it of great benefit. Research workers and engineers already experienced in on-line computing will find sections which make interesting and valuable reading.

P. F. Kilty

Organometallics

Organometallic Derivatives of the Main Group Elements. (International Review of Science. Inorganic Chemistry Series Two, Vol. 4.) Edited by B. J. Aylett. Pp. 417. (Butterworth: London; University Park Press: Baltimore, Maryland, August 1975.) £13.45.

ORGANOMETALLIC chemists are well served by surveys intended to ease the task of keeping abreast of the flood of papers on the subject. The Annual Surveys, forming part of the *Journal of Organometallic Chemistry,* provide detailed coverage of derivatives of individual metals or groups of metals; the Specialist Periodical Reports of The Chemical Society cover the whole field annually; and the series of which this volume forms a part covers derivatives of the main group elements, including group IIB, biennially (organic derivatives of the transition metals are included in other volumes in the Inorganic Chemistry series).

In this volume, chapters devoted to individual metals or related groups of metals review papers published in 1971 and 1972 (for arsenic, antimony and bismuth, early 1971 to March 1973; and for beryllium, magnesium and the alkaline earths, 1969 to 1972). The surveys are inevitably selective, and the judgment of the authors in their choice of significant papers can only be tested by subsequent developments. One omission did seem surprising: although work on various metallocarboranes is reported, there is almost no coverage of carboranes *per se.*

If the unavoidable limitations of this type of survey are accepted, this volume provides a useful key to the original literature, and the price is not excessive. There are, however, some defects, which it is hoped the publishers and editors will remedy in future editions: the apparently random order of the chapters, and the inconsistency in their titles; the brevity of the subject index (and absence of an author index); and the fact that a survey of the literature for 1971–72 has not appeared until August 1975.

B. J. Wakefield

Polychloroaromatics

Polychloroaromatic Compounds. Edited by H. Suschitzky. Pp. viii+543. (Plenum: New York and London, 1975.) $42.

MOST readers will find this book of greatest interest if they read first the last chapter, which is a comprehensive and stimulating survey of polychloroaromatic and -heteroaromatic compounds of industrial importance, by M. B. Green of ICI Mond Division. Insecticides, fungicides, herbicides and others are covered together with certain polymers and dyestuffs. This material gives special point to the earlier chapters.

In the first of these, Ballester and Olivella provide a lengthy account of aromatic and alkaromatic chlorocarbons which is clear, comprehensive and well organised. It contains very interesting material on relevant radicals, reactive and inert, and on carbonium ions and carbanions. It is followed by similar chapters on polychloroheteroaromatic compounds and on polychloroaryl derivatives of metals and metalloids by Iddon and Suschitzky and by Chivers and Wakefield, respectively.

The range of heterocyclic compounds covered is wide, including mainly mono- and bi-cyclic compounds containing one or two heteroatoms (nitrogen, oxygen and sulphur). Similarly, the coverage of metals and metalloids is comprehensive with major emphasis on alkali metals, group II metals, and group IIIA and IVA elements, particularly silicon.

The intrinsic chemical interest attached to all these compounds lies in an attempt to understand their unusual properties in terms of the cumulative electronic effects of the chlorine substituents and corresponding steric effects. Some progress in this direction has been made. The book has a traditional 'preparation and properties' flavour, but is a mine of information, indicative of many problems needing further research.

The book is well conceived and well produced, and each chapter has a full set of references. There is also a satisfactory author and subject index. It is, however, somewhat specialised for most organic chemists. Nevertheless they are all in Professor Suschitzky's debt for making available so conveniently a vast amount of useful and interesting information.

N. B. Chapman

Idealised models

Branching Processes with Biological Applications. (Wiley Series in Probability and Mathematical Statistics.) By P. Jagers. Pp. xiii+268. (Wiley Interscience: London and New York, October 1975.) £10.50.

ALTHOUGH biological populations often develop in extremely complex patterns, we may imagine idealised situations in which the underlying reproductive process has a simple structure which is free from the usual dependencies of competition, predation and the limitation of natural resources. Such simplified models lend themselves to a mathematical analysis rich in results, and the conclusions drawn from them often give great insight into the behavioural structure of the more complicated processes to which they relate. This mathematical theory has been studied in great generality and the results may be easily interpreted in a practical context.

The basic structure of such idealised models involves the concept of a branching process, in which a population of identical individuals develops in time as the individuals multiply independently of each other and eventually die. As a thorough survey of problems involving multitype branching processes is already in existence (Mode, American Elsevier, New York, 1971), their existence is mainly avoided in this book.

Within this framework questions may be asked which relate to the probability that a population becomes extinct, to the existence and structure of stable age distributions, to limiting rates of growth, and so on. The general theory surrounding such questions is developed in the first seven chapters, and applications are discussed in the last two. The reader is gently led into the text by way of a historical survey and an analysis of the simplest model available, namely the Galton–Watson process. Generalisations of this special case are considered and the first part of the text concludes with a short chapter on multi-type processes. In a brief interlude the reader is armed with the basic tools of martingales, renewal theory and point processes; and he is then presented with a full treatment of the general theory with all its attendant extensions and ramifications. These complex ideas are then illustrated by reference to several stimulating problems in the fields of demography and cell kinetics.

Dr Jagers writes in an extremely interesting literary style, rare for a mathematician, and his book is a delight to read. A high level of mathematical ability is required for full comprehension of all the theory contained in it, but it is to be hoped that biologists with little mathematical expertise will still find that his conclusions arouse considerable food for thought

E. Renshaw

Proteins

The Proteins. Volume 1. By Hans Neurath, Robert L. Hill and Carol-Leigh Boeder. Third Edition. Pp. xiii+547. (Academic: New York and London, 1975.) n.p.

THE two previous editions of *The Proteins* have achieved an honoured place in a literature that is fast attaining a complexity matched only by its subject. Is a new edition able to escape the ridicule that in these days such an all-embracing title immediately inspires? Only by the editors quickly informing the reader that generalities and unifying principles will be stressed. Eight volumes are envisaged, of which the first three will deal with general methods, and the remaining five with specific proteins that have unusual structural features or unique biological functions.

This first volume begins well with an admirable account of gel-chromatographic methods of analysis by G. K. Ackers. In view of the extent to which these methods have established themselves in protein chemistry, this seems a proper choice. In the next chapter J. Porath and T. Kristiansen describe the even more significant technique of affinity chromatography, which has achieved a major breakthrough in the last two or three years. The third chapter treats the electrophoresis of proteins in dissociated form in the presence of sodium dodecyl sulphate. A critical account is given by two of the most experienced workers in this field, K. Weber and M. Osborn. In a fourth chapter, K. E. van Holde considers sedimentation analysis. This is a topic where data analysis, and on-line computerisation, is proceeding apace behind the scenes, and we can regard this as a holding exercise for future developments. In chapter five, I. M. Klotz, D. W. Darnall and N. R. Langerman summarise what is known about the quaternary structure of some 300 proteins and describe new methods for chemically cross-linking subunits to detect near neighbours. They also bring the reader into contact with the flourishing study of protein hybrids.

The final chapter on electron microscopy by J. T. Finch provides a very thorough review of the application of image analysis to the determination of the quaternary structure of assemblies of protein molecules.

This is a very good book, written by experts who have had plenty of practice with earlier articles elsewhere.

G. A. Gilbert

Advances in Molten Salt Chemistry, Volume 3. Edited by J. Braunstein, Gleb Mamantov and G. P. Smith. Pp. xi+458. (Plenum: New York and London, 1975.) $46.20.

"MOLECULAR dynamics calculations of molten ionic salts", by L. V. Woodcock (chapter 1), is a comprehensive review of the methods and application of computer simulation techniques to interpreting the physical chemistry of molten salts. The author concludes that computer simulation offers the only presently viable approach to quantitative interpretation of ionic melt properties. "Gas solubility in molten salts" by P. E. Field reviews the literature up to 1972 and includes results for 14 gases in pure and mixed metal salts of seven anions. "Organic reactions in molten tetrachloroaluminate solvents" by H. L. Jones and R. A. Osteryoung concentrates on condensation-addition reactions, dehydrogenation-addition reactions and rearrangement-isomerisation reactions. The continuing importance of fluorides justifies a major review of "Experimental techniques in molten fluoride chemistry" by C. E. Bamberger. The detailed explanations will be useful to even a beginner in the field.

"The chemistry of thiocyanate melts" by D. H. Kerridge is the first review of the subject, covering thiocyanate melts in most groups of elements. The final chapter (171 pages) by R. E. Thoma describes "Phase diagrams of binary and ternary fluoride systems". This exhaustively catalogues every known phase diagram in which the liquidus is delineated. Hitherto unpublished data from Oak Ridge Laboratory are included, and the publication in English of much Russian literature is invaluable.

This book maintains the high standards of literary and technical excellence which have characterised the series. **H. C. Brookes**

Halonium Ions. (Reactive Intermediates in Organic Chemistry.) By George A. Olah. Pp. xiii+190. (Wiley-Interscience: New York and London, November 1975.) $22.75; £11.40.

THIS new book from Professor Olah is about species of the type $R\overset{+}{X}R'$, where R and R′ may be alkyl or aryl (including cyclic forms), and X a halogen. Aromatic iodonium salts ($Ar\overset{+}{I}Ar\ X^-$) were discovered in 1894 and are described in many standard organic texts. Aliphatic halonium ions are more recent and much of the work on them has emerged from Olah's laboratory in the last decade.

The book describes the preparations, spectroscopy (mainly nuclear magnetic resonance (NMR)) and chemical reactions (alkylation, arylation, nucleophilic attack) of the various types of halonium ion. Stability falls as the groups R change from aromatic to aliphatic and the halogen from iodine to chlorine (fluoronium ions are unknown). The wholly aliphatic $R\overset{+}{X}R'$ ions exist only at low temperatures and there is only NMR evidence (plausible rather than rigorous) for them. Olah is perhaps too certain here; although the balance of probability lies in favour of the halonium ions, more evidence that some of them are not present mainly as carbenium ions is surely needed. **J. Burdon**

Books brief

Statistical Prediction Analysis. By J. Aitchison and I. R. Dunsmore. Pp. xi+273. (Cambridge University: Cambridge, London, New York and Melbourne, September 1975.) £8.50.

ONE of the most important problems in applied statistics is that of predicting, on the basis of a number of observations, what a future observation will look like. In its simplest form, $x_1, x_2, \ldots x_n$ are n realisations of a random variable—what can be said about x_{n+1}? Although study of the problem goes back to Laplace and his law of succession, it does not occupy a prominent position in modern statistical thinking. This is a pity in view of the importance and frequent occurrence of the problem. The present book is a serious and successful attempt to remedy this situation. The introductory chapter contains some excellent examples and later chapters deal with applications to sampling inspection, regulation, optimisation, calibration, diagnosis and treatment allocation. Throughout the book, and particularly in these chapters, the theory is intimately related to practice and non-trivial examples are given in commendable detail. The authors have had to make an agonising decision about the mathematical level of the book. What they have chosen to do is to throw the reader in at the deep end after the gentle introductory chapter. He is sharply immersed in a whole series of distributions, and without some experience of probability distributions he will certainly be lost. The authors ease his way by full and intelligent tabulation of the distributions and by very clear writing. Within the limits of size they could hardly have done better. The philosophy of the book is largely Bayesian, although there are some deviations in chapters 5 and 6; but I think the reader will be so convinced by the good, sound common sense and practical relevance of the examples that he will scarcely realise that a serious point is at stake. This book is an important contribution to the statistical literature. **D. V. Lindley**

Chemistry, Biology, and Clinical Uses of Nucleoside Analogs. (Annals of the New York Academy of Sciences, Volume 255). Edited by A. Bloch. Pp. 610. (New York Academy of Sciences: New York, August 1975.) $46.00.

NUCLEOSIDE analogues have been used with increasing success over the past 20 years in the treatment of cancer and of bacterial viral and parasitic infections. Add to this the clinically useful immunosuppressive properties of some analogues and it is clear that they represent a therapeutically important group of compounds. In addition, some nucleoside analogues have other, perhaps no less important, actions as cardiovascular agents, specific fungicides, radioprotective agents, insect chemosterilants and as regulators of cell function. Some analogues are even growth stimulators (cytokinins), and on a socially responsible note, could, "in the food-short world of tomorrow, conceivably take on great importance". Such is the diversity of the biological properties of the agents described in this volume, that it is now evident that new analogues once isolated or synthesised, should be widely screened, since they may have any one of a number of important properties. Tubercidin (7-deaza-adenine), for instance, was rejected as a clinically useful anti-tubercular or antitumour agent because of unacceptable host toxicity. Since no toxicity is encountered on local administration to the skin, however, the agent now has potential value in the treatment of basal cell carcinoma.

This elegantly edited volume is a clear, interesting, and in places fascinating, account of nucleoside analogues, their present day uses and their future. Details are given of new synthetic routes, of the properties of novel analogues and of new ways of using already well-established agents. As the final chapter emphasises, there is still a great deal to be learnt from the study of nucleoside analogues. **T. A. Connors**

obituary

Theodosius Grigorievich Dobzhansky, world renowned population geneticist and evolutionist, died on December 18, 1975 in Davis, California. Correspondence concerning journal articles received by his colleagues suggest that he was working until the moment of death.

Dobzhansky was born on January 25, 1900 at Nemirov, near Kiev, in the USSR, where he studied biology at the University. After graduating, he became a Lecturer in Genetics at the University of Leningrad. In 1927 he received a Rockefeller Foundation fellowship to study with T. H. Morgan at Columbia University and at the California Institute of Technology, when Morgan moved there. Dobzhansky joined the faculty of the Institute after the expiry of his fellowship. He remained there as Professor of Genetics until he returned to Columbia University in 1940. In 1962 Dobzhansky joined the research staff of the Rockefeller Institute (later Rockefeller University) in New York City. On his retirement in 1971, he moved to the University of California at Davis, where he worked until his death.

Early in his career, Dobzhansky ('Dodik' or, as his American friends came to call him, 'Doby') led an expedition into central Asia studying the genetics of domestic animals. He developed a lifelong passion for horseback riding during that trip. Subsequently, nearly every site for field studies was selected to include accessibility to a riding stable; a ride of several hours on a 'splendid animal' was an essential feature of his daily routine.

Until joining Morgan's group, Dobzhansky spent some ten years studying the taxonomy, geographic variation, and polymorphism of coccinellid (ladybird) beetles. These studies, influenced by his former professor, S. S. Chetverikov, laid the foundation upon which he built his later theories of the origin of geographic races.

After joining Morgan's group, Dobzhansky started his work on Drosophila. He commenced a number of studies that would now be regarded as 'classical' genetics: in respect to the question of the pleiotropic (multiple) action of genes, he showed that a number of common mutant alleles in *D. melanogaster* had consistent effects on internal organs as well. His work on the location of gene loci through the use of chromosomal translocations led to the first cytological maps of gene loci. He pursued the genetics of sex-determination and intersexuality in Drosophila, and made valuable contributions to the then-baffling phenomenon of 'position effect'.

Dobzhansky's work on the population and evolutionary genetics of *D. pseudo-obscura* began in the early 1930s with studies on the hybrid sterility of 'inter-racial' crosses. After discovering a wealth of chromosomal inversions in these flies, he recognised that the order in which these inversions occurred could be deduced from present day gene arrangements. A phylogeny of chromosomal rearrangements spanning three species was eventually constructed.

The studies on the genetics of natural populations of *D. pseudo-obscura* and other Drosophila species were reported in a series of 43 papers, the last of which appears in the March 1976 issue of *Genetics*. These studies also formed the basis of Dobzhansky's classic text, *'Genetics and the Origin of Species'* (retitled *'Genetics of the Evolutionary Process'* in its 1970 edition). He constantly related knowledge gained firsthand from his beloved flies and beetles to appropriate biological aspects of human beings; out of such efforts came *'Mankind Evolving'*, a text that is often favourably compared with his earlier classic.

Dobzhansky will influence the course of population genetics for years to come. In addition to the 34 or so doctoral students whom he supervised, his laboratory was host to a phalanx of postdoctoral fellows from all parts of the world. At last count, Dobzhansky had been the recipient of 21 honorary degrees.

In concluding this review of Dobzhansky's many accomplishments, it is necessary to mention the vigour with which he opposed those whom he perceived as charlatans. For many years, he attacked Lysenko and Lysenkoism as that man and his followers sought to destroy both genetics and the geneticists within Stalin's USSR. Similarly, he criticised outspokenly the pseudo-science of those in the United States and elsewhere who preached the superiority of one racial group over another. And he had no patience with those who, on religious grounds, oppose evolution and the teaching of evolution in the public schools. Weakened by age and terminal disease, Dobzhansky could nevertheless muster the strength needed to thunder at a carping anti-evolutionist, "SIR! I do not question your honesty! I question your INTELLIGENCE!"

Lee Ehrman
Bruce Wallace

Professor Sir Alexander Haddow died on January 21, three days after his 69th birthday. Honours, high academic distinction and recognition of his work came to him from many institutions and countries, and these and the list of his numerous offices can be found in reference books. This is a more personal tribute and an account of his 40 years devoted to the Research Institute of the Royal Cancer Hospital (Free), known, after moving to new premises, as the Chester Beatty Research Institute.

In 1935 he arrived there from Edinburgh to join Kennaway, and in 1946 succeeded Kennaway as Director. The run-down inevitably associated with the war was reversed and he initiated a ten-year period of growth and expansion. He insisted that cancer research must not to be regarded in any narow light but must be pursued as with basic science, to which it, in turn, had to contribute. He thought himself "an anti-planner and an anti-organisation man" and he would have been appalled to hear himself described as a good administrator, yet he was just that. He provided an organisation which facilitated research, yet one that was quite free from bureaucratic complexity and he saw to it that no-one was diverted from what he described as 'their proper labour' by administrative tasks.

To achieve this took much time and effort but yet it did not stop Alex Haddow from pursuing his own research work, and from guiding the work of a large team. His knowledge of all aspects of cancer research was impressive and he took immense pains to help and advise. He never forced his own views, yet a large part of the work of the Institute, past and present, can be traced both to his guidance, enthusiasm and, not infrequently, to his own research discoveries. His attitude to research was that it was an intensely individual pursuit and that workers must be left to develop their own promise: the discipline was personal and that imposed by the subject. He impressed on all that while work had to be carefully planned, it must not be rigid to exclude or overlook the unanticipated chance or the unintended discovery which he considered to be one of the principal objectives of cancer research.

He gave up the directorship in 1969 because of his failing eyesight and retired as Professor of Experimental Pathology three years later. He did not allow this affliction to stop his work and he was active until a few weeks before his death.

His own research work, which covered a vast spectrum from the first properly conducted clinical trial of a cancer chemotherapeutic agent to studies of drug action at the molecular level, was dominated by the concept that there is a link between impairment of growth and the eventual induction of cancer. Early in his career he found that chemicals which induce cancer are almost invariably toxic to dividing cells, both normal and malignant. The full implications of this observation for the mechanisms of carcinogenesis have yet to be revealed, but for the development of the modern era of cancer chemotheraphy this finding was crucial. The study of the mode of action of carcinogens and of anticancer agents was seen by him to be closely associated, and led to the discovery within the Institute of some of the most valuable and widely used cancer chemotherapeutic agents.

While Haddow foresaw long before most the clinical possibilities of cancer chemotherapy, he appreciated the limitations of the available compounds and insisted that research efforts must be concentrated on their mode of action in the hope of achieving greater specificity. His belief that, in spite of the great diversity of carcinogens, there must be an underlying unity of mechanism and that a truly comprehensive synthesis is possible has been fully validated by recent findings that carcinogens of the widest heterogenicity induce, by various routes, very similar biochemical lesions.

His personality was complex but the key to it was his intense concern for people and causes. His idealism extended into many fields and he found the time to give active support to bodies involved with the prevention of nuclear war and the misuse of science in all its aspects, such as Pugwash. He wrote cogently on all these topics and to foster them accepted a seat on the Press Council and the advisory council of the B.B.C. He also contributed greatly to the international organisation of cancer research, both through the International Union, in which he served as President, and by personal contact.

His concern for people determined the atmosphere of the Institute. He was tolerant, generous, had an intense interest in the well-being of all who worked for him and with him and went to endless trouble to help with professional and personal problems. Haddow's immense mental and physical energy and his versatility derived from his conviction that problems intellectual, medical or social were capable of being solved and he had no sympathy for those who skirted their direct confrontation.

Peter Alexander

International meetings

March 31–April 2. **The magnetosphere/Particle physics,** Sheffield (The Meetings Officer, The Institute of Physics, 47 Belgrave Square, London SW1 8QX, UK).

April 2, **Chemically Active Species in Biology,** The London School of Hygiene and Tropical Medicine (Assistant Secretary, The Society of Chemical Industry, 14 Belgrave Square, London SW1X 8PS).

April 8–9, **Stress in Animals on Experiment,** a Symposium organised by LASA and BLAVA, Guildford (Dr P. Eaton, Charing Cross Hospital Medical School, Fulham Palace Road, London W6 9HH).

June 7–9, **Chlorophyll-Proteins Reaction Centres and Photosynthetic Membranes,** Brookhaven (Deadline for Contributions, April 16) (Dr John M. Olson, Biology Department, Brookhaven National Laboratory, Upton, New York 11973).

June 23–25, **First International Symposium on HLA and Disease,** Paris (Deadline for Abstracts, April 28 to Professor J. Dausset, Centre Hayem, Hôpital St-Louis, 75475 Paris) (Congrès-Services, 1 rue Jules Lefèbvre, 75009 Paris, France).

July 19–22, **Fifth International Symposium on Medicinal Chemistry,** Paris (Congress secretariate: 49 rue St-Andre-des-Arts, 75006 Paris).

October 27, **Ultrasonic Spectroscopy,** London (Papers: Professor A. F. Brown, The City University, St John's Street, London EC1V 4PB; Information: The Meetings Officer, The Institute of Physics, 47 Belgrave Square, London SW1X 8QX).

Person to Person

Some members of the Department of Mathematics at Edinburgh University, believe that there is scope for improved co-operation between mathematicians and R and D workers in industry, and a group has been formed to identify and work on industrial problems. They wish to hear of suitable problems and to meet representatives of the firms concerned to discuss possible co-operation.

Any problem submitted would be discussed at first by the group as a whole to decide whether the requisite skills are available. The problem would then become the main concern of one or more members, with the active support of the rest of the group for discussions and workshops.

Enquiries to The Director, Centre for Industrial Consultancy and Liaison, University of Edinburgh, 14 George Square, Edinburgh EH8 9JZ, UK.

There will be no charge for this service. Send items (not more than 60 words) to Martin Goldman at the London office. The section will include exchanges of accommodation, personal announcements and scientific queries. We reserve the right to decline material submitted. No commercial transactions.

Is the dual-support system really immutable?

Is a time of no-growth one for holding the line and stabilising institutions against erosive forces, or is it one for shaking up the system, bringing in reforms and generally ensuring that if and when growth returns a new structure is there to take advantage of it? This is a frequent question, in one of its many guises, which was asked last week by Mr Gerry Fowler, Minister of State at the Department of Education and Science when addressing heads of university chemistry departments on future government policy for scientific research. And, as if to underline the no-growth theme, later in the week the government announced that although the universities' recurrent grant for day-to-day expenditure would rise 11% to £581 million in 1976–7, this figure would be a cash limit, not to be supplemented (as in the past) for additional academic salary rises.

Mr Fowler gave the impression that his department had a fairly open mind on some of the major policy issues, or at least that views were still welcome on such matters as the customer-contractor principle, the quinquennial system and the dual-support system for university research. He also resurrected the question that many universities have been studiously avoiding for a long time: how to recognise more effectively the university teacher who is not inclined to do research as his primary occupation.

In the past year the dual-support system—the concept that one organisation gives general grants to support universities and provide a 'well-found' base for another organisation to support specific research projects —has been given some fairly widespread support. A Commons select committee has positively been angling for criticism of the system but has found relatively little; such criticism as there has been has tended to be about alleged shabby treatment by one arm or the other rather than about the concept as such. So should we all settle back and let the system run on as it is?

There seem to be two defects which have not been adequately discussed yet. The first was raised by Mr Fowler himself—the university teacher. The dual-support system should offer every encouragement to the teacher who wishes only to take advantage of the well-found base and not to go after research council money. But somehow academics have got it into their heads that the badge of office is incomplete without a research grant. Second, although the system should be a support to the teacher, it can very easily be a shelter to the mediocre whose proposals to research council are regularly turned down. There has recently been much talk, not all of it malevolent, about eliminating mediocre people, departments or even universities. At present the machinery for so doing would be cumbersome in the extreme. One prop can be knocked out, but hardly both simultaneously. Would any modification of the present system of financial support provide a more challenging environment without making the rôle of the teacher even more insecure?

Don't despise the miracle

Mr John Fagan of Glasgow, suffering from a stomach cancer, was on the verge of death. The doctors had given him up, and fully expected him to die within a day or two. But his fellow-parishioners from the Roman Catholic church of The Blessed John Ogilvie were busy praying to John Ogilvie, who had been executed in 1615 for refusing to recognise the supremacy of King James I on spiritual matters. Mr Fagan survived. Nobody could find any physical cause for the dramatic turn-around in his health, and now the Roman Catholic Church has accepted the cure as miraculous and set John Ogilvie on the way to becoming a saint. At which you might expect us to sneer.

After all, there are plenty of cases where remission has occurred inexplicably; one-in-a-million chances do turn up once every million times. And what about all those cases, not given publicity by the church, where saints have been prayed to and have failed to deliver a cure? Surely in a world of scientific objectivity there can be no room for the miracle cure; the church is capitalising on rare and random phenomena.

This laboratory-bench view shows well the limited horizons that we may impose on ourselves. For we cannot yet cure cancer, least of all of the advanced sort that Mr Fagan was afflicted with, in spite of the hundreds of thousands of man-years devoted to scientific study of the subject; does that allow us to pass judgement on others who are also groping, but in entirely different territory? It does not.

It might if we were successful in curing cancer and if the church were actively dissuading its members from accepting medical treatment as a substitute for prayer to the saints. It might if the church were, as do many purveyors of quack cures, to claim a high success rate and to demand a large fee. Until then it were better that saints and scientists co-exist and be thankful for any small mercy, whether it be Mr Fagan's cure or a flash of insight accorded to some cancer researcher.

Frozen mineral waters

Allan Piper looks at the obstacles to exploitation of the vast and varied resources of Antarctica

ASSESSMENTS of the economic potential of Antarctica involve issues stretching far beyond the obvious questions of how much and what sort of wealth might be there for the taking. With conditions on the continent hostile and often unpredictable, the successful operation of man, machines and extraction plant is hampered by extremes of climatic behaviour. Huge costs are imposed by Antarctica's extreme distances from the major centres of the commercial world. From the tip of the Antarctic Peninsula the journey to Cape Town is over 4,000 miles, and distances to the principal ports of the Northern Hemisphere exceed 7,000 miles. Moreover, during the winter months much of the continent is inaccessible by sea.

But there are other problems too, problems of particular relevance to any future sessions of the Law of the Sea Conference. The legal position in Antarctica is far from certain because nobody has been able to decide to whom the continent should belong. Territorial sovereignty is, and always has been, very much an open question, and the political jealousies run very deep. It is easy to see why. The history of Antarctica is characterised by diplomatic confusion. Conflicting claims for its discovery have never been satisfactorily settled, and in any case none of them was supported with the conventional backing of permanent occupation until over 120 years after the continent first became known around 1820.

What is certain is that a drive to satisfy commercial demands lay behind the eventual discovery of Antarctica, probably by the sealers who by the 1820s had penetrated southern waters as far as the South Shetland Islands bordering the Antarctic Peninsula; over the following century the whaling industry grew to become Antarctica's principal resource in the wake of brutal over-exploitation of the native fur seals and elephant seals. By 1959, when the Antarctic Treaty was signed, annual whale catches had risen to over 40,000.

Throughout the expansion of the whaling industry, however, commercial interest in Antarctica moved steadily back into second place as the continent became increasingly prized for its prestige value and potential strategic advantages. By the close of World War II national rivalries were running high. Seven countries—Argentina, Australia, Britain, Chile, France, Japan, and Norway—had asserted territorial claims and backed them up with permanent bases.

With 80% of Antarctica neatly divided into pie-slices the geographical borders became more satisfactorily defined than the diplomatic boundaries. Along with the seven existing claimants both the USA and the Soviet Union had established presences on the continent, but neither recognised other territorial claims and neither asserted any. Tensions between Argentina, Britain and Chile, whose claims partially overlap, had stretched to breaking point.

Taken in this context, the signing of the Antarctic Treaty in 1959 must be seen as a major diplomatic achievement. Belgium, New Zealand and South Africa joined the other nine states in agreeing to maintain Antarctica free of military presence, and to hold all territorial claims in abeyance, so that just as no new claim can be asserted, so none is recognised and none challenged.

It would be too charitable to suggest that none of the signatories had half an eye to the commercial potential of Antarctica when the treaty was signed, but nonetheless mineral exploration and exploitation rights are not mentioned—the feeling seemed to be that such a recognisably thorny issue could await the still-distant technological developments that would bring Antarctic exploitation closer to the realms of probability. Even seven years later most realistic prognoses tended towards the pessimistic: ". . . the exploitation of significant deposits", said a leading Australian expert, "presents enormous difficulties. It is very doubtful if minerals could be mined economically in the Antarctic, at least in the foreseeable future."

Plausible though they may have been at the time, such assessments reckoned without the economic downturn of the early 1970s, and when the signatories met in Oslo last June for the Eighth Consultative Meeting under the treaty, Antarctic resources and the likely effects of mineral exploration held centre-stage. The talks were predictably inconclusive, with a standstill agreed pending a full investigation of the environmental hazards; but the expression of environmental concern, though laudable, offers only the thinnest of disguises for the political rationale behind the delay. Exploration surveys, under the guise of scientific research, are well within the bounds of the treaty, but relationships stand to be irreparably undermined if exploitable resources are uncovered and raise again the intractable issue of sovereignty.

Antarctica's resources

The main resources are fossil fuels. Pre-continental drift reconstructions of the former Gondwana continent indicate that most of the Antarctic continental shelf includes thick sedimentary sequences likely to contain fuel reserves. The research vessel Glomar Challenger has already found evidence of natural gas beneath the Ross Sea, and an American estimate has put reserves in the eastern shelf at around 115 million million cubic feet of natural gas and 45 thousand million barrels of oil —almost ten times the estimated combined oil reserves of the Brent, Ninian and Forties fields of the North Sea. The chances of uncovering significant deposits have become so good that at the close of the Oslo talks one American delegate was moved to ponder openly the political effect of a rich strike beneath the zone disputed by Argentina, Britain and Chile.

Evidently the Soviet Union finds the notion equally as intriguing, for less than three weeks later it announced plans to open a new survey base on the Filchner Ice Shelf at the southern end of the Weddell Sea, an area within the disputed territory. Though in itself not a contravention of the treaty, the development is significant because the Soviet Union has never previously shown any interest whatsoever in that part of Antarctica. The Soviet targets are clearly fossil fuels and metallic ores, and it does not require an unduly cynical appraisal to conclude that the main objective of the move is to force an early definition of mineral exploitation rights. "The eastern part of the region", the official statement said, "has many common features with South Africa, the south is reminiscent of the ore-bearing zones of Siberia, while the west is a continuation of the American mountains, famous for their deposits of non-ferrous minerals."

The statement in no way overstates the possibilities, and even though prospecting techniques will be hampered by the enormous overlay of ice, the chances of small Soviet successes must be rated as reasonable. The sedimentary accumulation beneath the Weddel Sea, like those beneath the Ross and Bellingshausen seas, includes up to 15,000 feet of potentially productive strata. The once-contiguous continental shelves off South Africa and South America are already known to contain small fossil fuel reserves.

Opportunities for the discovery of coal reserves and mineral deposits are equally as good on the main landmass. The extensive coal deposits which crop out throughout eastern Antarctica, particularly in the Horlick, Prince Charles and Pensacola Mountains, and in Victoria Land and the George V Coast, suggest that reserves within Permian sandstones may extend at depth beneath the entire continent. As for metallic and non-metallic minerals, over 200 species have been recorded from localities throughout the continent over the past 75 years. Chromium, cobalt, copper, diamond, manganese, mercury, molybdenum, platinum and uranium are all present, and trace quantities of silver and gold, in amounts of up to 2 and 10 parts per million respectively, have been found in pyrite-rich rocks on the Antarctic Peninsula.

But even after the recent adjustments of world commodity prices, has the exploitation of Antarctic resources become an economic possibility? The answer for the moment must be no. Extracting fossil fuels is hazardous enough in the North Sea, where tens of lives are lost to the industry annually, and where unpredictable climatic behaviour has already pushed production costs way above the earliest estimates. Conditions in Antarctic waters are considerably worse. The depth of water overlying the Antarctic shelves is more than double the average 700 feet in the North Sea, and the insurmountable obstructions of floating pack ice and icebergs scouring the sea floor mean that even such technological innovations as flexible drilling apparatus are unlikely to prove feasible.

Just as daunting and commercially restrictive are the handicaps on the continent itself. Most deposits are isolated, away from the coast, and cut off by glaciers. Coal beds are in the majority of cases limited in their horizontal extent, and mineral finds are usually reported from glacial morraines, so that original outcrops are unknown. Moreover, quality and tenor are generally poor. As for the other minerals, not even high-value metals such as silver, uranium and gold will become viable failing unlikely upward shifts in world prices. The costs of USA gold production would need approximately to double before Antarctic deposits became economic.

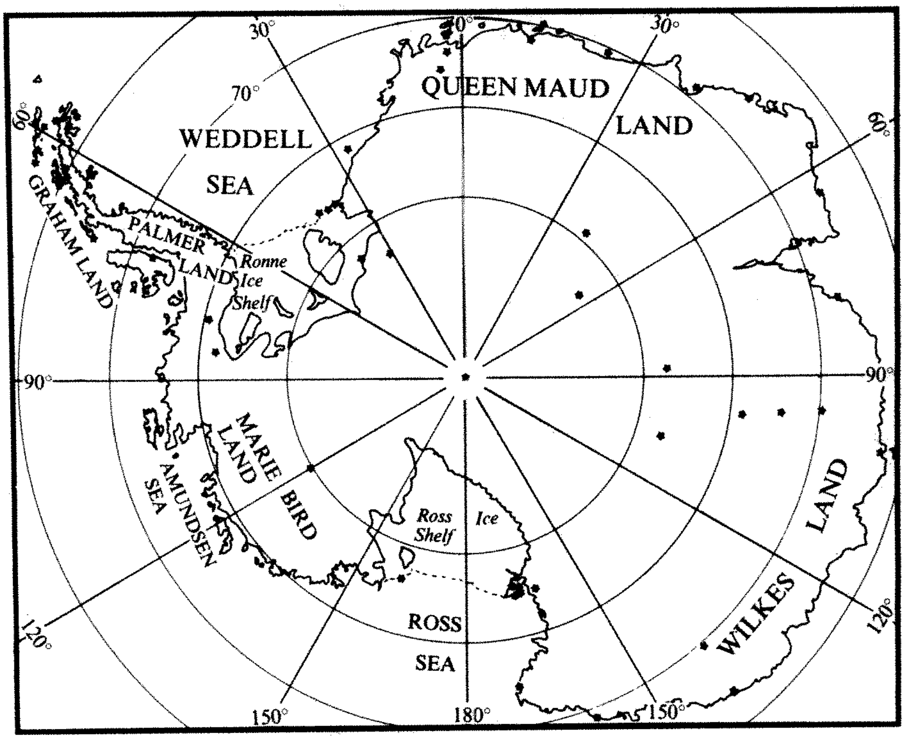
Exceptions

But any thorough assessment of the opportunities must take into account two possible exceptions to this general perspective. The first involves the manganese nodules lining the ocean floor between the continental shelf and the outer boundary of Antarctic territory at the relatively temperate latitude of 60°S. Manganese nodules are present throughout the world, and with the development of suitable extraction technology are likely to prove an extremely rich resource.

Just as promising is the economic potential of the igneous Dufek Massif in the northern Pensacola Mountains. So far, only viable deposits of iron-bearing magnetite ores have been found, but the complex so closely resembles the richly productive Bushveld intrusion of southern Africa that the prospects have to be viewed in a sanguine light. Further, there is no reason why the Dufek Massif need be unique in Antarctica.

In the final analysis, however, it is the biological resources of Antarctica which currently offer the greatest prospects for this future. Seals are now adequately protected under the Antarctic Treaty, and the whaling industry, which has declined from its level of 15 years ago, will probably continue to do so under the likely build-up of adverse world pressure. Even so, Antarctic waters are stocked with a superabundance of krill, *Euphausia superba*, the small shrimp-like creature forming the staple diet of the whales that visit the region to gorge themselves each year. One estimate has suggested that factory ships could economically take an annual minimum of 270 million tons—an amount far in excess of present yearly world fish catches—without upsetting natural balances.

As for the question of mineral exploitation, this will be discussed when the signatories to the Antarctic Treaty gather in London this summer for a preparatory session ahead of their Ninth Consultative Meeting in Paris next year. □



Antarctica, showing scientific stations in operation 1954–1975

An erosion of eminence?

Colin Norman reports from Washington on a document that examines the strengths and weaknesses in American science

AMERICAN pre-eminence in most areas of science and technology is gradually being eroded, largely because inflation has been eating into funds for research and development in the United States and many other countries have been ploughing large resources into their own science programmes for the past few years. That conclusion emerges from a detailed statistical portrait of American science from 1960 to 1974, published last month by the National Science Board, a committee of eminent scientists which directs the policies of the National Science Foundation.

A cautiously worded document which studiously avoids drawing many conclusions, it attempts to pinpoint strengths and weaknesses in American science and to analyse long-term trends. It covers a vast range of data, including funding levels for research and development, employment statistics, rates of innovation, output of scientific literature and the average number of citations per research paper.

Taken on its own, any one of those indicators probably doesn't mean very much, but together they seem to show a consistent trend—the quality and quantity of American science in relation to that of other countries appears to be headed downwards. The trend, in fact, is so consistent that early drafts of the report are said to have played an important role in securing a large increase for science and technology in the budget announced by President Ford last January. That budget would increase support for research and development by about 11%, while total federal expenditures would only grow by about 5.5%.

Shrinking funds

The clearest and most striking trend brought out in the report is that government funds for research and development have been shrinking steadily in terms of purchasing power since 1968. Support for basic research dwindled by 13% between 1968 and 1974, while expenditures per scientist dropped by a staggering 30% over the same period.

In an attempt to analyse trends in the United States in relation to those in other countries, the report brings out the fact that only two countries—the United States and France—have shown a long-term decline in the proportion of gross national product spent on science and technology, and the United States is alone in showing a steady decline in the number of scientists and engineers employed in research and development.

Though there have been some significant changes in the pattern of government support for research and development, the report shows that the United States devotes a larger share of its research budget to defence (about 50%) than other countries do. Over the past seven years, however, the share devoted to space science and technology has dwindled, while that devoted to other areas of science has increased.

It is difficult to measure the effect of shrinking support on the overall quality and productivity of American science, but several indicators suggest that the cuts are beginning to show some impact. One measure suggests that the proportion of research papers in several fields of science produced by Americans has reached a plateau; in some cases it has declined. The fields chosen are chemistry, physics, engineering, psychology, molecular biology, systematic biology, and mathematics; in all except chemistry and mathematics, the US still produces the largest share of the world's literature, however.

UK ranks high

As for the quality of research, the report indicates that in every field, research papers produced in the United States are cited on average more often than those produced elsewhere. According to that criterion, papers produced in the United Kingdom rank second in the fields of clinical medicine, biology, and earth and space science, while the UK ranks third in chemistry, physics and engineering. The report does not attempt to analyse whether there are any long-term changes in ranking.

As for technological invention and innovation, some indicators again suggest that American pre-eminence is being eroded by gains in other countries. One measure, the so-called 'patent balance', which relates the number of patents granted to nationals with those granted to foreigners in each country, has been dropping steadily in the United States since 1966. Over the period 1966 to 1973, the number of foreign patents granted in the United states increased by 65%, reaching 30% of the total granted in 1973. That, the report notes, "suggests that the number of patentable ideas of international merit has been growing at a greater rate in other countries than the United States".

Another striking example of that trend shows up in an analysis of rates of innovation. According to a study of some 500 innovations in various areas of science and technology, the US was producing about 80% of the world's innovations in the mid 1950s. By the mid-1960s, the US share had shrunk to about 50%, and although there has been a slight increase since, it has been caused more by a decline in the UK's share than by an improvement in the US position. (The share of technological innovations produced in Britain declined from 25% in 1965 to about 15% in 1973.)

The only indicator which seems to buck the trend of declining US leadership in science and technology is a measure of the balance of trade in high technology products. From 1960 to 1970, the US balance of payments in such products climbed steadily from about $6,000 million to about $12,000 million, but between 1972 and 1974, it suddenly jumped to $25,000 million a year.

Basic research affected

The area most severely affected by declining support in the United States is basic research. In terms of constant dollars, federal support for such research shrunk by some 13% between 1968 and 1974. Physical sciences were the hardest hit, declining by 25%, chiefly because of reductions in the space programme. Those declines have had considerable impact in the universities.

The report notes, for example, that the universities went through a period of rapid expansion until the early 1970s, with faculty numbers in science departments increasing by more than 60% between 1965 and 1972. But, because of declining funds for research, the academic job market has become relatively depressed recently. The result is that the proportion of faculty with tenure has increased from 47 to 65%, and the proportion of young doctoral faculty in postgraduate science and engineering departments declined from 42% in 1968 to 28% in 1974. The median age of faculty members consequently increased from 41 to 44.

Many of the trends and conclusions brought out in the report are hedged with caveats and cautions. The National Science Board hopes to refine some of the measures, and produce an updated report in a couple of years time, however. ☐

BRITAIN

Changing nuclear fortunes

News last week transformed uncertainty surrounding the reprocessing of nuclear fuel in Britain into certainty. For the Dragon reactor, the reverse seemed to occur. Allan Piper and Roger Woodham report

AFTER several months' delay British Nuclear Fuels Ltd (BNFL) has obtained Government approval for plans to import and reprocess 6,000 tonnes of foreign nuclear fuel. The go-ahead clears the way for an early settlement of the contract for BNFL to handle up to 4,000 tonnes of material from Japan's new generation of light water reactors at its Windscale plant in Cumbria. But further delays are expected following French moves to capture part of the deal, which is worth as much as £600 millions over the decade following 1979.

Mr Con Allday, BNFL's managing director, has indicated that the head of the French reprocessing organisation Compagnie Generale des Matieres Nucleaires (CGMN) may accompany him to Japan later this month. The French intervention, made possible by their involvement in a tripartite reprocessing alliance with Britain and West Germany, could mean the loss to BNFL of up to half of the Japanese contract.

Final settlement of the Japanese deal, which has aroused some controversy in the UK, has been delayed by a Government investigation into the issue. Granting Government approval last week, the Energy Secretary, Mr Anthony Wedgwood Benn, said that the Government had "given full consideration to the safety and environmental implications of accepting more work of this kind, taking account particularly of the views which have been expressed in the recent extensive public discussion of the question".

It is now clear that all waste, whether reprocessed or not, will eventually return to Japan, and that the deal does not contravene the Non-Proliferation Treaty. In further contracts clients must accept a break clause freeing BNFL if residual waste cannot be treated for safe return in a glassified form.

BNFL have already expressed confidence that successful completion of the Japanese negotiations will bring in other orders, and Iran, Italy, Spain, Sweden and West Germany have been unofficially mentioned in this connection. To meet projections for oxide reprocessing by 1990 BNFL plan to invest £900 millions in two new reprocessing plants at Windscale.

Meanwhile, the moribund Dragon High Temperature Reactor Project continues to attract attention. Whatever the politicians in Brussels may decide about a data retrieval programme to get the most out of the Dragon project, a sum of about £700,000 has already been committed by other interested parties to this end. The German nuclear research centre, KFA Jülich, has chipped in £480,000 to make sure that all the information it needs for its work on high temperature reactors is wrung out of the project, and even the European Commission and the United States Energy Research and Development Administration (which eventually declined at the end of last year to help keep the project afloat) are contributing to a brief continuation of the programme concerning the effects of helium in the primary cooling circuit on the metals used there. This work is likely to continue to the end of the year and involves carrying on existing Dragon contracts with the Norwegian research centre CIIR and the Fiat company in Turin.

Apart from the £130,000 which it is making available for this venture, KFA Jülich is also providing £350,000 towards a seemly winding-up of the work at Dragon on fuel elements, in which it has a particular interest. This will involve what remains of the Dragon staff in post-irradiation experiments on the test fuel, some of which is still in the reactor.

The German research centre does, however, stand to recoup that £350,000 if a more comprehensive plan put up by the European Commission survives the Brussels obstacle course. The commission is suggesting a data retrieval programme costing £1.16 million, of which it would pick up the tab for 90%—the assumption being that some of the smaller countries that have participated in Dragon would stump up the remainder, and that the UK Atomic Energy Authority would contribute nothing.

The indications are, however, that the polarisation of political views in the Council of Ministers is such that even this—an expenditure of some 2% of the total amount of money spent on Dragon since its inception in 1959 to see the project decently buried—is by no means certain to be acceptable. And, in addition, some of the smaller countries associated with the project have simply given up in disgust. ☐

AUSTRALIA

Probing the conservative mind

Peter Pockley reports from Sydney on the latest developments affecting Australia's scientific community three months into the new administration

SHELTERED from the blaze of publicity surrounding the activities of the Federal politicians as they jockeyed for position before the opening of the new parliament, Australian scientists have been working behind the scenes to protect their interests. During January and February, the Prime Minister, Mr Malcolm Fraser, was busy putting the axe into a number of Labor-initiated inquiries, commissions and authorities. As the Canberra grapevine identified the descending blades, all manner of interested groups hurriedly sought ways of protecting their areas of interest and influence. Some lost their heads in the scramble, partly for want of comprehending the conservative mind now in power. The leaders of the scientific community, though, were by then well versed in political techniques, and their burst of frenetic activity had considerable, possibly long-lasting, effect.

ASTEC survives—just

In the eyes of the scientific lobbyists, the principal institution to defend was the fledgling Interim Australian Science and Technology Council (ASTEC), which was under very real threat of abolition or absorption within the public service structure. To the

Chairing ASTEC review: Dr Louis Matheson surprise of some, for as Prime Minister he was largely an unknown quantity, Mr Fraser proved accessible to the principal lobbyists, and he demonstrated a close, personal interest in science matters.

In the few months of its existence under Labor, ASTEC had begun to work well, but this could only be perceived on an internal basis. It had not had time to show results in the form of well-considered reports and advice to government. The dozen members had defined the major policy targets to examine in depth, and they set about doing so through a series of "Task Forces", each comprising members of ASTEC and co-opted outside experts.

Task Forces on Energy, Health Science, Social Science, Marine Science and Public Understanding of Science were established as going concerns by the time Mr Whitlam's government was defeated at the polls in December. Further Task Forces on Industrial Research and National Science Budget were formed but had not met. Some criticism had been levelled at ASTEC for allowing itself to take on too much in the way of tactical detail. Some of this detail was no fault of the members, though, since quick advice was sought on occasions by the then Labor Minister for Science and Consumer Affairs, Mr Clyde Cameron.

A broader strategic approach was favoured by these critics, but it is likely that this would have evolved naturally anyway. The existence of the criticism, however, assisted the anti-ASTEC arguments of the Department of Science following the election. Butterflies fluttered in the bellies of those scientists who saw in ASTEC their best, and only, hope for policy advice which is independent of the large government establishments dominating the Australian science scene.

At the end of January, Mr Fraser published his list of cuts and abbreviations in the inquiry industry. Although many of the cuts were largely cosmetic, they carried the useful public relations impression of a tough hand at the helm of economic management by first curtailing public expenditure. It was nonetheless important that ASTEC did not appear on the list. For those involved, a further fortnight of anxiety followed, caused by the continuing uncertainties of learning to deal with a new political regime. Then, Mr Fraser personally announced the formation of an Advisory Group to advise him—significantly him—"on the role of a continuing Science and Technology Council, its terms of reference and all other matters concerning its operation."

Dr Louis Matheson, the part-time Chairman appointed by Labor to ASTEC with expectation of full-time status, is chairing the review, again in a part-time capacity. Three of the four other members are "heavies" of the Academy of Science; the numbers are made up by a retired industrialist.

The very existence of the review, now working actively, and the nature of its membership point to a recommendation for the continuance of ASTEC, but whether, in the context of a public service-oriented government, the Labor ideal of statutory independence can be sustained is more doubtful.

Labor disarray

The traumatic period of adjustment to the status of an Opposition is still eating into the heart of the Labor Party, and it is not surprising that they have been silent on science policy matters. They seem to have been too busy tearing each other apart (notably trying to downgrade their re-elected leader, Mr Gough Whitlam) to probe the government's uncertainties on science policy. The Labor shadow cabinet is an elected body from the caucus of members of both Houses. Mr. Whitlam was saddled with some shadow ministers whom he would rather not have seen again, such as Mr Rex Connor, whom he had sacked as Minister for Minerals and Energy when in government, and Mr Clyde Cameron, whom he had demoted to the portfolio of Science and Consumer Affairs.

Mr Whitlam's one area of choice were the "portfolios" allocated to his front bench. Mr Connor became spokesman for science. So far, the shadow has not materialised into substance. □

COMECON

THE Interkosmos programme for joint Comecon research in space has just celebrated its tenth anniversary. The intention behind the programme was to carry out research into four major fields—space physics, meteorology, communications and space biology and medicine. According to its chairman, Academician B. N. Petrov, it was envisaged as a cooperative effort by all Comecon countries, whose scientists "jointly drew up a catalogue" of the most interesting problems in space research. The Soviet Union has, of course, always been responsible for providing the rockets and launch facilities to place the Interkosmos probes in orbit, and theoretically all the member countries should provide instrumentation. In fact, the Soviet participants provide the major share; out of five experiments in the recent Interkosmos-14, three were of Soviet provenance, one came from Czechoslovakia and one from Bulgaria. This imbalance is despite the fact that some member states are competent to provide experiments—Poland, Czechoslovakia, Rumania and Hungary were represented, as well as France and the USA, in the experiments carried by the biological satellite Kosmos-782.

● Aid to Mongolia from the developed members of Comecon was an issue discussed when the Comecon Committee on Scientific and Technical Cooperation met at Budapest in January. Mongolia joined Comecon in 1962, and is now seen as a potential source of mineral wealth: teams from the Soviet Union, Hungary, the GDR, Poland and Czechoslovakia have carried out exhaustive geological surveys during recent years, making important finds of coal, copper, tin, gold, phosphorites and kaolin; prospecting is also going forward for tungsten, fluorite and zinc. Over the last three years, the Standing Commission of Comecon has been working out an integrated economic plan for the development of these resources. In addition to assisting with these surveying projects, the European members of Comecon will, during the coming Five Year Plan, assist the development of Mongolian science and technology in a number of ways, including the establishment of laboratories for genetics, radio-electronics, and the analysis of fuels and lubricants.

● Cooperation in the agricultural sciences between the USSR and the other member countries is an important aspect of Comecon policy, and a recent agreement between Hungary and the Soviet Union envisages joint research into the procurement, storage and processing of cereals and the production of mixed fodder. Agricultural experts in the two countries, says the Soviet Minister of Procurement, are working on a number of identical problems. But one particular problem of Hungarian agriculture—the sugar beet harvest—seems to have arisen directly as a result of copying Soviet models.

Hungarian agriculture has embarked on an extensive programme of "chemicisation", and, according to Budapest radio, while the 1975 campaign to raise sugar beet production increased both the area under beet and the crop-density, the sugar yield of the beet was actually lower than the pre-campaign level.

Vera Rich

IN BRIEF

EEC at sea

Member states of the EEC, which is currently preparing itself for 200-mile community fishing limits, went to the fourth session of the Law of the Sea Conference this week still facing a problem over national limits. Responding to the resistance expressed to the idea of a 12-mile limit by James Callaghan, the UK Foreign Secretary, at the Foreign Ministers meeting a fortnight ago, the EEC Agriculture Commissioner, M Pierre Lardinois, said last week that any extension of exclusive national limits beyond 12 miles would require a reversal of the Treaty of Accession, and indicated that catch quotas might offer a means of achieving the desired end. Delegates from over 150 countries are in New York for the Law of the Sea Conference, and apart from the problem of coastal states' jurisidiction, they are expected to tackle the issue of exclusive economic zones, particularly in relation to fishing and deep-sea mining.

ABRC confirms cutbacks

Figures contained in appendices to the second report (published this week) of the UK Advisory Board for the Research Councils (ABRC), which advises the Minister of Education and Science on the allocation of the science budget amongst the research councils, confirms the downward trend indicated by the recent public expenditure White Paper. The distribution of the £216 million science budget for 1976-77 shows that, while overall growth in real terms will amount to 1.7%, the Science Research Council (SRC) will experience a 1.6% decline. The SRC's share of the total will fall from 54.2% now to about 52% in 1980–81. The proportion going to "big science" will fall even faster, from 34% to 27%.

Asbestos check

The UK Health and Safety Executive is reportedly investigating compliance with and enforcement of the precautions contained in the 1969 Asbestos Regulations. The immediate cause of concern is a suspected link between mesothelioma (a malignant tumour in the stomach or chest) and exposure to asbestos.

Kissinger on nuclear trade

Speaking before a Senate committee last week, the US Secretary of State, Dr Henry Kissinger, stated his opposition to specific proposals designed to tighten control of international trade in nuclear technology, and rejected suggestions that the USA and USSR should jointly urge countries like France and West Germany not to export nuclear facilities. The proposals, Dr Kissinger said, would violate the spirit of international undertakings by the US.

Uranium resources report

A report on uranium resources produced by the OECD's Nuclear Energy Agency (NEA) and the International Atomic Energy Agency (IAEA) estimates that demand for natural uranium will increase from the present 18,000 tonnes a year to about 50,000 tonnes by 1980 and possibly 100,000 tonnes by 1985. Demand up to the next decade, the report indicates, could be met, but thereafter much will also depend on recycling and prevailing prices as well as new discoveries.

Ravished goddess

THOMAS H. JUKES

ONE place in California exceeds all the rest in scenery and fame: Yosemite Valley, a national and international shrine of acclaimed splendour. Two Congressional subcommittees have just recommended that the US Interior Department take immediate action to prevent Yosemite from becoming "a major Walt Disney-type attraction". Hopefully, the analogy bodes ill for an actual plan by Disney to destroy another mountain treasure: Mineral King in the southern Sierra Nevada, where restaurants, chair-lifts and garages have been proposed.

I have not seen the report, but I know some of the circumstances leading to it such as the egregious and repulsive proposal that a tramway be built on Glacier Point. This wretched idea was turned down, but the very suggestion should have been enough to call for immediate expulsion of its proponent, the Music Corporation of America (MCA), from the concessions now assigned to MCA in Yosemite.

The Valley has been described in the prose of John Muir and the poetic photography of Ansel Adams. I can do no more than footnote their achievements. Yosemite, the goddess of fatal beauty, in spring is the deep roar of stupendous waterfalls, profusions of azaleas and dogwood blossoms, soaring sculptures in immense granite cliffs, the fragrance of ponderosa pine trees mingled with new foliage of black oaks and green leaves of manzanita, the harsh call of dark-crested Steller jays.

A rock-climber, Yvon Chouinard, has spoken of, in summer

> "the tremendous heat, the dirt-filled cracks, . . . the filth and noise of Camp 4 (the climbers' campground), and, worst of all, the multitudes of tourists . . . but then there are times when I should rather be here than anywhere else in the world . . . It is a strange, passionate love that I feel for this Valley"

Clinging to the sun-warmed rock, high above the valley floor, a climber sees Yosemite better than anyone else. The sounds below fade to a faint murmur.

Golf courses, tennis courts, a bank, service stations and garages, barber and beauty shops, and nineteen places where liquor can be purchased, have invaded the delicate tissues of Yosemite like a festering sore. The best therapy would be debridement. All buildings could be removed by using the equipment and machinery that work so successfully for this purpose in run-down urban areas. It would, of course, defeat the basis of the restoration if visitors were kept out of the Valley, but the less agile could travel in sight-seeing buses (many do so now) and the more able-bodied could move on bicycles or on foot, thus combining the benefits of scenery and exercise. (Last October, I gave a lecture on nutrition in an auditorium in Yosemite. I should have asked the audience, in the name of John Muir to leave the building, forget the meeting, and walk with me to Vernal Falls).

These changes, which are doubtless too radical to be considered, would disrupt jobs and sensibilities. But their adoption would do nothing but good to Yosemite Valley. ●

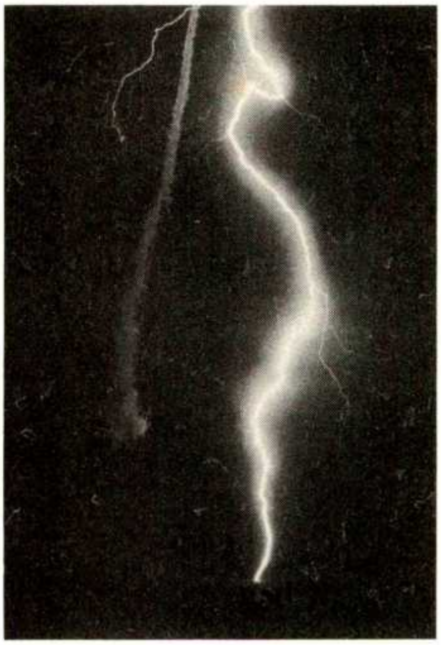
Triggered lightning hazards

SIR,—Following the publication of our paper entitled "Artificially triggered lightning above land" (*Nature*, **257**, 212; 1975) we hear that several specialists elsewhere are thinking of embarking on similar programmes. Therefore, safety considerations prompt us to discuss some recent findings about unexpected lightning strokes to the ground in the vicinity of such experiments.

Among a total of 45 successful triggerings using a rocket carrying a thin steel wire attached to the ground, the following sequence of events occurred on six occasions. First, when the ascending rocket was more than 150 m high, the device attracted a small current detected only because the vaporised wire emitted a faint glow. This glow passed through a maximum and then began to decrease. Between 40 and 80 milliseconds later, a bright flash occurred striking the ground or an object in the near neighbourhood. The maximum distance between the expected and actual point at which the lightning struck has been as much as 145 m.

Evidence obtained at various distances with still and movie cameras reveals that in the upper region the arrangement of the luminous branches is typical of upward development, whereas in the lower part the streamer shapes indicate downward propagation. Therefore it is likely that the main channel is created by propagation in both directions, starting from the upper portion of the wire.

The photograph is of an anomalously triggered flash striking the ground near our experimental site. Another flash which struck a pine grove damaged several trees and in the next twelve months these and adjacent ones died.



The anomalous triggering effect is of great interest but calls for more stringent safety measures in the experimental area. A detailed report is available on request.

Yours faithfully,

R. FIEUX

CPSU Congress

SIR—A notable feature of the recent Twenty-Fifth Congress of the Soviet Communist Party is the adherence of the hard-core communists to Karl Marx's principle of the scientific interpretation of history.

Mr Pytor Masherov, party chief of the Byelorussian Republic, in an attack on some Western communists, said: "To say Marxism-Leninism has become antiquated is like saying that Newton's 300-year-old law of gravity is antiquated too".

Mr Gus Hall, the US Communist Party Chief, went a step further. He said: "The ideas of Marxism-Leninism penetrate the whole contents of Leonid Brezhnev's speech like the bright ray of a powerful laser".

Perhaps in the following congress we shall hear of quasars, black-holes, big bangs, etc. As a scientific community we should feel elated!

Yours faithfully,

SREEDHAN ROY

Department of Mechanical Engineering,
University College,
London, UK

The pace of life

SIR,—Bornstein and Bornstein's paper (February 19, page 557) leads to fascinating conclusions. Their data suggest that in the case of the smallest human conurbation (one person) the average walking speed is 0.05 feet s^{-1} (50 m h^{-1} or 1.3 km d^{-1}). Fortunately this quantity is not negative. On the other hand, its value is small and a value of zero is probably compatible with the experimental data. This may be the explanation of the fact that those few people who are known to live alone show a propensity for spending extended periods of time on the tops of poles, in caves or in barrels.

Yours faithfully,

J. A. EADES

H. H. Wills Physics Laboratory,
Bristol University,

Competition 6

LITTLE jingles are being put in advertisements by the British Metrication Board to speed the public's passage into a metrical world. Specimen—

Two and a quarter pounds of jam,
Weigh about a kilogram.

A prize of £10 is offered for the best rhyming couplet on one of those forgettable SI units. Closing date for entries is April 21.

Competition 5 demanded an anagram on a scientific concept to rival the irreverent one on *Nessiteras rhombopteryx*. There was a large entry—most people couldn't stop when they got into the swing of things.

To W. A. F. Watson of Aberdeen goes £6 for "Fie, Mendel! Result cheating, score *all* peas!" (These DNA molecules are self replicating).

H. J. Taylor of Sheffield wins £4 for "Natural Science men musn't interpolate inapt ideas" (Entia non sunt multiplicanda praeter necessitatem).

C. K. Thornhill of Orpington received honorable mention for "O, so in fact G not t-variant?" (Constant of gravitation). Hard luck on several good candidates whose anagrams weren't.

news and views

First mammalian results with genetic recombinants

from Bob Williamson

BREAKTHROUGHS in science occur in weird and wonderful ways. The scenarios for genetic engineering (forming recombinant molecules of bacterial virus DNA and animal or plant DNA) vary, as most now know, through the entire gamut of the fanciful—from joy to horror, depending more upon the mood of the speaker and the receptiveness of the audience than on anything as mundane as fact. During the past 2 months four reports have appeared of the first integration of portions of a mammalian gene into a bacterial plasmid—as might be expected, a portion of the gene coding for the protein haemoglobin. In the event, the recombinants obtained well illustrate the tremendous technical usefulness of genetic engineering, with little of the fiction one way or the other. For the next few years at least, recombinants will provide molecular biologists with a versatile tool to prepare pure probes with which to dissect the fine structures of genes and the way they are expressed. The experiments which will be done have been attempted before, but the probes will now be better.

Basically, all four groups have made a double-strand copy in DNA of purified globin messenger RNA prepared from rabbit reticulocytes. Since the mRNA is already very pure (as judged by direct sequence analysis, among other things) there is little chance of introducing any Pandora's box of nasties into the plasmid—the experiment must be judged one of the safest imaginable, much safer than any planned integration of DNA fractions made from mammalian cell nuclei.

In each case the first step is to make a single-strand copy of the globin mRNA with DNA-dependent RNA polymerase, the 'reverse transcriptase' isolated from tumour viruses. Rougeon, Kourilsky and Mach (*Nucleic Acids Res.*, **2**, 2365; 1975) from Geneva and Paris, prepared this in the conventional way, and then made the complementary DNA strand using DNA polymerase, giving a double-strand DNA indistinguishable from part of the globin gene. (Since cDNA is rarely a full length copy of mRNA, it is likely that the double strand globin gene DNA is only partial as well, though full data on this is not yet available.) This 'gene' was then elongated with another enzyme, terminal transferase, which adds homopolymer tails, in this case of oligo(dG), to the 3′-ends of both strands of DNA.

A plasmid, pCRI, was then joined to the partial copy of the double-strand globin gene. pCRI is derived from colEI-kan, which can be selected because of the resistance to the antibiotic kanamycin it confers on infected cells. It grows in that favourite organism of bacterial geneticists, *Escherichia coli*. The plasmid used is, like all plasmids, circular, but can be broken in just one specific place by the bacterial restriction nuclease *Eco*R1. This linear plasmid DNA was first repaired with reverse transcriptase to reconstruct the double strands at the overlapping cuts of the *Eco*R1 enzyme, and then oligo(dC) was added to both 3′-ends (again with terminal transferase).

The plasmid DNA, with its oligo(dC) tails, was mixed with the globin gene, with its oligo(dG) tails—strong hydrogen bonds form between oligo(dC) and oligo(dG). The globin gene with tails 'fills in' the rest of the nicked circle—only plasmids picking up globin genes are circular, and only a circular plasmid is infective. Therefore only recombinants which have picked up the added globin genes will grow and multiply in the bacteria. When it enters an *E. coli* cell the plasmid is held together only by hydrogen bonds, but the bacterium does the rest, and repairs the plasmid by filling in any gaps and forming covalent closed circles. The elegance of Rougeon's experimental approach is that the inserted fragment can in theory be cut out again using restriction enzymes, since each R1-sensitive site has been carefully reconstructed on either side of the inserted gene.

The results are not quite so simple—the efficiency of transformation is still rather low, and most recombinants do not contain inserted fragments—but at least one of the plasmids isolated contains a portion of the rabbit β-globin gene, as shown by hybridisation to globin cDNA (single stranded, this time) enriched in β-globin sequences. The grapevine (extraordinarily efficient in this field—I find it hard to imagine anyone getting a positive result without everyone else knowing within days at most) tells us that an α-globin gene recombinant has also been prepared by this group.

Tom Maniatis and his colleagues at Cold Spring Harbor and Harvard (Efstratiadis Kafatos, Maxam and Maniatis, *Cell*, February, 1976) have chosen a somewhat simpler technique to make full-length double-strand cDNA once again using rabbit globin mRNA as the starting material. Single-strand cDNA is first prepared with reverse transcriptase, and this acts as a template for a second strand made with DNA polymerase, even in the absence of added primer. The double-strand cDNA was shown to be a single polynucleotide chain, looped round at the end, the primer being part of the original single-strand cDNA. The loop can be cut with single-strand specific S1-nuclease and each of the strands elongated with terminal transferase. Plasmid recombinants containing both α- and β-globin gene sequences were obtained. Full experimental details of the recombination and transformation are not given and will follow in a later paper, but it is likely that a poly(dA)–poly(dT) hybrid was used to link the cleaved plasmid and the globin gene fragment. Higuchi, Paddock and Salser, of the University of California, Los Angeles, have independently carried out similar experiments linking rabbit globin double-strand cDNA to plasmid pSC101 by poly(dA)–poly(dT) tails and have obtained at least 28 recombinants. They have been able to demonstrate in some cases that the inserted DNA truly codes for the globin sequence by the presence in this sequence of a specific R1 restriction endonuclease site shown to be present by this group's previous RNA sequence analysis.

Several British laboratories have also been interested in this technique, and the first person to report a positive result is Terry Rabbitts, of the MRC Molecular Biology Laboratory at Cambridge (this issue of *Nature*, page 221). He has used a different and elegant trick to integrate the gene. First, a related *E. coli* plasmid (mini-ColEI) was cut with restriction enzyme to give a linear molecule as before, and then oligo(dT) added directly to the cut ends. Rabbit globin mRNA binds to this oligo(dT) by its poly(A) tail, and the cDNA was synthesised with reverse transcriptase directly onto the plasmid. Poly(dT) tails were again added, this time to the globin cDNA. The mini-ColEIs containing globin cDNA were melted and reannealed with plasmids containing no globin cDNA but with a poly(dA) tail. Circles form between elongated cDNA-containing plasmids (containing poly(dT)) and strands from those with poly(dA) and when these infect *E. coli*, once again the bacterium repairs them, seals them up and the plasmids replicate normally.

Maniatis, Rabbitts and Salser all finish with a piece of rabbit globin gene bound covalently to plasmid by two oligo(dA)–oligo(dT) stretches, which cannot be cut by an available enzyme as neatly and easily as Rougeon's R1-sites. dA–dT hybrids are less stable than normal DNA double strands, and when the temperature goes up or the salt concentration goes down, they melt first, and form little single-strand bubbles while both inserted globin gene and original bacterial plasmid remain annealed. Therefore they can be broken by nucleases (such as S1) that attack single-stranded DNA preferentially. While not as elegant as Rougeon's technique for removing the inserted DNA, this should prove quite as effective.

One worry of bacterial geneticists has been stability of these recombinants —will they keep growing in culture, or will the inserted gene be eliminated? The two sequences (whether oligo(dA)–oligo(dT), or R1 sites) at either side of the insert could provide an active cross-over site for recombination with elimination of the mammalian DNA. Since the newly made recombinant grows more slowly than the original plasmid, any revertants would outgrow the carefully made hybrid plasmids. Fortunately, this does not seem to happen at a very fast rate, since the hybrids are stable for several months at least.

Ironically, only one of the four labs reporting so far is particularly interested in globin genes—several groups have already shown that α-globin or β-globin-specific cDNA can be prepared using other techniques, albeit rather tediously. Salser and his colleagues, however, should find the new technique very useful in their attempts to sequence globin mRNA. Both Rougeon and Rabbitts have been hoping to purify sequences complementary to mouse immunoglobulin mRNAs; Maniatis' colleagues hope to study the appearance of a complex series of mRNAs during insect development. The problem for all these groups in extending this technique is the purity of their mRNAs. In the case of immunoglobulin, it has proved very difficult to get mRNA greater than about 60% pure; the insect mRNAs are an even more complex mixture. Using genetic recombinants, scientists could now clone pure populations of double-strand cDNAs derived from each mRNA separately. Separating α- and β-globin genes represents a simple model system to this end. The fact that this has proved so simple will be very encouraging to people studying more complex systems.

The recent National Institutes of Health guidelines (outlined in part in *Nature*, **258**, 561; 1975) suggested that the containment facilities used should be mentioned by groups publishing in this field, to act as a guide to others. It is appropriate that one of these papers includes such a discussion—particularly as the guidelines are only just available. No doubt the full reports from the other groups, when published, will follow suit. The fact that the recommended safe procedures are followed for completely non-hazardous experiments should help to ensure that they are followed in the more delicate experiments which will no doubt be reported soon.

One last point—at the 'big' Asilomar meeting a year ago, several of us suggested that anyone obtaining a recombinant such as those discussed here should make it available to other laboratories as soon as the data on it have been published. This is because the major 'danger'—in this case virtually nil, but in future cases perhaps more substantial—arises during the first recombination and isolation of the plasmid containing the foreign genes, when the DNA integrated is not yet fully characterised. The power of these techniques is such that many others will be tempted to follow on immediately, perhaps with less experience and poorer facilities. I only hope that Rougeon, Rabbitts, Maniatis, Salser and their co-workers and followers will make their recombinants freely available. In this field, the way we start will determine whether others will act responsibly later. ☐

Great step forward for multiple sclerosis research

from Cedric Mims

RESEARCH into multiple sclerosis (MS) has been in a somewhat rejuvenated, exciting state ever since the discovery 10 years ago that two uncommon diseases of the central nervous system of man, subacute sclerosing panencephalitis and progressive multifocal leucoencephalopathy were both caused by viruses (measles and a new human papovavirus). At about the same time two other rare neurological diseases, Kuru and Creutzfeld–Jacob disease were found to be infectious in origin, and transmissible to subhuman primates. The causative agents in this case were unique virus-sized microorganisms, very similar to scrapie, and the incubation period was exceedingly long, occupying a large fraction of a life time. Earlier epidemiological studies had pointed to a possible infectious origin for MS, and these findings stimulated a serious hunt for a virus.

For some years a favourite candidate for the MS virus has been measles, but the evidence has been indirect, based on the high titres of antibody to measles found in the blood and cerebrospinal fluid of patients with MS. But not all patients have raised antibodies to measles, and antibodies to viruses such as mumps and rubella may also be elevated (Norrby *et al.*, *Infect. Immun*, **10**, 688; 1974). The association of MS with certain histocompatibility types (HLA 3 and 7) has prompted various virological suggestions. Perhaps the histocompatibility antigens on the cell surface act as virus receptors and thus promote susceptibility to MS, or perhaps certain immune response genes linked to these histocompatibility genes determine the immune response to a virus responsible for MS. A recent modest sized survey from Canada, however (Lamoureux *et al.*, *Brit. med. J.*, Jan 24, 183; 1976) indicates that patients with MS have unusual antibody responses to a variety of different antigens, antibody levels to certain viruses and to tetanus and diphtheria being lower than normal.

There have been a number of false alarms, virologically speaking, and when Dick Carp and his colleagues from the Institute for Research in Mental Retardation, Staten Island, New York, reported on a transmissible factor present in the brains and serum of MS patients (*J. exp. Med.*, **136**, 618; 1972), this was greeted with some scepticism, especially because the transmissible factor could only be demonstrated by its ability to decrease the number of circulating polymorphonuclear leukocytes in the blood of infected mice. The agent was titrated, and MS brains were found to have about 10^{12} infectious units per gram; it passed 50 but not 25 nm filters, and was serially transmissible in mice. Although it replicated after injection into mice there were no other signs of infection. But the test for a fall in circulating polymorphs was very difficult to standardise. These cells are notoriously variable in number, often difficult to identify in mouse blood films, and other laboratories were unable to confirm the findings. Carp then found that the same transmissible agent when added to a line of cultured mouse fibroblasts, caused a slowing of the rate of cell division, and this effect could be titrated out and the agent serially passaged through the cultures (*Infect. Immun.*, **9**, 1011; 1974). He later extended these findings, and described reduced cell yields of cultures after inoculation with various MS tissues, including brain, spleen, serum and cerebrospinal fluid (Carp *et al.*, *Neurology*, **25**, 492; 1975). As if to further strain our credulity his laboratory had reported that brains from mice infected with scrapie also caused a lowering of circulating polymorphs in mice (*Infect. Immun.*, **6**, 370; 1972). Titres were high and by diluting out his inocula, he was able to separate the polymorph lowering agent from scrapie itself (*J. infect. Dis.*, **128**, 256; 1973). The polymorph lowering effect was confirmed with scrapie from a variety of sources in a publication from Dickinson's laboratory in Edinburgh (*Nature*, **248**, 510; 1974). So far there have been no reports of reduced cell yields in tissue cultures inoculated with the scrapie-associated agent.

The status of all this work was raised dramatically by the recent publication of two papers from the Henles' laboratory in Philadelphia (Koldovsky *et al.*, *Infect. Immun.*, **12**, 1355; 1975; Henle *et al.*, *ibid*, **12**, 1367; 1975). They too found that the brains and serum from MS patients contain an agent that depresses the polymorph counts of mice. The effect was seen not only in all strains of mice tested, but also in rats, hamsters and guinea pigs. Titres were up to 10^9 infectious doses per gram in MS brain, and up to 10^3 in MS serum. The multiple sclerosis-associated agent (MSAA) was transmissible from animal to animal and passed through 50 nm but not 25 nm millipore filters. Perhaps the most important and convincing addition to Carp's work was the demonstration that nearly all MS sera and cerebrospinal fluids contained antibodies that neutralised the polymorph lowering effect. Many of the MS patients' relatives and nursing personnel also had serum antibodies, whereas only 1 of 59 sera from people without MS contacts had antibodies. Interestingly, 37 of 68 sera from East Africa were positive.

The evidence, therefore, is for a new microorganism infecting man, somewhere between poliomyelitis and polyoma virus in size, of unknown structure and nucleic acid, and strikingly associated with multiple sclerosis. Although the agent is present in large amounts in MS brains, and should be 25 to 50 nm in diameter, it has so far not been seen in the electron microscope. The long and mostly fruitless searches for virus-like bodies in MS brains make it seem unlikely that it will turn out to be a regularly sized or shaped object.

The stage is now set for intensive investigation of this new microorganism. It is especially to be hoped that there will be confirmation of Carp's report that the agent replicates and causes detectable changes in cultured cells. Strictly speaking the MSAA could turn out to be merely associated with some as yet undiscovered agent more directly responsible for MS, in much the same way that the other polymorph-lowering agent (possibly related to the MSAA) could be separated from scrapie. In recent years scrapie and MS have seemed to have been drifting away from each other, but there is much in these recent findings to suggest a closer association. Perhaps the MSAA is also membrane-associated as suggested by the susceptibility of both MSAA and scrapie to periodate. If both of these agents are mere membrane fragments or vesicles and of nondescript structure, then the failure so far to demonstrate either by electron microscopy is more understandable. One important difference, however, is that scrapie gives no sign of inducing the faintest flicker of an immune response in the infected host, whereas specific antibodies seem to be formed to the MSAA. If we accept the work on the scrapie-associated agent, scrapie becomes much more relevant for MS, reminding us that medical virologists neglect the field of veterinary virology at their peril.

Even if multiple sclerosis is an infectious disease, it is still vital to study the "soil" (host) as well as the "seed" (virus). Biochemical, cell culture, immunological and other investigations have been of great importance in MS research and they can now be oriented towards the associated microorganism. There is evidence for a strong immunological component in the disease process, and sophisticated immunological techniques can be brought to bear on this matter now that antigens of a specific microorganism seem to be available.

A hardened investigator might well at this stage still have some doubts and reservations about all this work, but it has given a fresh transfusion of life and hope to MS research. Evidently the new agent poses formidable technical problems, but it will nevertheless be further investigated and characterised, while serological studies should help to provide us with some understanding of its epidemiological behaviour. Finally if the agent proves to be causative rather than merely associated with MS, a vaccine could perhaps be produced to prevent infection and thus prevent the disease. □

Transferring nitrogen fixation genes

from J. E. Beringer

DURING the past few years considerable interest has centred on *in vitro* methods of joining together fragments of DNA from different sources, and the advantages and disadvantages of what is now called 'genetic engineering' have been the subject of much debate. This debate has tended to obscure the fact that some plasmids, such as the *Escherichia coli* sex factor F, have long been known to be able to pick up chromosomal DNA *in vivo* forming F′ factors. It is timely, therefore, that two papers in this issue of *Nature* (pages 268, 271) should remind us of the type of genetic manipulation that can be done *in vivo* and also show that such techniques are not only academically interesting, but have a real use—in this case to facilitate genetic studies of nitrogen-fixation genes. These papers by Dixon, Cannon and Kondorosi, and Cannon and Postgate describe first the transfer of *Klebsiella pneumoniae* nitrogen-fixation (Nif) genes from an F′, which has a very limited host range, to the plasmid RP4, which has a very wide host range, and then report on the transfer and functioning of these genes in such diverse bacteria as *K. pneumoniae*, *Rhizobium meliloti* and *Azotobacter vinelandii.*

Two particularly interesting points arise from these reports. The first concerns the transfer of this plasmid to *A. vinelandii.* Cannon and Postgate were able to show that the *Klebsiella* Nif genes it carries could overcome mutations in *A. vinelandii* that have resulted in the loss of either component I or component II activity of the enzyme nitrogenase. Whether functional hybrid nitrogenases were formed in *A. vinelandii* remains to be demonstrated. If this is indeed the case, and it also applies for other Gram-negative nitrogen fixers, then genetic studies of the *Klebsiella* Nif genes will not only provide a model for studies of nitrogen-fixation genes, but may also enable one to produce a range of plasmids carrying mutations in known Nif genes that can be used for complementation studies of these genes in other bacteria. Furthermore, studies of the transfer and expression of the *Klebsiella* Nif genes in a range of nitrogen-fixing and non-fixing bacteria should help to answer some of the simplest questions that can be asked about the feasibility of performing wide intergeneric transfers of nitrogen-fixation genes. In this respect the observation that transfer to *Pseudomonas aeruginosa* did not occur is slightly discouraging, since RP4 (the parent plasmid) was isolated in this organism and a derivative of it carrying the *E. coli* histidine operon produced by Olsen and Gonzalez (*Biochem. biophys. Res. Commun.*, **59**, 377; 1974) is both transmissible to, and stable in, *P. aeruginosa* The other point concerns the formation of the RP4-Nif plasmid. This was made in *E. coli* as the result of recombination between an F′ Nif previously produced by Cannon, Dixon and Postgate (*J. gen Microbiol.*, in the press) and the R factor RP4. In the present report Dixon, Cannon and Kondorosi suggest that this recombination occurred as a result of an interaction between identical translocating sequences carried on both plasmids These sequences, corresponding to the carbenicillin resistance determinant on RP4 (TnA) and the same resistance determinant on the F′, are capable of translocating on to a wide range of plasmids (Hedges and Jacob, *Molec. gen Genet*, **132**, 31; 1974). If the authors' suggestion that these translocating sequences can indeed facilitate recombination between plasmids that carry them, then they may well have demonstrated a general procedure for producing recombinant plasmids *in vivo*.

These studies would not have been possible without the availability of a group of R factors having the apparently unique property of being transferable to a very wide range of bacteria The R factors, which all belong to the incompatibility group P (Datta *et al.*, *J. Bact.*, **108**, 1244; 1971), first appeared in the late 1960s in isolates of *Pseudomonas aeruginosa* found to be highly resistant to carbenicillin, a particularly efficient semi-synthetic penicillin for use in pseudomonas infections. Studies of these pseudomonads soon showed that in many of the isolates resistance to carbenicillin was plasmid borne (that is, R-factor mediated) and linked to determinants for resistance to tetracycline and kanamycin. Although at the time a number of plasmids were known in *Pseudomonas*, R factor mediated drug resistance in these exceptionally antibiotic-resistant bacteria had not been reported. The most unusual property of these R factors, however, was their ability to transfer from *P. aeruginosa* to *E. coli* (Sykes and Richmond, *Nature*, **226**, 952; 1970). Although the publications that have followed this original observation suggest that all Gram-negative bacteria can act as recipients, as yet no report of transfer by conjugation or transformation to a

Membrane nearest neighbours

from Howard Goldfine and Alan F. Horwitz

ALTHOUGH the series of twelve papers describing the total synthesis of the structural gene for a tRNA precursor in the February 10th issue of the *Journal of Biological Chemistry* is undoubtedly the more impressive achievement, two other papers from the laboratory of H. Gobind Khorana may be of even greater interest to those concerned with membrane structure and function. These papers describe the synthesis of various photosensitive fatty acids and phospholipids and provide evidence that these compounds can be incorporated into natural biological membranes. These new analogues should prove useful as membrane probes to study previously inaccessible interactions between lipid and protein in the membrane.

Chakrabarti and Khorana (*Biochemistry*, **14**, 5021–5033; 1975) describe the relatively easy four-step synthesis of azidostearic acids from commercially available hydroxystearate isomers By standard synthetic methods they have put these and other photosensitive fatty acids on the middle carbon of the glycerophosphate backbones of phosphatidylcholine and phosphatidylethanolamine, both with palmitate esterified at the C-1 position. When the phospholipids were dispersed in an aqueous medium as sonicated vesicles and irradiated at 253 nm for 1 hour, extensive photolysis and cross linking occurred.

Greenberg, Chakrabarti and Khorana (*Proc natn. Acad Sci. U.S.A.*, **73**, 86–90; 1976) now report that an unsaturated fatty acid requiring mutant of *Escherichia coli* utilises the series of azidostearic acids with the azido group at various positions along the hydrocarbon chain. Most of these compounds were capable of supporting growth to the extent observed with the common unsaturated fatty acid, oleic acid. 12-Azido-oleic acid, a 16-azido *trans*-hexadecenoic acid, and two fatty acids with a bulkier 4-azido-2-nitrophenoxy group were also active, but the azidonitrophenoxy group on oleic acid did not permit growth at or above 25 °C. These studies show that the azido fatty acids are incorporated into cellular phospholipids to the extent usually observed with *cis*-monounsaturated fatty acids. Furthermore, they were incorporated largely at the middle carbon of the glycerophosphate backbone as is usually the case with unsaturated fatty acids. Since the photosensitive fatty acids behave like unsaturated fatty acids, the MIT group looks forward to being able to study the interactions of lipids with functional membrane proteins.

When irradiated the azido groups form highly reactive intermediates, which attach covalently to nearest neighbours. This cross linking should provide information on the amino acid residues in close apposition to phospholipids, and since the photosensitive group can be placed near either the carboxyl or methyl terminus of the fatty acid chains, it should be possible to determine the depth of penetration of proteins into the bilayer and to map the exposed amino acid residues as well.

Reconstitution of membrane proteins with specific photosensitive phospholipids provides an alternative means of determining such spatial relationships. The polar head group of the lipids is another potential site for lipid–protein interaction, and two affinity labels have already been synthesised by Chakrabarti and Khorana, in which a polar photoactivable group replaces ethanolamine.

Extension of their work with an *E. coli* mutant to a similar mutant of a *Pseudomonas* species is already in progress, and they visualise future work with *Neurospora* and yeast mutants and even with mammalian cells grown in fatty acid deficient media. Although not specifically mentioned, questions of lipid–lipid "nearest neighbours" and membrane lipid asymmetry can also be approached with these compounds in either natural membranes or artificial systems. One caution, however, is noted. The azido group absorbs weakly in the ultraviolet and there is obvious overlap with nucleic acid and protein absorption The use of radioactively tagged azido fatty acids may permit shorter irradiation times but other more photoreactive groups are being sought.

Gram-positive bacterium has appeared. Whether this represents a true difference in the ability of either group of bacteria to allow the replication and maintenance of plasmids from the other group, or simply that conjugation cannot occur and transformation has just not been reported, remains to be elucidated.

Future research using P-group plasmids carrying Nif or other genes looks promising, both for studies of gene function in different environments and for the genetic analysis of Gram-negative bacteria. However, problems of instability and the reduction in the host range of such plasmids, as reported by Dixon, Cannon and Kondorosi, will need to be overcome. Also it has yet to be demonstrated that the type of recombination event involved in the formation of the RP4-Nif plasmid will provide a general method for making R′ factors in the future. ☐

PETRA : come and help

from David J. Miller

PLANNING the future of European high-energy physics is not a very cheerful exercise just now, but there is one major ground for optimism, despite the budget squeezes which seem to be happening all round. The Germans have announced that they will go ahead rapidly with the construction of their electron–positron colliding-beam accelerator—PETRA. This machine, which should begin operations before its American equivalent, called PEP, is very similar to the EPIC project which Britain recently decided to abandon. It gives European physicists a chance to play a leading part in understanding the "new physics" which has emerged with the discovery of weak neutral currents and of the J/psi family of particles.

In deciding to build PETRA, Germany has shouldered a very heavy financial burden and it has been made clear that she cannot, by herself, afford to provide the large detection systems which such a machine will need. International collaborations are therefore being encouraged to bring equipment, expertise and manpower to join in the experimental programme. As a first houseparty to introduce possible collaborators to one another, the European Committee on Future Accelerators (ECFA) sponsored a meeting during the first week of March at the Frascati laboratory near Rome. It was attended by physicists from universities and laboratories throughout Europe, the United States and Japan. Theoretical predictions were reviewed, confirming the enormous range of worthwhile physics available to the machine; experimental techniques were considered, and the basic parameters of PETRA were presented. The meeting became more political during the later part of the week when people put forward specific ideas for experimental equipment, and possible collaborators began discreetly to have lunch together. Professor Schopper, head of the laboratory where PETRA will be built, warned of the three essential steps in setting up a "marriage" between collaborating groups. First it is necessary to recognise the beauty of the prospective partner—how good are their ideas? This is usually clear on brief aquaintance, but the second question is more delicate—do they have money, or rather, do their parents (their governments) have money? Finally, one has to judge whether the collaborating groups are likely to be compatible throughout three or four years of hectic collaboration, with many crises to be survived.

A large proportion of the first sketches of apparatus for PETRA looked almost identical. The classic general purpose detector has a superconducting solenoid magnet with diameter and length between $1\frac{1}{2}$ and 6 metres. It is filled inside with drift chambers to reconstruct charged-particle tracks coming from $e^+ e^-$ collisions, and it is surrounded by electron, photon and muon detectors. Other schemes were also suggested which laid greater stress on detecting electrons and photons in particular, or on muons, or on recognising the exact identity of strongly interacting particles. The British contingent, representing half-a-dozen universities and the Science Research Council laboratories, presented a general purpose solenoid detector which had been costed more carefully than many of the other systems discussed. The estimated price is about £2 million, and it is unlikely that all of this could be found from Britain alone since it would consume too large a fraction of the total national funds available for experiments at CERN and during the last years of NIMROD. In fact, none of the nations represented at the meeting seemed keen to pay for the whole of such a device by itself.

Courtships begun at Frascati must progress quickly. In order to have equipment ready for the first 15 GeV PETRA experiments in 1979 it will be necessary to start building the apparatus in the autumn of this year at the latest. The machine will eventually be able to accommodate six separate detectors, each enclosing a collision point of the two beams, but only two collision points are to be available at first so there will be strenuous competition to win one of these places. The British group, backed by the expertise of the Rutherford Laboratory in superconducting magnets, seemed to be among the more popular debutantes at Frascati. If the SRC is able to provide a respectable dowry, commensurate with expenditure on individual CERN experiments, then there is a good chance that a match can be made with one or more of the strong European groups, and that Britain will take part in $e^+ e^-$ physics in 1979 despite the loss of EPIC.

The strong, weak and electromagnetic interactions are so fundamental to all modern science and technology that we often behave as if we understood them, merely because we can use them. But major changes in our understanding are now taking place, and no-one doubts that results from both CERN and PETRA will be important in consolidating these ideas. European collaborations have played a major part in the first wave of the "new physics". Even in a time of economic troubles it would seem foolish for any government to allow its physicists to lose touch with this frontier of knowledge. ☐

New view of the cell cycle

from Robert Shields

THE period between successive cell mitoses is conventionally divided into four phases—G_1, the period between mitosis and the onset of DNA synthesis, S the period of DNA synthesis, G_2 the time between completion of DNA synthesis and the beginning of mitosis itself. Measurements of these phases show that whereas G_2, M and S are of relatively constant duration G_1 can attain widely different values depending on the conditions. Even within cell populations G_1 is usually highly variable in duration and the distribution of intermitotic times (times between successive mitoses) is invariably skewed towards longer time intervals. The conventional explanation for this skewness has been that it is some kind of reflection of heterogeneity in the cell population, but the reason why G_1 is much more variable than the rest of the cycle has never been adequately explained.

A new concept of the cell cycle has recently been proposed which not only predicts that cell cycle times must be heterogeneous but accounts quantitatively for their observed frequency distributions (Smith and Martin, *Proc. natn. Acad. Sci. U.S.A.*, **70**, 1263; 1973). The model divides the cell cycle into two parts. One termed the B phase is regarded as a deterministic and highly coordinated process; it corresponds to the conventional S, G_2, M and part of G_1 phase. The other part (contained within G_1) is called the A state and is a sort of limbo in which the cell is not progressing towards mitosis; the cell may remain in this state for any length of time subject to the condition that under steady state conditions the probability per unit time (termed transition probability) of the cells leaving the A state and entering the B phase is a constant. In other words, cells leave the A state exponentially with respect to the time they have spent in that state in much the same way as a radioactive material will decay at a rate determined by its half life. In a population of cells the shortest intermitotic time is then given by the cell that leaves the A state immediately it enters, intermitotic times greater than this minimum should be exponentially distributed. The theory can account satisfactorily for the distribution of intermitotic times in a wide variety of cell types from bacteria to animal cells. What is more remarkable is that the theory predicts that the difference in intermitotic times of sibling cells should also be exponentially distributed (Minor and Smith. *Nature*, **248**, 241; 1974). This is observed in practice.

In principle the transition probability can take any value, high values would mean that most of the cells spend very short times in the A state, have fairly short homogeneous intermitotic times and so grow relatively rapidly. Low values would mean that the G_1 period would in the main be long or equivalent to so-called G_0 periods postulated for slowly or non-proliferating cells. Viewed in this way the problem of changing growth rate reduces to one of changing transition probability.

The paper by Brooks in this issue of *Nature* (page 248) examines the relevance of transition probability to mitogenic stimulation by serum of so-called G_0 cells. Since the characteristics of this type of stimulation are shared by systems as diverse as lectin-stimulated lymphocytes and liver regeneration after partial hepatectomy, the experiments may be relevant to other systems as well. When serum is re-added to serum-starved fibroblasts there is a characteristic lag (which is independent of serum concentration) before any increase in DNA synthesis is seen. After this lag cells begin making DNA asynchronously. In a previous publication (*J. cell. Physiol.*, **86**, 369; 1975) Brooks showed that the apparent asynchrony in DNA synthesis was a result of the cells entering S phase with first order kinetics (that is exponentially), the actual rate constant depending on the concentration of serum used. Initiation of DNA synthesis can then be regarded as a random event occurring with a transition probability determined by the serum concentration. What serum does is to change abruptly the transition probability from the low value seen in quiescent fibroblasts to a higher value and so cells will leave the A state and enter the B phase (and hence DNA synthesis) at a faster rate.

The important aspect of these results is the observation that suboptimal doses of mitogen do not commit a subfraction of the population to enter DNA synthesis at a fixed time but cause the entire cell population to enter S phase with slower first order kinetics. The concept that a fraction of cells is committed by suboptimal doses of mitogen can now be seen as erroneous because it fails to take into account the kinetics of entry into S phase. Furthermore, the new value of transition probability produced by the serum is constant. This shows that mitogens such as serum do not trigger a sequence of events leading to DNA synthesis, for if they did, with increasing time after stimulation it would be more and more likely that the putative sequence was completed and hence the probability of entering DNA synthesis would increase with time. This is not the case.

In the present publication Brooks approaches the problem of the lag before any marked increase in DNA synthesis is seen. By following the kinetics of the entry into DNA synthesis after switching the serum concentrations from low to high values and *vice versa*, he comes to the conclusion that the lag after mitogenic stimulation represents the time required to effect any upward change in the transition probability regardless of its initial value and not the time taken to irreversibly commit all the cells to DNA synthesis.

It seems that the concept of there being a probabilistic transition within the cell cycle not only accounts for the heterogeneity of cell cycle times in a cell population, but positively predicts that such heterogeneity exists. Furthermore, the theory can account satisfactorily for the kinetics of entry of cells into DNA synthesis after mitogenic stimulation. The biochemical basis for the probabilistic transition remains obscure, however, but it is only through an appreciation of the dynamics of the cell cycle that its nature will be elucidated. ☐

Pop goes the weasel

from a Correspondent

MOST mammalian carnivores tend to be fairly choosy about what they eat when food is plentiful but rather less so when it is not. An ability to cope with a wide range of food species has a high survival value for weasels (*Mustela nivalis*) which depend on characteristically fluctuating rodent populations. Brown and Lasiewski (*Ecology*, **53**, 939; 1972) have drawn attention to the difference in size between males and females and to the energetic problems their shape causes. The long, thin body is costly to keep warm and to compensate, weasels have a metabolic rate between two and three times higher than that of other mustelids (Iverson, *J. cell. comp. Physiol.*, **81**, 341; 1972). Not only are they territorial, thus reducing intraspecific competition for food, but they quickly reduce their reproductive rate should food become scarce (Erlinge, *Oikos*, **25**, 308; 1974) and, additionally, demonstrate a special kind of prey switching behaviour (Erlinge, *Oikos*, **26**, 378; 1975).

In spruce woodland in southern Sweden, weasels feed on whatever prey is available. A slight seasonal change in diet is observed with fewer young rabbits taken during the winter when they are less abundant. Other changes broadly reflect fluctuations in the rodent populations. Erlinge's data indicate that during spring and summer, when rabbits are relatively abundant and rodents relatively scarce, male weasels, which weigh almost twice as much as females, switch their attention to rabbits, leaving more of the rodents available to the smaller females. Rabbits constitute 40% of the males' diet in spring, with *Microtus agrestis* accounting for 35%; at the same time of year the latter species constitutes 86% of the diet of female weasels and rabbits just 6%. Similarly, males prey quite heavily on the large vole *Arvicola terrestris* and leave the bank vole *Clethrionomys glareolus* for the females. During autumn when rodents are abundant such segregation does not occur. Although Erlinge has shown that weasel populations are sometimes limited by food shortage, prey switching presumably allows the persistence of higher overall numbers.

British weasels are larger than their Swedish cousins but still show a marked difference between the sexes. Their catholic approach towards food has been demonstrated most recently by Moors who observed their feeding habits on two farmland study areas in north east Scotland (*J. Zool., Lond.*, **177,** 455; 1975), and found a similar situation to that in Sweden. *Microtus agrestis* and rabbits were particularly favoured items. But there was one marked difference between the studies which is as interesting as it is difficult to interpret. *Clethrionomys glareolus*, highly favoured by the Swedish female weasels was almost totally shunned by Scottish weasels of both sexes, yet on one of the two study areas bank voles were actually more abundant than *Microtus agrestis*. The little work done on the diet of British weasels does suggest that nowhere is *Clethrionomys* a food species of major importance, although it is very abundant (Day, *J. Zool.*, **155,** 485; 1968, Walker, *J. Zool.*, **166,** 474; 1972). Are British habitats in general and Scottish farmland in particular that much more favourable to weasels than southern Swedish spruce forests in producing sufficient numbers of the favoured and, perhaps, the less abundant rodent species? If they do, the size differential which has been shown to facilitate prey switching behaviour in Sweden is of lesser survival value to British populations. It may, however, enhance survival in years when all species of rodent are in decline. Further studies on weasel feeding ecology will be of the greatest interest to population ecologists and evolutionary strategists alike. □

A hundred years ago

THE general staff of the German empire has published a report of experiments made in Germany on ballooning at the expense of the Imperial Government. The conclusions throw no new light on the subject, but the German officers believe that the mechanical direction of balloons is by no means an impossibility. They even suppose that the problem of ascending or descending without using ballast or the valve, is very likely to receive a speedy solution. They propose to the Government to determine by means of experiments what is the best diameter for the helix when it is applied to a balloon of a certain capacity. They propose also to try the efficacy of wings for propelling balloons. They are not of the common opinion that the diameter of balloons can be indefinitely enlarged.

Galactic gas dynamics

A meeting on Galactic Gas Dynamics was held by the Royal Astronomical Society in London on February 13, 1976.

from a Correspondent

THE principles of fluid dynamics can be applied with quite remarkable generality to problems in astrophysics. At the meeting astronomers learnt of the great versatility of gas dynamics in coping with the varied conditions in astrophysical plasmas. Within the basic theme of Galactic Gas Dynamics, we saw how ideas of fluid flow have been applied to plasmas with vastly different densities and scale sizes, from hot gas clouds occupying clusters of galaxies, to the problems of star formation.

Astrophysicists have long been intrigued by how such well-defined and apparently long lived spiral structures such as our own galaxy can exist without winding up in a disk of gas and stars that is rotating faster in its central regions than at the edge. The modern view is that these spiral patterns, or density waves, may persist as stars and gas move through them, and that a gravitational torque is developed, continually driving angular momentum outwards from the centre of the galaxy. According to V. Icke (Institute of Astronomy, Cambridge), gas has a particularly important role in the transport of this angular momentum. The more gas in a galaxy, the easier this transport becomes and a relatively open spiral results. He believes that this is the probable cause of the observed correlation between the proportion of gas in a galaxy and its classification in the famous Hubble Sequence of spiral galaxies.

T. Matsuda (University College, Cardiff) then spoke on the case of the peculiar 'barred' spirals, in which a rod-like structure or 'bar' is seen in the central regions. He considers that the complications introduced by this asymmetrical potential make the problem into a case for numerical techniques. The resulting computed flow patterns show that a suitably shaped bar can indeed set up a two-armed spiral flow, with shock fronts that agree well in position with regions of star formation seen in actual galaxies. What did not emerge from the calculations, however, was why such a bar should have formed in the first place.

The afternoon was devoted to smaller scale galactic phenomena, the formation of stars and HII regions and the interaction of supernovae with the interstellar medium. With the recent widespread use of numerical techniques, F. Goldsworthy (University of Leeds) sounded a cautionary note with regard to the treatment of ionisation fronts, the sharp boundaries between neutral and ionised hydrogen surrounding young, hot stars. Unlike the relatively simple shock fronts that occur in ordinary gas dynamics, an ionisation front can be of two species, each with two strengths, and one of these, the strong 'deflagration' front, is characterised by an inherent indeterminacy difficult to overcome in computer solutions. Goldsworthy reported on a noble attempt to exorcise this particular devil by means of a scheme that at least manages to avoid its invocation.

S. Falle (University of Manchester) made a similar point about the usual numerical method of treating shocks by including an artificial viscosity term. He showed that this method can be greatly in error if used to estimate the luminosity of the radiating shocks that occur in the late stages of supernovae. By using more accurate shock-fitting techniques, Falle has so far managed to distinguish five separate types of old supernova remnant. On the other hand, F. Kahn (University of Manchester) was prepared to use an analytical approximation in his treatment of this subject, and reported that very substantial amounts of hot gas must exist in a supernova remnant, even a million years after the supernova explosion. At this late stage remnants are likely to bump into, and coalesce with, their nearest neighbours in the Galactic plane. He calculates that about 30% of the Galactic gas is kept hot in this way.

As the meeting progressed it became clear that an impressive array of numerical techniques is now available to tackle these gas dynamical problems. During the day the results were shown from two massive computer codes using two spatial dimensions and no less than four one-dimensional programs appeared. But the talk by A. Nelson (University College, Cardiff), who was concerned with the small scale warping or corrugation of gas in the Galactic plane, served as an illustration of one of the cardinal rules of gas dynamics. Fluid flows, no matter how symmetrical they might appear, are inevitably three-dimensional, and it will still be some time before numerical methods can catch up in this tricky subject. □

Analysis of function

John R. Krebs

Function and Evolution in Behaviour. (Essays in Honour of Professor Niko Tinbergen, FRS.) Edited by Gerard Baerends, Colin Beer and Aubrey Manning. Pp. xxxi+393. (Clarendon: Oxford, Oxford University: London, February 1976.) £16.50 net.

IN his introduction to a volume of Tinbergen's collected works published a few years ago, Sir Peter Medawar recounted the story of an eminent neurophysiologist who said of ethology "Why, that's just bird-watching, isn't it?". The point of the story is, of course, that Niko Tinbergen has done more than any other single person to transform the biological study of behaviour from descriptive natural history into a hard experimental science. After emphasising description as a starting point, Tinbergen and his associates have succeeded in carrying out simple, but rigorous and incisive, experiments in the laboratory and field to elucidate problems ranging from why seagulls are white, to how digger wasps find their nests.

Five years ago, I think that most ethologists would have agreed that the most exciting developments in what might broadly count as ethology involved the meeting point of ethological and neurophysiological research—for example, in the mapping of neural pathways underlying simple behaviour patterns in molluscs. In the last year or two, however, things have changed, and there has been a dramatic upsurge of interest in the area in which Tinbergen made some of his most important contributions. We used to call it behavioural ecology, but now it is known as sociobiology. Sociobiology (as defined by the contents of E. O. Wilson's book) involves much more than the work of Tinbergen and his students, but the studies carried out by his group are without doubt among the best in elucidating how natural selection acts to mould the social organisation of a species. Work on the adaptive significance of colonial nesting in gulls, and on the social organisation of carnivores are examples which spring to mind as typifying the blend of ecology, behaviour and evolution which characterises much of the work of the Tinbergen group.

In the past, ethologists as a whole can be faulted for having been somewhat careless in thinking about how natural selection influences behaviour, and it is a pity to see the confusion continue in this volume dedicated to one who thinks so clearly about the problem. There seem to have been three types of difficulty in the literature dealing with the function or survival value of behaviour, all of which occur in this volume of essays. The first, and most widely appreciated, is the old Panglossian fallacy that natural selection favours adaptations that are good for the species as a whole, rather than acting at the level of the individual. This type of argument crops up in the article by Immelmann on early learning—he suggests that imprinting is advantageous because it enables a species to evolve rapidly—as well as in the article by Baerends in which he makes a similar case for the advantage of flexible motivational control displays. The second 'function' fallacy is discussed at length in articles by Hinde and Beer. It is partly a semantic issue arising from the oft-posed question "What is the function of such-and-such behaviour?", which is of course shorthand for asking why natural selection, the differential survival of genotypes, favours that particular behaviour. The problem with this question is, as Beer and Hinde point out, that most behaviour patterns (or structures) are likely to have several functions. Territorial behaviour may increase fitness because it preserves a food supply near the nest, it reduces the chance of predation and so on. The confusion arises when one tries to ask which function came first, an historical question which cannot be answered by 'survival value' experiments. Sometimes it is possible to deduce which function came first on logical grounds or on features of design. Thus one can conclude that any population-limiting effect of territorial behaviour is likely to be secondary; and the design of a reddish egret's (*Dichromanassa rufescens*) wing suggests it is primarily a locomotor organ, although it may be held outstretched in feeding, to cut down reflection from the water surface. The use of its wing in feeding, however, increases a reddish egret's chance of survival, so this has to be counted as one of the functions of wings. It is difficult to see how one can distinguish, as Hinde claims in his essay, between 'functions' and 'biologically advantageous consequences which change reproductive success'. It is clear that function is, to quote G. C. Williams, an "onerous concept", so perhaps the best solution would be to rephrase the question mentioned above as "How does such-and-such behaviour influence fitness?".

The third difficulty in the analysis of function is that ethologists often make the implicit assumption that behaviour is more responsive than are other features of an animal to the action of natural selection. To give an example, it is a widely accepted ethological fact that many courtship and threat displays in which the participants suddenly face away from each other, serve the function of cutting off stimulating visual input and so allow the animals to control their motivational state. Another familiar example is the 'Fraser–Darling Effect': the idea that colonial nesting and communal displays function to enhance gonad growth through mutual stimulation. Both of these arguments imply that natural selection is not very good at designing animals with efficient physiological systems, so that it has to call on behavioural adaptations to sort things out. This is not to say that the cut-off hypothesis is wrong, but without careful thought it is all too easy for the ethologist to dream up glib functional explanations for behaviour by assuming that other features of the animal are not subject to natural selection as well.

In addition to the two general discussions of function, to which I have already referred, the book contains several more specific studies of the effect of natural selection on behaviour. Of special note are the papers by Liley and Seghers who show how predation pressure influences morphology and behaviour in guppies, Kruuk on the relationship between social organisation and feeding habits in carnivores, and Patterson's attempt to disentangle the factors influencing fighting in rook flocks. Baerends reviews the literature on the motivational and evolutionary origin of displays, and the overall impression is that little progress has been made since Tinbergen wrote his major paper on this subject in 1959. Although it does not seem to have filtered through to the ethological community, I think it likely that the recent game theory analysis of ritualised conflicts, by Maynard Smith and Parker, will provide a starting point for totally new insights into the nature of courtship and threat displays.

Without listing the contents in detail, I think it is fair to say that, although there are good discussions of various areas of important progress in ethology as a whole, the book does not reflect the exciting new developments—for example, in the quantitative analysis of function—which have arisen specifically out of the lines of research initiated by Tinbergen himself. Perhaps by including contributions from some of Tinbergen's recent students and collaborators, the volume could have given a better impression how his particular inspiration is as much as ever at the very forefront of ethological research.

Description before analysis

Roger French

The Great Instauration: Science, Medicine and Reform, 1626–1660. By Charles Webster. Pp. xvi+630. (Duckworth: London, November 1975.) £13.50.

"THE history of science has predominantly assumed the character of an index of progress towards our present intellectual position". With these opening words, the author proceeds to justify an examination of science in seventeenth century England, and to criticise the growth of a rather whiggish internalism in historical accounts of the sciences. Now, one of the reasons for regarding history of science, and in particular, history of medicine, as an independent discipline, is because the evidence to which the historian first turns his attention is of the same nature as that presented to the figures he is studying—that is, textual evidence—whereas the historian-at-large is faced rather more often with written evidence of something that is not documentary, like a political action. The directness, continuity and the subject matter itself of the former lead naturally to a history-of-ideas approach, whereas the inferential nature of the latter directs the attention to the historical circumstances of the object of study. Those with an interest in the history of science know that the historian of ideas can sometimes neglect every other historical factor, and that on the other hand a circumstantial history can degenerate into the merest sociology. By and large, history of medicine at least is underworked. We should resist the temptation to frame hypotheses and find causes in history before we are done with the texts that furnish us with the historical evidence. Description should precede analysis.

Robert Boyle (1627–91), a seventeenth century English natural philosopher

Ronan Picture Library

The study of seventeenth century English science has many pitfalls of this kind. Although his book is 'history-at-large', Webster falls into none of them. He makes us aware that historical circumstances in the sense used above can be intellectual, and the plan of his book is to reveal the progress of the *idea* that man can restore himself to the state of knowledge of, and command over, nature that he possessed before the Fall. In working out this idea, attention was given to education, to agriculture, to public health, and above all to Reform. Webster examines in considerable detail the social, political and religious groupings of the exponents of these ideas in a way that adds another dimension to the more usual and more technical accounts of the Baconians and Harveians of the English seventeenth century. So consistently is this approach followed that it disarms the critic who might expect a technical exposition of Harvey's work in a book with this title. Webster also reminds us that description should precede analysis in not attempting too great a correlation between the results of the internal and external approaches. It would be nice to know why Culpeper felt that his reforming zeal could best be served by translating the traditional, rather scholastic and largely discredited *Ars Medica* of Galen. Indeed, Culpeper's whole notion of medicine was Galenic, as was that of the College of Physicians whose monopoly he attacked. It would also be nice to know more precisely the relationships between the professional institutions of the physicians on one hand and on the other the internal changes in Galenism that led to its retention as a doctrine, or to its collapse. Webster's exploration of the intellectual and social context of the 'most intrinsically interesting' scientific developments, the examination of 'the worldview of a particular society' is pursued without the distortion caused by the spectacles of modern science, but with a wealth of detail that will make the book invaluable to historians of all shades and the natural authority for those working in the period. • ☐

Riding roughshod over cancer research

John Cairns

The Biology of Cancer: A New Approach. By P. R. J. Burch. Pp. 452. (MTP Lancaster, January 1976.) £11.50, $23.23.

PROFESSOR BURCH has recently acquired a certain fame thanks to his much publicised assertion that cigarette smoking is not a cause of lung cancer. This is just one consequence of his theory that most diseases are largely determined by random events within us that owe nothing to external agents in our environment. He has now written a detailed account (one might call it a polemical tract) describing how he came to his present, unorthodox position.

The argument runs as follows: Over most of our lifespan the incidence of the common cancers rises roughly as the fifth power of age. This is usually explained by saying that cancer is the end result of several independent steps (mutations) whose frequency among the cells at risk accumulates linearly with time. On further scrutiny it turns out, however, that many other diseases—ranging from arteriosclerosis and osteoarthritis to certain forms of psychosis—show a similar relationship to age. As these diseases are clearly multifocal in origin, they can hardly be ascribed to a particular set of rare mutations having occurred in one of the cells at risk in artery, joint, brain, and so on. If we want to persist with multistep models for disease, we should therefore try to come up with some formulation that allows a set of mutations in one cell to be the cause of unifocal or multifocal changes among other cells. So let us postulate that the main tissues of the body are divided up into a large number of subsets containing a few hundred cells whose growth is controlled by a central system of cells divided into a similar number of subsets, and let us postulate that most diseases are due to defects in the central controlling cells; unifocal diseases like cancer are due to mutations that fall within a single subset of controlling cells; multifocal diseases like arteriosclerosis are due to mutations in the primordial stem cells which are the parents for many subsets of controlling cells. Burch goes on to suggest that the central controlling cells are lymphocytes, that the dialogue between central and peripheral systems is conducted by means of pairs of specifically interacting molecules, and that these molecules are coded for by genes which contain palindromic base sequences and therefore are apt to be read backwards as well as forwards.

Professor Burch. Photo: Leeds University

The theory owes an acknowledged debt to such notions as the control of growth by 'chalones', the recognition of self and not-self, the creation of 'forbidden clones' and the control of cancer by immune surveillance—ideas championed by many people, Burnet in particular, at one time or another. As formulated by Burch the theory provides a plethora of independent variables—the mutation rates for the particular genes involved, the number of genes that must be altered to inactivate an appropriate central controlling cell, the number of such cells that have to be affected, the proportion of people that are genetically susceptible, and so on. Because some of the functions that can be generated with the model do not increase steadily with time but go through a maximum, the theory can be made to take in even such things as the age distribution of a childhood disease like measles (for me, the clinching *reductio ad absurdum*). Further, as Burch modestly points out, "so far as I am aware, our theory is the only one that offers a general solution to the problem of the anatomical specificity of the lesions of natural disease".

Now, all this curve fitting would be just innocent fun, albeit of a rather old-fashioned kind, were it not that somehow the idea of chance events scattered randomly among central controlling elements has been taken to mean that the events cannot be due to external agents. I must say I do not understand the logic here; after all, one of the first collections of biological data shown to follow the Poisson distribution was the number of men killed by horses each year in the Prussian army, and there the external agent was plain for all to see, on the hoof as it were. Anyway, that is what Burch believes and so he sets out to show that the incidence of the common cancers is not perceptibly influenced by environment and therefore that nothing can be done to prevent cancer, or most other diseases if it comes to that. (I might sympathise with this attitude if he were an old scientist subconsciously wishing to make the virtues and rewards of science decline to zero coincidentally with his retirement, but Burch is hale and hearty as far as I know and has no reason to go round preaching a kind of molecular nihilism).

Obviously the theory rides roughshod over most forms of cancer research. For example, the connection between external agent and susceptible cell is too direct to be denied for the various experimental cancers in animals and for most industrial cancers, and so Burch is forced to say that these are exceptional and have no bearing on the common 'natural' cancers. As for the copious epidemiological evidence that the incidence of the common cancers changes with alterations in habits and environment, he argues for a combination of illusion and conspiracy—for example, Japanese migrants to the US show altered cancer rates because they have a genetic constitution that drives them to migrate to a country where coincidentally the population suffers the same spectrum of cancers as they themselves; similarly, the apparent steady decline in stomach cancer and rise in lung cancer over the past 50 years are artefacts due to changes in diagnostic fashions.

Now, I believe that all this is what might euphemistically be called wrong. Indeed, I think that even Burch will come round to that opinion. Were the biology of cancer a normal branch of science, his unorthodox beliefs might be stimulating and would add a certain piquancy to the lives of cancer research workers, like the pleasure one gets on meeting someone who really believes the earth is flat. Unfortunately the biology of cancer is not that kind of subject. This book will undoubtedly persuade many people to continue smoking who might otherwise have stopped, and may confuse those who legislate on the search for and control of carcinogens in our environment. Some of these people will, I am sure, have been persuaded not by actually reading the book and being swayed by the inexorable logic of his argument, but simply by the thought that when a professor writes a fat, obscurely mathematical tome on any subject whatsoever, there must be something in what he is saying. And that is why I wish this book had not been written. □

Genial corrective

A. R. Ubbelohde

The Royal Society and Its Dining Clubs. By T. E. Allibone. Pp. xv+457. (Pergamon: Oxford and New York, 1976.) £10.

EFFECTIVE pursuit of natural science demands much concentration. Dr Johnson once compared a course of chemistry in this respect with a course in walking the tight-rope, as a cure for Boswell's melancholy. Clearly, a Dining Club provides genial correctives for any excessive abstraction scientists may have to practice. This adds a distinctive relish to the long history of 'clubbable' Fellows of the Royal Society dining together. Dr Allibone's narrative is the present successor to earlier chronicles of the Royal Society's Dining Clubs. Two of these histories, by Sir Archibald Geikie and Dr Bonney only stretch down to 1901, so that Dr Allibone has had to grapple with some most memorable events in science as well as in world affairs. From his 'history' it is entertaining and fascinating to mark the uneven penetration of such events into the after-dinner discussions of the Club.

At the present time, the club numbers rather less than 100 members. Only a fraction come to dine on any one evening. It is also the custom for individual members of the Club to bring distinguished visitors, often from overseas, to a dinner. Quite often the President of the Royal Society is in the chair. Under the Chairman's guidance the talk ranges informally, over narrow specialist interests as well as widely in relation to the world at large. Week by week and year by year the Senior Treasurer for that year keeps records of those present, their dinner menu, and the heads of discussion, for storage in the club archives, which are kept private until the next history is due to be written.

Much praise is due to Dr Allibone for the way in which he has tackled this tremendous task. He makes it clear how formal continuity of the present Club can be traced back to 1743; but the Club can claim plausible links with earlier diners up to 1645. Samuel Pepys records his evident satisfaction with the fare as well as the discourse in the seventeenth century. Now, the club fare has become decidedly 'plainer' even if our thinking is 'higher'. It may be some mitigation too of any euphoria at present meetings of the Royal Society that dinners of 'The Club' now follow these, instead of preceding them as in Pepys' time.

With over 200 years of continuous archives to deal with, the present history has perforce concentrated much information in the form of nourishing pemmican, or sometimes by presenting well articulated skeletons from amongst the scientific worthies of the past. The long list of famous names cited makes the book valuable as well as fascinating. Different readers will probably let their imagination seize on different personalities to clothe, and Dr Allibone is to be congratulated that the choice provided is large. Thus it is striking to find that Henry Cavendish, who is often pictured as a millionaire scientific misanthrope, was one of the most assiduous diners. Clearly, a 'clubbable' man of his day. The colourful personality of Sir Joseph Banks receives rather lurid light from the record of his having purchased a silver bowl holding a gallon of punch and also of his having led a breakaway dining club into schism. When later he was elected President of the Royal Society, however, the schism was gradually healed. Then, too, there is the rather sad little note that Lavoisier in 1786 established a monthly dining club of scientists, the 'Philomatic Society', almost under the shadow of the guillotine.

This does raise the question (with one eye on Dr Johnson and perhaps one on Mr Pickwick) whether elite dining clubs (however chosen) are truly congenial only to the British temperament. One may hope that modern conditions of living will never extirpate such an amiable weakness or custom. So far as the Royal Society dining club is concerned, Dr Allibone's history will certainly help to perpetuate its remarkable longevity. □

Authentication in art

Harold Barker

Authenticity in Art: The Scientific Detection of Forgery. By Stuart J. Fleming. Pp. 164. (Institute of Physics: London and Bristol; Crane, Russak: New York, 1975.) £6.50.

THE majority of published books on authentication in the art world are concerned either with stylistic criteria or are purely anecdotal in character and do little to illustrate the significant contributions made by scientific methods of examination in this field, particularly during the past few decades. The author of this book, himself a scientist who has made noteable contributions to the development of thermoluminescence dating which has revolutionised the authentication of pottery, has set out to redress the balance and describe how scientific methods are applied to the detection of forgeries.

The book is divided into four main sections, the first of which provides a general introduction to the subject in which the author discusses the limitations of stylistic judgements; presents some early examples of the detection of forgeries; discusses different types of fake, the forger's technical approach and the errors and stylistic anachronisms which he is likely to perpetrate, and the role of surface examination by microscopy and ultra-violet fluorescence in uncovering forgeries. The other three sections are concerned with paintings, ceramics and metals, respectively. There is also an appendix devoted to X-ray fluorescence of Chinese blue-and-white porcelain, radiocarbon analysis, and lead isotope analysis of ancient objects.

These sections are concerned much more specifically with scientific techniques of examination covering many case histories and ending with fairly extensive bibliographies which deal adequately with case histories but could perhaps have benefited by the inclusion of at least a few more references to the fundamentals of the scientific techniques used for the benefit of readers who may wish to widen their background knowledge. For example it is rather surprising to find no reference to Zimmerman's development of the fine grain technique of thermoluminescence dating in the section on ceramics nor any reference to a basic metallurgical text in the section on metals. Also, in this age of high specialisation, the expert, when writing outside his own field, is not immune from mistakes and misconceptions, sometimes of an elementary nature. Thus in the section on metals, one discovers a statement (p125) which assumes that the production of tin bronze is associated with a significantly lower temperature technology than that of copper alone.

It is also inevitable that any publication concerning the authentication of valuable objects must be somewhat circumspect in its treatment of the material in order to avoid possible legal complications. Thus in its reliance on published examples in which the results of scientific examination are unequivocal, the book tends to give the impression that scientific techniques are rather more certain in the answers that they can provide than is actually the case. In general, however, and in spite of these limitations, the book is an excellent introduction to the scientific detection of forgeries and a good source of references to the literature of authentication and associated scientific studies. □

Life Sciences Research Report 1

NEW Prepublication Offer (valid until 1976 April 15)**

THE MOLECULAR BASIS OF *CIRCADIAN RHYTHMS

J. W. Hastings, Harvard University, and H.-G. Schweiger, Max-Planck-Institute für Zellbiologie, Wilhelmshafen, Editors, with an introduction by C. S. Pittendrigh.

Report of the Dahlem Workshop on The Molecular Basis of *Circadian Rhythms, Berlin 1975 November 3 to 7.

*Circadian Rhythms are defined as those rhythms with the following basic features:
They persist for some time in the absence of diurnal fluctuations in temperature and illumination; their phase can be altered by a brief disturbance of the constant regimen; and their period is relatively independent of the constant external temperature, at least within the physiological range.

to be published 1976 May 15, approx. 500pp. price approx. $30.00/£14.50/DM80.00; Pb.

Life Sciences Research Report 2

NEW Prepublication Offer (valid until 1976 April 30)**

APPETITE AND FOOD INTAKE

T. Silverstone, Editor
St. Bartholomew's Hospital, London

Report of the Dahlem Workshop on
Appetite and Food Intake
Berlin 1975, December 8 to 12

The report of this interdisciplinary workshop evaluates present knowledge regarding the factors concerned with eating behaviour and its control. It contains individual contributions on the state of the art by some of the most distinguished scientists working on these problems, and the group reports formulated during the workshop.

to be published 1976 June 15, approx. 500pp. price approx. $28.00/£13.50/DM75.00; Pb.

**prepublication order advantages:
—clothbound Library Edition at paperback price, or
—10% prepublication discount on paperback edition.

The Library Edition may be subscribed to on prepublication order basis only. If the minimum number of orders are not received, this edition will be cancelled and paperbacks will be substituted at prepublication discount.

Source of constructive thinking

Marcel Florkin

The Evolution of the Bioenergetic Processes. By E. Broda. Pp. vii+211. (Pergamon: Oxford and New York, 1975.) £8.30; $20.

In this much needed synthesis about the sources of free energy and their evolution in organisms, Professor Broda has collected and integrated a vast body of knowledge. He begins with a detailed exposition of current views on the origin of 'eobionts' and considers as most ancient those bacteria which are able to make ATP (the universal source of free energy in metabolism) anaerobically in a solution of organic compounds without direct participation of light. Such 'fermenters' (found among *Clostridia* and among methane formers, both gram positive) could only depend on the chemical energy of solutes. As the biomass increased, critical conditions arose—the production of compounds with high energy content by radiations, and so on, falling behind the rate of consumption of redox compounds useful in metabolism. At this point additional sources of free energy were acquired by photosynthetic bacteria through emergence of photosynthetic phosphorylation: in light, useful carbon compounds were regenerated from waste, and life could persist on the basis of antagonistic dark and light reactions.

Photo-organotrophs such as purple non-sulphur bacteria use as electron donors in the light, in anaerobic conditions, those organic electron donors which were used by fermenters in the dark. In addition to ATP, the expansion of life required, for the assimilation of CO_2, an external supply of electrons. Photolithotrophs such as *Thiorhodaceae* or purple sulphur bacteria and *Chlorobacteriaceae* or green sulphur bacteria) learned, through photochemical promotion, to use inorganic reductants as electron donors.

Photolithotrophs are removed from fermenters by one more step than photo-organotrophs. As photolithotrophic bacteria never produce oxygen (they do not extract electrons from water) the atmosphere remained anoxygenic, but sulphate (a mild oxidant) became plentiful in the biosphere. Oxygen increased in the atmosphere after the emergence of the ability of green plants (phytotrophs) to photolyse water and use it as reductant. Oxygen is toxic for anaerobes and it must be considered that a progressive oxygen tolerance was acquired by aerobic organisms who developed enzymes (oxygenases) through which oxygen was first exploited in biosynthesis. The author concludes that all respiring bacteria (relying on electron chains) have developed from photosynthetic bacteria and that the electron chains of respiratory phosphorylation were derived from the electron chains of photosynthetic phosphorylation.

It should be noted that non-photosynthetic lithotrophs (chemoautotrophs) as well as respiratory organotrophs, rely on oxidation in air to obtain ATP, resulting, in both, from respiratory phosphorylation, with the distinction that in the case of non-photosynthetic lithotrophs, the reductants are inorganic. The author also discusses the evolutionary positions of the variants of respiration (anaerobic and aerobic) in prokaryotes. He suggests that sulphate respirers (using sulphate instead of oxygen as the terminal electron acceptor in the electron flow mechanism characterising 'respirers') arose from some purple non-sulphur bacteria.

Bacteria and blue-green algae are prokaryotes; all other algae, higher plants, fungi, *Protozoa, Metazoa* are eukaryotes. Eukaryotes possess specific organelles (mitochondria, chloroplasts) housing the enzymatic machinary or respiration or photosynthesis. All eukaryotes are aerobic and are derived from eukaryotic protists (Metazoa, or higher animals, derived from Protozoa; Metaphyta, or higher plants, derived from green algae).

Professor Broda discusses the evolution of intracellular organelles in eukaryotes and the theories considering mitochondria and chloroplasts and endosymbiotes.

The book is completed by a discussion of the aspects of differentiation of tissues in the frame of oxygen need, that is, the further line of bioenergetic evolution among animals and plants. The author also considers the incidence of paleontological and geological evidence on the path of bioenergetic evolution deduced from the properties of extant prokaryotes and eukaryotes, and in the last chapter, retraces the history of atmospheric oxygen.

All students of evolution must be grateful to Professor Broda for providing such a lucid and documented discussion of this important topic. His book fills a gap in the literature on evolution and will certainly remain for a long time a source not only of bibliographic information, but also of constructive thinking. ☐

Photoreceptors

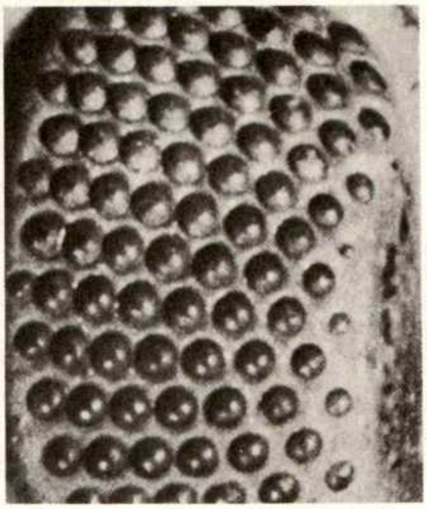
Aubrey Knowles

Photoprocesses, Photoreceptors and Evolution. By Jerome J. Wolken. (Academic: New York and London, November 1975.) $19.50; £10.15.

I WAS sadly disappointed that the promises of the title of this book, and its preface, were not fulfilled. The rapid progress of research into photosynthesis, vision and other fields of photobiology would make an overview of the relationship of the sun to life processes most timely. Unfortunately, Dr Wolken's approach is seriously biased by his own interest in invertebrate photoreceptors, resulting in a book that is badly out of balance—for example, the vision chapters occupy 110 pages, photosynthesis is confined to 27, and evolution, although appearing in several section headings, is barely mentioned in the text.

At best, the book presents a survey of visual photoreceptor structures in vertebrates and invertebrates, but most of the information, including the illustrations, appeared in Dr Wolken's earlier monographs. Beyond this, the text is a mixture of wide-eyed statements about the wonders of nature, and a mass of unrelated and often misleading facts, making a book that is not only difficult to read but that has to be read with the greatest wariness. In his preface, Dr Wolken says that the book is not intended for experts, but I find it hard to recommend it to anyone without a fair knowledge of both photobiology and evolution: there is much that is irrelevant, out-of-date, and—more serious—much that is omitted; for example, a Jablonski energy level diagram (carelessly copied from another author) is included without any explanation; a page is devoted to the geological time scale, but this is not mentioned again; 10 pages are given to a short account of bioluminescence that seems to have no place in the text, for in the author's own words, "The relationship of bioluminescence to photoreception . . . in evolutionary development is far from understood"; and so on.

The book is nicely produced, but I am curious about the two-inch wide margins; are these intended to raise the book into the 'coffee table' category, or are they for the reader's own additions? I had hoped to learn more about the bearing of light on evolution, but beyond token references to Darwin, Mendel and Karl Marx, the only photobiological system discussed in evolutionary terms is vision. Even in this restricted field, the fascinating story of the development of photoreceptors is barely mentioned, and we are given little more than a repetition of George Wald's 20-year-old theories on the evolution of visual pigments. There is no mention of the work of Bridges, Munz, McFarland and others over the past 10 years even though this has provided some hard facts about the relationship of visual pigments to environmental factors. In view of this poor treatment of evolution, and the sketchy information on primary photoprocesses, I suggest that the intending reader should ignore the first and third words in the title, and regard the book simply as a rather limited survey of photoreceptors. □



Part of compound eye of *Phacops rana*, a Devonian trilobite fossil

George Duncan

Photoreceptor Optics. Edited by A. W. Snyder and R. Menzel. Pp.x+523. (Springer: Berlin and New York, 1975.) DM 97; $41.80.

THIS book comprises a collection of papers that were presented at a colloquium in October 1974. Any text that is published within nine months of the meeting that conceived it is indeed remarkable and *Photoreceptor Optics* is doubly laudable because its chapters are so cross-referenced and deftly edited that we are made to feel that the authors were interested and indeed stimulated by the papers of their coparticipants.

The text is concerned with "how the optical properties of photoreceptors —their arrangement, orientation, shape, size, refractive index and membrane properties—influence their absorption of light and establish many of their specialised functions", and the initial section gives the most comprehensive treatment available of the role of wave guide optics in photoreceptor processes. The excellent theoretical chapter by A. W. Snyder is essential reading for all who debate the reasons for the intrinsic directionality of photoreceptors, or the importance of optical coupling between receptors.

After the mathematical rigour of the initial section, the second and third sections on photoreceptor membranes provides light relief, especially when introduced by a contribution by P. A. Liebman that manages to be both nutritious and easily digested. He provides a good review of the classical problem of determining the contents of photoreceptor cells by optical means, but he also gives us a glimpse of his very interesting present work on the axial diffusion of photopigment in cones. His findings go a long way to explain the difference in the distribution pattern of radiotracers in vertebrate rods and cones found by R. W. Young. He also focuses our attention on the small and hitherto unnoticed axial gradient of birefringence in rods, and on the basis of the observation, he spins a marvellous (and convincing) tale of the ageing of lipids in the rod–disc membrane.

Although the importance of pigment granule migration is acknowledged throughout this book, there is only one short paper on the possible photomechanical mechanisms at play, and that, by W. H. Miller, simply amplifies an earlier work by Miller and Cawthon. They suggest that microtubules mediate the movement of pigment granules in *Limulus* and they base their argument on the fact that the application of colchicine causes the same centripetal movement of shielding pigment as light does. It would be interesting in this respect for someone to repeat the experiments of W. A. Hagins who reported in a brief communication ten years ago that there was in fact no pigment migration when the illuminated photoreceptor (in this case cephalopod) was bathed with sodium-free medium.

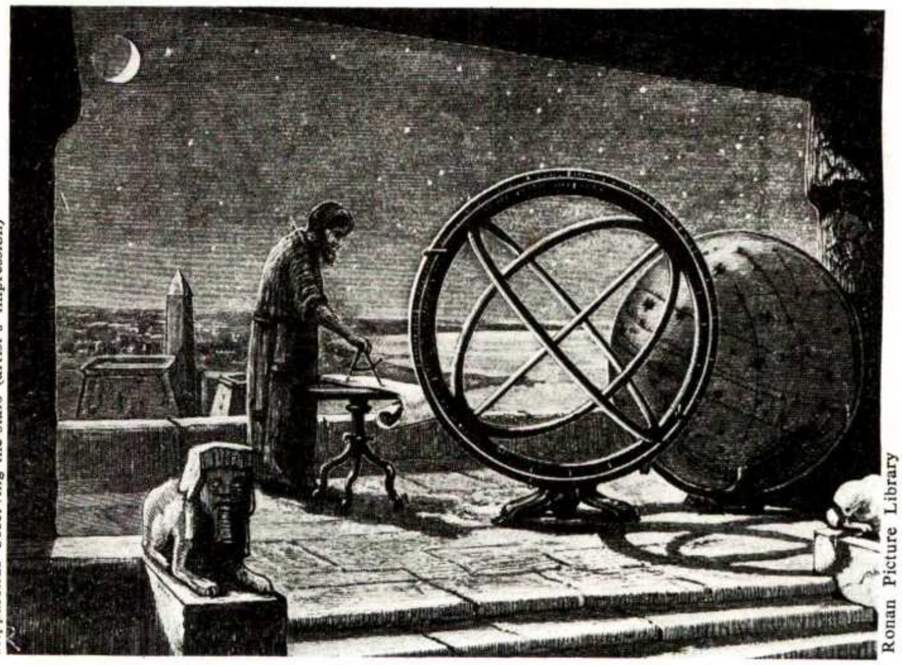
The great complexity of the arthropod photoreceptor system is highlighted by G. A. Horridge in the concluding section. From an analysis of intracellular microelectrode data, he found that there were two discrete sizes of quantum bumps in cells 1–6 of the fly's ommatidium. The miniature potentials elicited by 333-nm light are in fact larger than those produced by 500-nm light incident on the same cell, and so it seems that there are probably two transduction mechanisms within the same cell. It also seems likely that one pigment lies above the other and therefore orthodromic illumination and antidromic illumination may be differentially absorbed.

Although this text is within reach of the corporate rather than individual pocket, the conscientious researcher in the field of photoreceptor optics should ensure that he has ready access to a copy. □

Classic work on astronomy

G. J. Whitrow

A History of Ancient Mathematical Astronomy. Part 1: Pp. xxi+1–555. Part 2: Pp. 556–1,058. Part 3. Pp. 1,059–1,456. (Studies in the History of Mathematics and Physical Sciences, Volume 1.) By O. Neugebauer. (Springer: Berlin and New York, 1975.) DM 290; $118.90.



Hipparchus observing the stars (artist's impression)

Ronan Picture Library

PROFESSOR Otto Neugebauer, of Brown University, presents us with a magnificent work that will surely become a major classic in the historiography of ancient astronomy, a three-volume treatise devoted almost entirely to the mathematical astronomy of the Babylonians and of the Greeks.

He begins by solemnly warning his readers that "Many things are omitted here. The reader who wants to read about Archimedes taking a bath or about the silver nose of Tycho Brahe can find innumerable books which dwell on these important, biographical matters . . .". Instead, Neugebauer deals exclusively with "numerical, geometrical and graphical methods devised to control the mechanism of the planetary system". He omits any discussion of the theory of instruments (and also of Chinese and Mayan astronomy, neither of which had the slightest influence on the work of those about whom he writes).

For about 1,500 years (from the second century AD to the seventeenth century) mathematical astronomy in Europe and Islam was dominated by Ptolemy's *Almagest.* Book 1 of Neugebauer's *History* is therefore devoted to that tremendously influential work and its direct predecessors. He begins with two chapters on the plane and spherical trigonometry known to Ptolemy (about 150 AD), chords being used instead of halfchords, or sines (a later invention of the Hindus), and absence of knowledge of the fundamental formulae for right spherical triangles being compensated for by ingenious use of an important theorem attributable to Menelaus (98 AD). There follow three chapters on spherical astronomy before we plunge into Ptolemy's lunar theory (pp53–144) and his planetary theory (pp145–261). The remaining 80 or so pages of Book 1 are devoted to Apollonius and Hipparchus. The most important question of attribution confirmed by Neugebauer's authoritative analysis, although originally attributable to H. Vogt (*Astronomische Nachrichten,* 1925), is that the still widely held view that Ptolemy's star catalogue was largely based on Hipparchus's, a hypothesis accepted by the influential early nineteenth century historian of astronomy Delambre (because of his "preference for any theory which would detract from Ptolemy's merits"), cannot be sustained. This conclusion has been accepted by K. Lundmark, Owen Gingerich, and others.

Neugebauer is convinced that Hipparchus used arithmetical as well as geometrical methods. Just as the latter were the peculiar contribution of the Greeks, so the former, it now seems, (due to the researches this century by Kugler, Neugebauer, Van der Waerden, Aaboe and others) owed much to the Babylonians. Consequently, we can view Greek astronomy in what Neugebauer calls "an entirely new historical perspective", for we now realise that Babylonian arithmetical techniques greatly influenced both ancient Greek and also medieval astronomy. Book II (pp347–555) of Neugebauer's treatise is therefore devoted to Babylonian astronomy. A significant difference between the records of Babylonian and Greek astronomy available to us is that the former are authentic contemporary documents, dating from the last three centuries BC, even if some are copies of earlier tablets. Nevertheless, we have no information about the development of the completed system of Babylonian astronomy, unlike Greek astronomy. "In short", comments Neugebauer, "we probably know as much and as little about Babylonian astronomy as a Greek astronomer of the Hellenistic age knew". It is a mathematical astronomy that "operates without any model of a spherical universe, without circular motions and all the other concepts which seemed 'a priori necessary' for the investigation of celestial phenomena". It is entirely arithmetical.

Book III, only 12 pages long, is on Egyptian astronomy, the only important contribution of the Egyptians being the 'Egyptian year' of a fixed length of 365 days. It was the 'backbone' for the computation of astronomical tables down to the Renaissance.

Book IV (pp571–776) is concerned with pre-Ptolemaic Greek astronomy. I cannot resist quoting a short passage from page 572: "I see no need", Neugebauer writes, "for considering Greek philosophy as an early stage in the development of science . . . One need only read the gibberish of Proclus' introduction to his huge commentary on Book I of Euclid's *Elements* to get a vivid picture of what would have become of science in the hands of philosophers . . .".

Book V is devoted to astronomy during the Roman Imperial Period and Late Antiquity (that is, down to the seventh century AD). Book VI (pp1,061–1,456) contains Appendices, a Subject Index (including proper names), Bibliographical Abbreviations and so on, a short Greek glossary, and nearly 250 pages of diagrams and other figures, often as many as six on a page.

There is no doubt that here at last we have an up-to-date definitive textbook of ancient mathematical astronomy. I have so far noticed only one minor omission, and it may be deliberate. It concerns Thales, the sole reference to whom (p604) is to discredit his alleged prediction of the solar eclipse of 28 May 584 BC. Twenty years ago Professor A. Wasserstein contributed a paper to the *Journal of Hellenic Studies* (114–116, **LXXV,**

Star-studded journey

Paul Davies

The Dark Night Sky: A Personal Adventure in Cosmology. By Donald B. Clayton. Pp. xii+206. (Quadrangle/New York Times: New York, 1975.) $9.95.

I HAVE never read an astronomy book quite like this one. The author, who is an American astrophysicist at Rice University in Texas and an internationally respected scientist, has managed to weave a remarkable synthesis of personal narrative and descriptive astronomy into the same text. Not for Professor Clayton the dry old facts, figures and theories of conventional introductory astronomy books. Instead, reader discovers the motions of the Earth with the youthful Clayton delivering newspapers in Dallas. The mysteries of Stonehenge are unlocked as we accompany him in later years on a "sudden impulse" visit. Olbers' paradox unfolds from a detective story, as the author describes attempts to track down the family home of the eighteenth century astronomer de Cheseaux.

Much of this unusual book is taken up with the author's own research interest in stellar nucleosynthesis. Famous personalities like Fred Hoyle, William Fowler, Margaret and Geoffrey Burbidge appear as real people rather than mere names associated with pieces of work. To those, like myself, who worked in the early 1970s alongside Clayton and his friends at the Institute of Theoretical Astronomy in Cambridge, much of the account is nostalgic. In particular, the author's close friendship with Fred Hoyle (who has written a short foreword) comes through clearly—one whole chapter is devoted to their climbing exploits together in Scotland.

There is in fact much good science buried away in the text, but always interspersed with comment, narrative and a little Texas philosophy. The theory of relativity and some nuclear physics emerge from stories about Einstein and Rutheford, always embarked on by some personal incident. Emerging from the story is the unmistakable stamp of a romantic, helping to dispel the tired old idea of the cold, calculating scientist. The reader shares in the personal excitement which has changed the author's life. As we follow his daily experiences, science jumps out from everywhere: "Every aspect of nature" he explains "holds connections to the rest of the universe in my own mind . . . This sense of unity and knowledge has transformed my life from something mundane to something exciting".

Whether the reader wishes to learn astronomy by guided discovery, or to enjoy engaging stories of colourful personalities, Professor Clayton's book will provide an entirely welcome new perspective into the mysteries of astronomy and astronomers. ☐

(continued from previous page)

1955) on *Thales' Determination of the Diameters of the Sun and Moon*, followed soon afterwards by a further short note on the same subject, in which he argued that these determinations (ascribed to Thales by Diogenes Laertius) may have been obtained by angular measurement and not "as is generally supposed by time measurement". One other point concerns Neugebauer's conclusion (p643) that, in view of the highly inaccurate numerical values given by Aristarchus in his famous treatise *On the Sizes and Distances of the Sun and Moon*, this work should be regarded as "a purely mathematical exercise which has little to do with practical astronomy". I remember hearing a lecture by Professor Wasserstein ten or more years ago, in a colloquium at Imperial College, in which he made the same point.

The printing and presentation of all three volumes are up to the high standard we expect from Springer. Alas, not the least astronomical feature of this publication is its price. ☐

Flavour of excitement in modern astronomy

J. E. Beckman

Astronomy and Cosmology: a Modern Course. By Fred Hoyle. Pp. xiv+711 +23 plates. (Freeman: San Francisco, 1975.) $15.95.

ASTRONOMY has been a shining beacon in the subdued world of physical science during the last decade. Whereas research funding for most branches of physics and chemistry has been in the doldrums, money for astronomical research has been expanding in real terms. The opening up of new ranges of the spectrum by new techniques and by the use of satellites, has meant new discoveries. One needs only to run through a familiar list—radio galaxies, supernova remnants, quasars, pulsars and black holes—and to realise how many of these have become almost household terms, to understand why students have been turning towards astronomy and astrophysics as rapidly as they have turned away from some other branches of science. As a cultural subject, astronomy has further attractions for students and teachers. The history of the subject, the oldest recorded branch of natural science, subsumes a series of revolutions in the way man has viewed his place in the world. Even today the cosmological questions about the origin, the future and macrostructure of the universe exercise a unique fascination for both laymen and professionals.

Against this background Fred Hoyle has written a textbook aimed at first-year undergraduates. In US terminology it is a college rather than university text. A rapid glance through the book gives a most favourable impression. The author has made full use of the excellent illustrative facilities of his publisher, and their *Scientific American* style of didactic drawing. The book is well provided with photographs, mainly from the Hale Observatories, of nebulae, galaxies, and spectra. Above all the beautiful typography and layout go well with the leisurely presentation, in whose 700 pages the author has felt free to develop his favourite topics at considerable length.

One necessary reason for this spread is the deliberate abstinence from formal mathematics other than simple algebra and the use of logarithms, throughout the book, and the relegation of most algebraic development to chapter appendices. Although this had led to many elegant verbal explanations of topics as diverse as star formation, the quantum theory of spectra, and Kepler's laws, the result is to weaken the presentation. A perceptive student's feeling of inferiority before the mathematics will be increased; worse, a less able student will not realise the pervasive need for mathematical method in linking the concepts presented.

Nevertheless. the concepts are well presented and physical insight is demanded of anyone working through the interesting sets of problems, whose main virtue is to foster a feeling for orders of magnitude. The choice of material is a useful balance between classical introductory astronomy, and such modern topics as plate tectonics, and the physics of the 'big bang'. The author's occasional sallies into idiosyncrasy are carefully prefaced by "it is my belief" and like caveats.

I find the book excellent value at $15.95, and although not entirely suited to a British first-year undergraduate course, as a gift to educate and interest a sixteen- to eighteen-year-old it is almost ideal. It does convey the flavour of excitement in modern astronomy. ☐

Mysteries of the angiosperm

W. G. Chaloner

Palaeobiology of Angiosperm Origins: Problems of Mesozoic Seed-Plant Evolution. (Cambridge Earth Science Series.) By Norman F. Hughes. Pp. vii+242. (Cambridge University: Cambridge, London and New York, January 1976.) £7.80.

THE past decade has seen a renewed surge of interest in the evolutionary origin and diversification of the angiosperms. Four major books (Hutchinson 1969, Taktajan 1969, Sporne 1974 and Stebbins 1974) have dealt with the problem, placing varying degrees of emphasis on comparative studies of living forms, with a proportionate lack of emphasis on the fossil record. This approach takes its most extreme form in Stebbins' assertion that "the fossil record of angiosperms can be more misleading than enlightening as a means of interpreting the major trends of their evolution". Hughes offers an encouraging refutation of Stebbins' morbid view. His book is a palaeontologist's unrepentantly partisan survey of the fossil record of angiosperms, and of the reputedly relevant gymnosperms of the past 200 Myr. He has as little time for comparative studies of living forms as Stebbins has for fossils.

Two important facts emerge from his thorough and well-illustrated analysis. First, there is no acceptable evidence of angiosperms before the early Cretaceous. Second, all those characteristic attributes of angiosperms which have a sporting chance of surviving in a fossil (wood with vessels, dicot-type leaves, multiaperturate tectate pollen and seeds enclosed in a fruit) appear within the timespan of one geological stage, during or close to the Aptian (late early Cretaceous). A vital contribution here has been the palynological evidence, repeated synchronously at widely separated sites, showing the sequential change from monaperturate to multiaperturate pollen types.

Hughes places great emphasis on the data-handling aspect of the angiosperm evolution problem. He is rightly concerned that a question-begging nomenclature should not conceal the inadequacies of our fossil record. But in some instances this is carried to alarming lengths. He worries over the application of 'dicot' to Cretaceous woods or leaves, because the number of cotyledons is not directly evident in the fossils (he prefers the label 'dubiocot'). One wonders whether as a palaeontologist, he objects to attributing Cretaceous skeletal material to the mammals, since that designation is equally based on an attribute so singularly lacking in the fossil record?

The author offers us no snap answer to the mystery of angiosperm origins. But he has faith that the fossil record, properly documented, will eventually yield an answer. He hints that he believes the angiosperms to be polyphyletic, and that most of the major Mesozoic gymnosperm groups are under suspicion of duplicity. While we are awaiting that answer, this book is a most readable source of well-ordered factual information, and a strong goad to a renewed assault on one of the most rewardingly unsolved problems of biology. ☐

Jurassic-Cretaceous geology in Russia

John W. Neale

The Jurassic-Cretaceous Boundary and the Berriasian Stage in the Boreal Realm. Edited by V. N. Saks. Pp. vi+345+46 plates. (Israel Program for Scientific Translations: Jerusalem; Wiley: Chichester, September 1975.) £17.50.

ONE welcomes the translation of this impressive work which starts with a historical review of classification about the Jurassic–Cretaceous boundary, followed by detailed descriptions of the lithology, faunal succession, ethology and taphonomy of each relevant section in the Boreal Realm of the USSR. Western European developments are covered, although some up-dating is necessary in the light of recent publications, and correlation between the various areas is suggested. It is refreshing to find oneself in accord with this authoritative team of Russian workers in their reservations and strictures on the use of the term 'Ryazanian' and their preference for 'Berriasian'.

An extended review of the ammonites, belemnites, bivalves, brachiopods and foraminifera, read in conjunction with the 46 plates at the back, provides a fascinating insight into the Russian faunas. Although individual specialists may take issue with some of the generic or trivial assignments, this part provides an invaluable guide to current Soviet thought on the interpretation of these groups. Both here and elsewhere a considerable number of new fossil species has been described by the editor/author whom the Russians transliterate as 'Sachs', so that the use of this form is obligatory in the attribution of these taxa and is correctly used in the translation. It is a pity that the translators feel obliged to follow western precedent and use 'Saks' on the cover and elsewhere in the running text. That 'Sachs' and 'Saks' are one and the same is a potential source of confusion, particularly to the non-specialist.

Otherwise, the translation is good, the occasional infelicities only serving to suggest the flavour of the original. Incidentally, both original and translation show a curious anomaly—in table 24, in which the *Bojarkia mesezhinkowi* zone is placed in the Valanginian in contrast to its firm placing in the Berriasian elsewhere. Interesting chapters on palaeogeography (although the maps take no account of continental drift and are rather small in the translation) and on palaeogeographic zoning, close the book. This handsome, if somewhat expensive, volume is beautifully produced and besides being an exciting mine of information to dip into, will remain an indispensable work of reference for many years to come.

Ecology and Evolution of Communities
Martin L. Cody and Jared M. Diamond, editors
This book contains 18 major original papers, offering new models, methods and applications for analysing and interpreting a wide variety of empirical data. *Part I, The Evolution of Species Abundance and Diversity;* Richard Levins, Egbert G. Leigh, Jr, John W. MacArthur, Robert M. May, Michael L. Rosenzweig. *Part II, Competitive Strategies of Resource Allocation;* William M. Schaffer and Madhav D. Gadgil, Henry H. Hespenheide, Arthur M. Shapiro, Henry S. Horn. *Part III, Community Structure;* Martin L. Cody, James R. Karr and Frances C. James, Eric R. Pianka, James H. Brown, Jared M. Diamond, Ruth Patrick, Joseph H. Connell. *Part IV, Outlook;* G. Evelyn Hutchinson, Edward O. Wilson and Edwin O. Willis. *Belknap Press* **£17.70**

Anatomy of the Guinea Pig
Gale Cooper MD and Alan L. Schiller MD
This is a thorough description of guinea pig anatomy illustrated with over 400 drawings by Dr Cooper, covering: external anatomy; the skeletal, muscular, cardiovascular, lymphatic, central nervous, peripheral nervous, respiratory, digestive, urogenital and endocrine systems; the ear; the eye and orbital contents. *Commonwealth Fund* **£20.00**

Larger-than-life characters

M. J. S. Rudwick

The Dawnseekers: The First History of American Paleontology. By R. W. Howard. Pp. xiii+314. (Harcourt Brace Jovanovich: New York and London, October 1975.) £3.95.

THIS is a popular history of palaeontological research in the US, from the first great vertebrate finds in the eighteenth century to the full professionalisation of the science in the twentieth century. The style is journalistic, with racy narrative and fictional dialogue. The subject matter should be ideal for a good popularisation of the history of science, for many of the personalities involved were as colourful and as larger-than-life as the extinct animals that they discovered and reconstructed. The author claims that "*The Dawnseekers* was not meant to be a definitive history", but even the most modest popularisation should utilise the more accessible results of modern historical scholarship. The best parts of *The Dawnseekers* are those that describe the epic feats of Cope, Marsh and others in the newly-opened American West; but it is sad that the opportunity of setting this work reliably in its historical context has been so completely missed.

The story is still framed in the terms set (or at least, propagated) by that old warhorse of the 1890s, Andrew D. White, as a conflict between crusading scientists in shining armour and a benighted army of clerics and other obscurantists defending the sanctity of Ussher's date of 4004 BC. This kind of interpretation is inexcusable in the 1970s, when several readable books based on accurate historical research are easily available. To mention only one, the omission of which is all the more surprising because it rightly emphasised the importance of American discoveries, John Greene's *Death of Adam* (1959) placed those discoveries firmly in their historical context as part of a continuing debate on the implications of the history of life for human self-understanding.

Science needs good popularisations, and popularised history of science is an excellent way of communicating the historical dynamics and humanity of the scientific enterprise. Unfortunately the simplistic journalism of *The Dawnseekers* will do little to advance the lay understanding of science. □

Geological clocks

A. Hallam

Growth Rhythms and the History of the Earth's Rotation. Edited by G. D. Rosenberg and S. K. Runcorn. Pp. xvi+559. (Wiley-Interscience: London and New York, September 1975.) £22.50.

IN the 12 years that have elapsed since Wells published his pioneer paper on corals as geological clocks a large amount of research has been conducted on growth rhythms in living and fossil organisms in relation to solar and lunar periodicities. This book, the outcome of a NATO conference held in Newcastle-upon-Tyne, summarises this work, and contains in addition a number of interesting papers by geophysicists and astronomers on the Earth's rotation. These range from an analysis of eclipses from ancient historical records to more theoretical studies of the dynamics of the Sun–Earth–Moon system. Greatest interest attaches to the study of rhythmicity in fossil growth layers as the best hope of obtaining hard data on diurnal, monthly and annual cycles in the distant geological past. Although it is impossible to summarise adequately in a brief review the results of so many diverse contributions, it is apparent that early efforts in the field greatly underestimated the complexities in growth patterns that emerge from more detailed analysis, and that stromatolites come a poor third to bivalves and corals as research material. Some rhythms perceived in living organisms relate more to varying environmental conditions than to astronomical periodicities, and misinterpretation of fossils is likely to arise unless one has access to large amounts of excellently preserved material with continuous growth records. There is also a need in the future for more objective measurements utilising, for instance, the optical densitometer. Nevertheless there still seems to be qualified support for a gradual slowing down of the earth's rotation throughout most of Phanerozoic time.

The editors are to be congratulated on a finely produced and splendid interdisciplinary effort. □

Of crops and men

Joseph Hutchinson

Crops and Man. (Foundations for Modern Crop Science Series.) By Jack R. Harlan. Pp. xi+295. (American Society of Agronomy and Crop Society of America: Madison, Wisconsin, 1975.) $11.25.

THIS is a good book. The expansion of studies of crop plant evolution in recent years has been so great that to produce a survey of the field in one volume is a daunting proposition. de Candolle and Vavilov provided respectively the roots and trunk of a tree that has now grown a crown almost too great to be encompassed by one man. Nevertheless, Jack Harlan has set out to do this. In his Preface he says: "The time has come for a third round of summary on what is known about crop origins".

Harlan has not only succeeded in accomplishing such a summary; he has contributed a most timely addition that substantially enlarges the field. de Candolle's interests were primarily botanical and geographical. Vavilov's were botanical, geographical and genetic. Harlan's are botanical, geographical, genetic and human. Although de Candolle was well aware of the human influences in the phenomena he studied, it was natural that for a long time the study of the origins of crops and of agricultural practice should be pursued separately. Their natural interrelation has been apparent in the past decade, and there are now numerous examples of the way in which biological and archaeological evidence together contribute to the elucidation of crop plant history. Harlan has taken these disciplines and fused them into a comprehensive account of the social as well as the biological changes that went into the evolutionary progression from hunting and gathering to a full agricultural economy.

The sponsors of the series of which this is the first volume, have sought to meet the needs of "upper level undergraduate college students". For students reading subjects in applied biology, archaeology, anthropology and geography this will be mandatory reading for a long time. It will also be invaluable for teachers who are developing 'A'-level Environmental Studies in schools.

This subject is my absorbing interest, and it would be surprising if I agreed with all of Harlan's views. I would add a South Asian Region to his list of original crop regions, and would assign to it such crops as the Indian pulses (including pigeon pea), *Gossypium arboreum*, and some tetraploid and hexaploid wheats. I think he has overdrawn the protein shortage, and I do not think one can accept his statement (p253) that "it was not until World War II that significant increases in per hectare yields were achieved". There were at least two earlier periods in British agricultural history during which substantial advances in yield were made. But these are matters for debate, and it is a measure of the stimulus of the book that one constantly made a mental note of a new or unrealised aspect of the subject—that the hunter–gatherer lived in a golden age, for example—or of an interpretation one did not accept and would like to discuss with the author.

The book begins with a discussion of the way people lived before they farmed, how they began to farm (leaving open the question why they should want to), and our present ideas of the areas in which farming began. Then there are chapters on crops and weeds—which is which and why— and on the classification of cultivated plants. Genetic and evolutionary topics follow. Five chapters are devoted to regional studies, and finally there is one on recent spread much of which can be documented historically, and one of interesting and well controlled speculation on future prospects and possibilities.

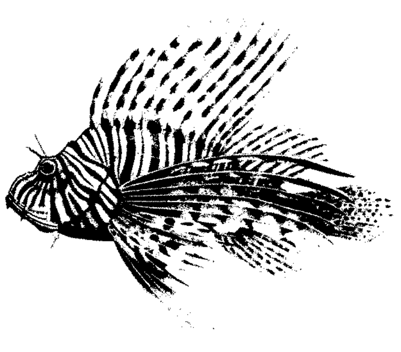
I enjoyed it. □

Air pollution

C. P. Whittingham

Responses of Plants to Air Pollution. (Physiological Ecology: a Series of Monographs, Texts and Treatises.) Edited by J. B. Mudd and T.T. Kozlowski. Pp. xii+383. (Academic: New York and London, November 1975.) $29.50; £15.35.

THE study of the response of plants to aerial pollutants is relatively new. In our present state of ignorance it is important to differentiate between proven facts and generalisations which have become established only by frequent repetition. There is a need to pose pertinent questions which require experimental investigation and to formulate primary problems in analytical terms. Unfortunately this book does not attempt these tasks. It consists largely of literature reviews of current work and since all the authors are American most of the book relates to conditions in America and to work undertaken there.



Scorpion fish (*Pterois volitans*). Taken from *An Age of Fishes: The Development of the Most Successful Vertebrate.* By Joy O. I. Spoczynska. Illustrated by Melchior Spoczynski. Pp. 145. (David and Charles: Newton Abbott, London and Vancouver, February 1976.) £3.95.

Separate chapters discuss the influence of sulphur dioxide, ozone, fluorides and peroxyacyl nitrates, oxides of nitrogen, and particulates. Some chapters include more references than others and are correspondingly more valuable, but essentially all are concerned with reviewing the literature rather than discussing principles. Subsequent chapters deal with the response to mixtures of pollutants and the interaction of air pollutants with vegetation. There is little reference to the importance of the physiological status of the plant—for example, the influence of water stress or mineral deficiency in relation to plant response to pollutants —and there is only a limited reference to the importance of aspect in relation to pollution damage. One chapter is concerned with the interaction of pollutants with vegetation canopies; unfortunately there is little discussion relating the spread of pollutants to physical processes. Other chapters are concerned with the specific effects of pollutants in forests and in relation to agriculture. There is also a chapter on the influence of pollutants on plant structure and on the growth of lichens and bryophytes. In many chapters reference is made to the biochemical action of specific pollutants and perhaps it is premature to seek an account of the general interaction of pollutants with plant metabolism.

The book will be useful to those who require an introduction to the literature of plant response to pollutants. It does not provide a critical view of our present state of knowledge of the subject. It makes general statements without quoting evidence such as "yields of virtually all important crop plants have been greatly depressed by air pollution"; with certain exceptions it fails to emphasise the important facts which still need to be established in the face of the possible need to define air quality standards for future legislation. □

Ecology of rivers . . .

D. H. Mills

River Ecology. (Studies in Ecology, Vol. 2.) Edited by B. A. Whitton. Pp. x+725. (Blackwell Scientific: Oxford and London, 1975. Distributed in US by University of California Press.) £18.

River Ecology is the second volume in this internationally-based series concerned with ecology which aims at the production of scholarly integrations of established topics and critical assessments of newly-opened fields. This volume offers a comprehensive treatment of river ecology, and its prime aim is to provide a fundamental framework for the subject. Such an approach will be of value both to the more advanced student and to the research worker and river management officer who needs some guidance to the mass of literature which is now appearing about rivers. The 28 contributions to this book go a long way to fulfilling these aims and have certainly guaranteed that it is one of the few, although not the cheapest, books in English which covers so many aspects of river ecology.

Unavoidably the contributions vary in their quality and length, and their uneven size does not necessarily correspond to the importance of their subject. Some are disappointingly short, whereas others are surprisingly drawn-out. For example, only 31 pages are devoted to fish, whereas a similar number of pages deal with lotic periphyton. No-one would question the great importance of zonation in river ecology but the 63 pages devoted to this subject are more than twice the number of pages given to any of the other contributions except two.

In a book of this sort, where the size of the author's contribution is necessarily limited, it is not difficult to find omissions. The most glaring omissions occur in the chapter on Ecological Aspects of River Impoundment. This chapter tends to dwell almost entirely on the effects within the impoundment, and the downstream effects of impoundment on rivers are described in two pages. Only ten lines are devoted to the effects of hydroelectric installations on river flows and fish movement, and no mention is made of the effects of water transfer, either directly from river to river or indirectly through a regulating reservoir. This is a subject of paramount importance in the water resources field in this country at the moment, and its omission is to be deplored.

In the chapter on River Zonation and Classification a number of photographs are included which depict the various zones, named after the dominant fish species present, in a number of river systems. A number of these do not correspond with the physical appearance of these same zones in other river systems. For instance, the example given of the minnow reach or grayling zone (Fig. 14.2a) is nothing like the grayling zone on the River Tweed or the River Clyde; and the minnow reach in some Welsh mountain streams would correspond almost to the head stream depicted in Fig. 14.1a. The author refers to the River Wye, at Newbridge-on-Wye, (Fig. 14.2b, and the front cover of dust jacket) as being an upper salmonid zone although grayling, dace and chub are abundant in this stretch of the river. I would not refer to the Wye being an upper salmonid zone until one reached a point upstream of Llangurig.

The book ends with an Appendix which gives a guide to Further Literature on Particular Rivers. There are a number of glaring omissions, however, which include the Teifi and Towy in Wales, the Bran, Conon, Don, Forss, Meig and Tay in Scotland and the Fraser, Margaree, Miramichi and Pollet in Canada.

This is, however, a most valuable work on river ecology and I recommend it being purchased by all appropriate university departments and research institutions, and by more affluent research workers. □

. . . and animal populations

M. E. Solomon

Animal Population Ecology. By J. P. Dempster. Pp. x+155. (Academic: London and New York, August 1975.) £3.80; $10.00.

THIS thin, hard-backed volume provides good, if mostly brief, coverage of its subject, dealing with 'basic concepts', competition, social behaviour, qualitative changes, natural enemies, weather, and examples of field studies, and concluding with population theories and applied population ecology. The comparative account of selected field studies is a major and valuable feature. For each of them, life tables are presented and analysed by the Varley and Gradwell method for key factors, to diagnose where, if at all, in the life cycle there occurs a mortality that is the chief component of the fluctuations in numbers over successive generations. The book also attempts to diagnose which process is responsible for the limitation of numbers. In four of the six examples, this density dependent process seems to be intraspecific competition, for food in the cinnabar moth, wood pigeon, and pine looper in its outbreak areas, for settlement sites in the edible cockle, or for territories in the tawny owl. Three other field studies, on larch tortrix, red grouse and rock ptarmigan, are considered in connection with the problem of how periodic cycles of these species are engendered.

The author's grasp of the theory of population dynamics seems to falter in places. The intrinsic rate of increase (r) equals births minus deaths (p. 4) only in the infinitesimal interval of the calculus equation describing increase; over a finite period the relationship is not so simple. It is not true that k-factor analysis necessarily enables us to recognise "any density dependent relationships which exist" (p. 15). The statement (p. 140) that "the maximum sustainable yield......in the logistic model......is $K/2$", can hardly be correct, since in this context yield is a rate, whereas $K/2$ is a quantity.

The exposition is occasionally faulty. On page 17 the explanation of k-values is confused by the introduction of an index of mortality that is insufficiently explained by the footnote. In Table XVII the values are divided by 10^6 and so on, not multiplied as indicated above the columns. The phrase "sufficiently density-dependent to prevent extinction" (p. 105) may lead students to suppose that a density-dependent influence at low density can avert population extinction in some positive way (whereas the most it can do is to cease its adverse action). On the verbal level, it is disconcerting to find Pimentel, one of the theorists whose views are examined, misspelled in both text and reference list. 'Epidemic' should not be treated as a synonym of 'epizootic' (p. 43). Hassell's term is 'aggregative', not 'aggregate' response (p. 49).

In spite of these blemishes, however, this is a valuable book that should appeal to university students and research workers. It has an index and an up-to-date reference list of some 200 items. Its scope overlaps that of the earlier book by Varley, Gradwell and Hassell (*Insect Population Ecology*, Blackwell, Oxford, 1973), which goes more deeply into population dynamics and the relevant methods of analysis, but is confined to insects. □

On trial

Griffith Edwards

Brain, Behaviour and Drugs. By David M. Warburton. Pp. x+280. (Wiley: London and New York, December, 1975.) £6.95; $15.30.

TEXTBOOKS on psychopharmacology are these days appearing thick and fast and there might be a case for a 'Which' report. The present book is certainly a good buy, but as in every consumer's report there are a few things to niggle about. The particular attraction of this subject is that it enables authors to put on it an individual stamp, and here the stamp is characterised by authority and enthusiasm.

Dr Warburton first discusses the chemistry of synaptic transmission, and the effect of drugs on transmission. An interesting chapter then focuses on control of homeostatic motivation, with particular reference to water balance and food intake. A chapter on the biochemical basis of mood competently covers essential ground, and the section on control of attention gives a careful account of a difficult area. There is a good section on schizophrenia but affective illness does not get similar treatment, and intelligence and learning are also covered.

It is in the later sections that there is occasion for a few criticisms. The review on the influence of alcohol on the EEG is not up to date. The section on the biochemical basis of drug dependence, although basically very well handled, shows some flaws. For instance, the statistic is quoted that 22.5% of the psychiatric admissions in Brazil, India, Morocco and Nigeria were between 1957 and 1964 as a result of an acute cannabis reaction—a statement so bizarre as usefully to be put before students to test their critical faculties, but not to be coldly retailed as fact. To say that personality changes consequent on cannabis use "seem to be irreversible", runs some leagues ahead of the evidence, and the cannabis literature is in general not sufficiently well treated.

The chapter on anxiety and stress is also a little bit disappointing. The concept of anxiety and the concept of stress could both have done with greater eludicidation: the student might expect more about the measurement of psychophysiological correlates of anxiety. The discussion on the clinical application of anti-anxiety drugs on human beings errs on the side of optimism—not every psychiatrist would agree that "the debilitating effects of pathological anxiety have been reduced to a remarkable extent by a number of psychoactive drugs."

The usual difficulty with the teaching text on this subject lies in effectively making the linkage between the psycho- and the -pharmacology. This book succeeds more than most. The real way to test such a new product must of course be to try it out live on a panel of consumers, and here that means seeing how the book actually goes as a teaching text. This book certainly deserves that kind of trial. □

Neural organisation

H. F. Bradford

The Synaptic Organisation of the Brain: an Introduction. By Gordon M. Shepherd. Pp.xi+364. (Oxford University: London and New York, 1975.) £3.80.

WE have not yet reached the position where a definitive account of the synaptic organisation of the brain can be given, but Professor Sheperd provides us with a useful current appraisal of our degree of success in the drive towards that objective. He begins with a brief introduction to the morphology of synaptic and related structures and of neural connexions, and proceeds to expound the biophysical mechanisms which probably underlie resting transmembrane potentials and their displaced versions, the action and synaptic potentials. This is done in an explanatory way rather than with a vigorous mathematical approach. This leads on to an analysis of dendritic organisation in relation to passive spread of potential change due to synaptic activity, and the work of Wilfred Rall in this area. The second and most dominant part of the book deals with neural organisation in the ventral horn of the spinal cord, the olfactory bulb and cortex, the retina, the cerebellum, the thalamus, the hippocampus and the neocortex. The text is based on an advanced seminar course given by the author in recent years at the Institute of Neurological Sciences at the University of Pennsylvania, and its aim is to isolate and propose principles of synaptic organisation in these regions for the consideration of advanced students and research workers in neurophysiology. Neuropharmacological and developmental aspects of the subject are purposely restricted to keep the length of the book within reasonable bounds.

I found the flow and content of the book interesting and engaging as well as informative, and it is well linked to the literature of the subject with copious references (a large proportion dating from 1970 onwards). The absence of the more recent developments in our knowledge of catecholamine and indoleamine-operated pathways in the mammalian brain does detract from the success of the book as a description of synaptic organisation, but one appreciates the reasons for their absence. The accounts of the neurophysiological mechanisms of the various brain regions are clearly explained and well illustrated, and the rather conversational style of the text, together with the author's determination to present complex mechanisms as interplay of simpler more universal processes, adds to the ease of its reading. Each regional account deals with the range of neurone types present and the major types of synaptic connections existing between them. This is followed by an account of organisation in terms of circuit diagrams and the special features of that region in this respect. This is accompanied by a discussion of specialised dendritic properties crucial to the synaptic interactions. There are a large number of books in this area appearing at present, but this should prove to be among the most popular. By modern standards its price is attractive for its size and content, and in this respect too it should compete successfully on the bookstalls.

Tranquillisers no answer to schizophrenia

Malcolm Lader

Drugs, Madness and the Brain. By Solomon H. Snyder. Pp. 287. (Hart-David, MacGibbon: London, 1975.) £6.

It would be a macabre task to draw up a league table of the most terrible diseases which can afflict mankind. In such a list, schizophrenia would be very near the top as this illness disrupts and destroys normal mental functioning. It is common, one in a hundred adults succumbing. The outcome is uncertain, some recovering unscarred, others with residual symptoms and strange behaviour, and an appreciable unfortunate group who occupy the majority of the 'chronic beds' in health services throughout the world. These patients exist in institutions ranging from true mental hospitals, with rehabilitation and return to the community as the aim, through lunatic asylums, where the patients are cared for to a greater or lesser extent, to 'bins', a pejorative but accurate slang term.

New hope dawned for schizophrenic patients, their families and medical attendants with the advent of the major tranquillisers 20 years ago, coinciding with more liberal attitudes towards the mentally ill. The numbers of patients in hospital declined although the number of admissions rose.

In this book, Solomon Snyder, a psychiatrist-*cum*-pharmacologist, sets out for the layman recent research into the biology and treatment of schizophrenia. In part I he outlines concepts of insanity, the treatments for schizophrenia and the effects of the psychedelic drugs like mescaline and lysergic acid diethylamide (LSD) pointing out that the psychoses which these drugs induce differ in several crucial respects from schizophrenia. Part II provides a superb non-technical description of the many mental aberrations and behavioural peculiarities of the schizophrenic patient. Finally, Snyder describes the psychosis induced by repeated high doses of amphetamine and shows how similar the mental state is to that of paranoid schizophrenia.

One tantalising question remains unanswered. What is the clinical type of action of the major tranquillisers such as chlorpromazine? Are these drugs anti-psychotic, that is, lessening psychotic symptoms whatever the causation, or are they truly anti-schizophrenic, influencing the schizophrenic disease process itself? Although Snyder heads one chapter "Anti-schizophrenic Drugs", he is at pains to point out the contradictions implicit in this rubric. For example, schizophrenic patients are not all cured and some sceptics have suggested that the major tranquillisers are merely 'chemical strait-jackets'.

The most relevant pharmacological effect of the major tranquillisers has recently become clearer. All these drugs have the common property of attenuating the action of the neurotransmitter dopamine by competitive, postsynaptic blockade. This explains extrapyramidal side-effects like Parkinsonism and some hormonal effects of the drug. It is tempting to postulate that schizophrenia involves dopaminergic overactivity in the brain but Snyder points out the dangers in such a facile extrapolation. This area of pharmacology is growing rapidly and should uncover the biochemical and physiological mechanisms associated with psychotic behaviour in general and (dare one hope) schizophrenia in particular.

The book is well written in non-technical language. It is entertaining, vigorous, optimistic in outlook but balanced in opinion. It can be heartily recommended to any intelligent layman who wants to keep abreast of research development in a major area of health concern. It should also be read by medical and scientific professionals from medical and psychology students to researchers involved in the field. And our administrators and politicians involved in the provision of health care might also take time to learn about schizophrenia—this dreadful life-long mental condition which afflicts so many thousands of patients vegetating in institutions or existing precariously in the community. Major tranquillisers are still not a substitute for adequate health services. □

Pervasive role for acetylcholine

T. J. Crow

Central Cholinergic Systems and Behaviour. By P. V. De Feudis. Pp. x+422. (Academic: London and New York, 1975.) £6; $15.75.

At a conservative estimate, established chemical transmitters in the central nervous system must now number at least seven, even excluding polypeptides which act as hypophyseal releasing factors, the recently discovered endogenous morphine-like compound, and the elusive substance P. Why so many substances should be needed to carry messages from nerve cell to nerve cell is a major unsolved question. The classical concept of postsynaptic excitations and inhibitions suggests a requirement for two, and the present surfeit might be thought to support the view that major varieties of action at the post synaptic cell have yet to be described.

Among these agents acetylcholine has a particular place, as the first such substance convincingly to be demonstrated to have a neurohumoral role, and by reason of the detailed knowledge we have of its release and action in the periphery. Yet its functions in the brain might be thought recently to have been neglected by comparison, for example, with the monoamines. This monograph by de Feudis contributes toward redressing the balance and reviews in detail the information which suggests that acetylcholine undoubtedly has a pervasive role. Although much of the subject matter concerns experimental findings at the electrophysiological and cellular level, the book is organised in terms of functional systems and behaviour. The author does not flinch from plunging the reader into a first chapter on cholinergic mechanisms and consciousness, and follows this with sections on motor systems, and the role of acetylcholine in autonomic and endocrine control, and in motivated behaviours, emotion, learning and memory. The reference in the title to behaviour is therefore justified and the book will be of particular interest to physiological psychologists. De Feudis has been unusually successful in his attempt to bring together a variety of relevant studies at the biochemical and cellular level and at the level of gross structure and function.

A text organised around a single neurotransmitter substance invites questions concerning the lead which information concerning this substance might give us to the functional organisation of neurotransmitter mechanisms in general. When does a pathway need to use acetylcholine as a neurotransmitter? Anatomical precision is crucial here, and as de Feudis makes clear, in spite of the development of the cholinesterase technique, there are many limitations in our present knowledge of the anatomical identity of cholinergic neurones. □

Adrenergic transmission

A. D. Smith

Adrenergic Neurones: Their Organisation, Function and Development in the Peripheral Nervous System. By Geoffrey Burnstock and Marcello Costa. Pp. xi+225. (Chapman and Hall: London, August 1975.) £8.50.

THIS comprehensive little book presents a summary of our knowledge of the peripheral adrenergic nervous system. It serves as an excellent entry into the literature, for the authors have quoted nearly 1,200 references which occupy 80 pages. Since only 136 pages remain for the text, it is inevitable that much of the writing is very descriptive. This is particularly so in the first two-thirds of the book, which gives a rather superficial account of the general organisation and structure of adrenergic nerves, the biosynthesis and metabolism of noradrenaline, and the basic features of neurotransmission. The remainder of the text, starting with a discussion about adrenergic transmission, continuing with a chapter reviewing the growth and degeneration of adrenergic neurones and ending with a general discussion, is much more original and contains some important new ideas.

It is hardly surprising that, in their wish to be both brief and comprehensive, the authors have occasionally oversimplified and have tended to make dogmatic statements. The reader is likely to be rather confused by the account of ganglionic transmission where it is stated that inhibitory muscarinic cholinoceptors occur on adrenergic neurones (p14) although elsewhere the muscarinic inhibitory effect is said to be mediated by interneurones that release a catecholamine. No mention is made of the excitatory muscarinic cholinoceptors in ganglia; perhaps it would have been wiser to admit that the events in the ganglion are complex and not fully understood. Likewise, it would have been better to say that we know nothing about the electrogenesis involved in the muscarinic action of acetylcholine on nerve terminals, which leads to inhibition of the release of noradrenaline evoked by orthodromic stimulation, rather than to imply that it is due to hyperpolarisation of the membrane. I assume that the authors supposed that hyperpolarisation of the membrane in the varicosities might block the invasion of the varicosities by the action potential; however, if the action potential is in fact conducted in the varicosities, then hyperpolarisation would increase its amplitude and so increase the amount of transmitter released.

The authors claim that the re-use of synaptic vesicles in nerve endings is not compatible with the idea that noradrenaline is released, together with dopamine-β-hydroxylase, from the vesicles by exocytosis (p34). I can see no inconsistency since after a vesicle, that has newly arrived in the terminal following transport from the cell body, has released its noradrenaline and soluble dopamine-β-hydroxylase, the vesicle membrane can probably be retrieved from the plasma membrane to form a new type of vesicle. The new vesicle is perfectly functional since it contains the (non-releasable) membrane-bound dopamine-β-hydroxylase and can store noradrenaline by means of the pump in its membrane. Such a re-use of the vesicle membrane provides an answer to the authors' problem that, if each vesicle is only used once, then the supply of vesicles by axoplasmic transport from the cell body to the terminal is apparently not adequate to maintain transmission (p91).

"Freckie (the otter) is displeased". Taken from *The River People.* By Philip Wayre. Pp. 180. (Collins and Harvill: London, 1976.)

One of the best features of the book is the discussion of neuroeffector transmission. Here the authors illustrate the key importance of the size of the gap between the terminal varicosity of a neurone and the effector cell. In some tissues (for example, vas deferens, nictitating membrane, sphincter papillae) the gap is about 20 nm, whereas in blood vessels the minimum gap is larger and is also more variable (80–400 nm). Functionally, this range of distances means that those tissues in which the gap is small respond to nerve stimulation more quickly and at lower frequencies of stimulation than do tissues in which the gap is greater. Many of the differences found by pharmacologists in the responses of the various adrenergically innervated tissues to drugs can now be accounted for in terms of the size of the neuromuscular gap. In tissues in which the gap is fairly wide, the peak concentration of noradrenaline at the receptors following nerve stimulation may be close to the threshold concentration. In these tissues, decreasing the amount of transmitter released, either by depleting the vesicle stores (with reserpine) or by interference with the release process (with bretylium), is likely to inhibit neurotransmission. In contrast, in tissues in which the gap is small these two drugs have little effect on transmission because the peak concentration of noradrenaline at the receptor may normally be more than 100 times the threshold concentration. Such a high peak concentration following nerve stimulation could also account for the lack of effect of α-blocking agents on neurotransmission in the vas deferens since the concentration of blocking drug would not be high enough to compete with the transmitter. Finally, the ability of drugs like cocaine to potentiate neurotransmission in some tissues but not in others is most easily explained by the different size of the neuromuscular gap.

The lack of uniformity in the organisation of adrenergic neuroeffector systems has led the authors to propose a fascinating new hypothesis that the terminal network of an adrenergic neurone not only permits direct control of the smooth muscle by the nervous system but also acts in those tissues that are densely innervated, to protect the tissue from the influence of circulating catecholamines. This protective function is the result of the ability of the adrenergic neurone to sequester catecholamines that are in the extracellular space; the denser the innervation, the more effectively are catecholamines removed. The authors point out that densely innervated organs such as the vas deferens and iris perform functions that are quite unrelated to those of the adrenal medulla. This hypothesis represents the first serious challenge to the classical views of Cannon, who saw the sympathetic nerves and the adrenal medulla as, functionally, one physiological system. This book is thus doubly welcome for it not only serves as a useful and comprehensive introduction to the field but also provokes physiologists and pharmacologists to take a fresh look at adrenergic neurotransmission. □

Brain power for astronomy

W. H. McCrea

The Place of Astronomy in the Ancient World. (A Joint Symposium of the Royal Society and the British Academy.) Edited by F. R. Hodson. Pp. 276+25 Plates. (Oxford University: London, 1975) (Published for the British Academy.) £13.

'ASTRONOMY in ancient literate societies' (Part I) starts with a useful introduction to needed astronomical concepts and closes with an account of two uses of ancient astronomy, both contributions by R. R. Newton. These ensure maximum comprehensibility of the work and appreciation of some of its objects, the two chosen by Newton being the study of the non-gravitational acceleration of the Earth and Moon, and the study of chronology, particularly from ancient eclipse records. The intervening contributions are on Babylonian mathematical astronomy, Babylonian observational astronomy, ancient Egyptian astronomy, astronomy in ancient and medieval China, and Mayan astronomy in central America. For most readers the striking general features must surely be the widespread character of astronomy in the ancient world and the inference that scientific astronomy in Greece, India, Islam and western countries was so much derived from Assyrian and Babylonian astronomy. Indeed, there is no chapter on Greek astronomy as such; presumably the characteristic Greek contribution is to be regarded as one of interpretation rather than discovery.

Part II is on 'Ancient astronomy: unwritten evidence' with contributions on 'Neolithic science and technology', 'Polynesian and Micronesian astronomy', 'Prehistoric monuments in western Europe', 'Astronomical alinements in Britain, Egypt and Peru', 'Archeological tests on supposed prehistoric astronomical sites in Scotland'. These deal with the most recent sort of study of ancient astronomy and that which has attracted most popular attention. There follows a chapter by H. H. Lamb on 'Climate, vegetation and forest limits in early civilised times' and one by D. G. Kendall on 'Hunting quanta'. These two are highly relevant in topic and they show the extraordinary range of science that has to be brought to bear on the problems concerned. The investigation as to whether the dimensions of megalithic sites reveal the use of a quantum (5.44 feet, 1.66 m) demands novel mathematical statistics of subtle ingenuity (but it seems not to have been tested by re-discovering the foot or the metre!). The book includes brief reports of some informed discussion at the meeting.

Within the allotted space, the book provides surely the best possible accounts of its topics. It is a feast of learning and scholarship, strongly spiced with wit and wisdom. It is thought-provoking in innumerable ways; some of these are noted in the concluding remarks by D. G. King-Hele and by S. Piggott from the sides of the physical scientists and the archaeologists. Naturally one of the most obvious features of some of the unwritten evidence is its uncertainty. On the whole, readers may be inclined to agree with King-Hele that some features of prehistoric sites did indeed mark extreme rising and setting points of the Sun and Moon, and the like, whereas a connection with eclipse prediction seems less likely. As regards the alinements, E. W. MacKie in his contribution remarks explicitly on the difficulties of the subject, but he then asserts: "The plausibility or otherwise of these alinements is something all can assess by visiting the sites". Actually a party of Cambridge undergraduates did subsequently visit some of the sites and came away rather dubious about the alinements (M. E. Bailey *et al.*, *Nature*, **253**, 431, 1975). But MacKie's assertion is surprising because the problem tackled by Kendall is the most straightforward in the subject and yet all his powerful statistical apparatus is unable to produce a definite conclusion from the available evidence. All the other inferences about the sites seem to be *a fortiori* quite indefinite—but fascinating and deserving of the most thorough-going investigation.

The brain power of even the most ancient of the peoples concerned—as King-Hele says—cannot have been appreciably different from that of our contemporaries. This raises all manner of questions about the progress of knowledge and understanding of the astronomical world. Our knowledge is more than that of the ancients, but is our ignorance as great as theirs? Does almost constant brain power produce accelerated growth of technique and accompanying increase in knowledge? Or do developments occur in fits and starts with peaks of knowledge and understanding and great gaps between the peaks? Is our knowledge placed on record in such a way that people 3,000 years hence will be aware of what we know much better than we are of what people knew 3,000 years ago? This book will provide material for endless debates. □

Scientific Research in British Universities and Colleges 1974-75

At a time when utilization of expertise is greater than ever before, these volumes form a guide to the location of experts, and help to avoid duplication of effort. They cover an enormous sector of the research field with economic as well as scientific/engineering aspects listed, so they have wide application in industry, commerce and public service as well as in the academic world.

Volume I, (Physical Sciences) Covers pure and applied sciences from Aeronautics and Astronomy to textile Technology. **£14.80** (£15.55)

Volume II (Biological Sciences) Includes a wide range of agricultural and medical subjects among its 46 groupings **£11.25** (£11.87)

Volume III (Social Sciences) Includes research from government departments and many non academic institutions as well as work from Ph.D. students: subjects listed include Business; Industrial and Management Studies, Economics, Education, Law and Social Medicine. **£10.65** (£11.27)

Peaceful Nuclear Explosions IV

Proceedings of a Technical Committee. Vienna 20-24 January 1975 *IAEA Publication* **£13.50** (£13.98)

Promoting Health in the Human Environment

A review based on the Technical Discussions held during the Twenty-Seventh World Health Assembly 1974. *WHO Publication* **£1.80** (£1.91)

Natural Environment Research Council

Institute of Terrestrial Ecology

Annual Report 1974

Reviews the first year of the ITE, covering areas such as vertebrate and invertebrate ecology, plant biology, soil science, analytical services and research and development. **£2.75** (£3.03½)

Prices in brackets include postage

Worm's eye view

Neil A. Croll

The Biology of Free-Living Nematodes. By Warwick L. Nicholas. Pp. viii+219. (Clarendon: Oxford; Oxford University: London, August 1975.) £8.25.

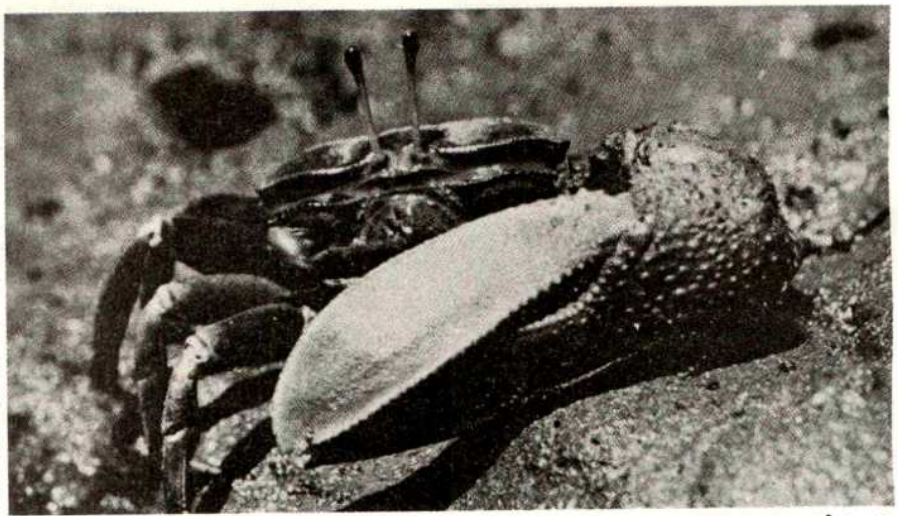
THE study of nematodes, perhaps more than with any other group of animals, is divided by the artificial barriers of professional groupings, journals and institutions. Too little communication exists between 'helminthologists', 'plant nematologists' and 'invertebrate biologists'. Dr Nicholas's book brings establishment to another faction, the free-living nematodes. As such it further frustrates the attempts of those who would study nematodes as a single biological grouping; it does, however, recognise the important role of the new nematologists who specialise in 'free-living' forms. 'Free-living' is a difficult notion; essentially it describes what is left when the parasitic species are taken away. Such a definition has hazy edges: parasites often have 'free-living' larvae, fungal feeders are free-living, but species which feed on higher plants are parasitic. Dr Nicholas wisely does not attempt strict definitions and emphasises soil, fresh water and marine forms.

As a series of essays some chapters can be recognised as those in which Dr Nicholas has had direct personal experience—such as 'Culture and Nutrition', Cytogenetics and Development' and 'Biochemistry'—and these achieve a high level of comprehension and accuracy. The chapter on 'Ecology' is a clear and thoughtful assemblage of a very heterogenous subject area, and is the best short review of the subject currently available. One of the most attractive features of the book is that marine nematodes are not neglected. Furthermore, they are set apart from other free-living species on basic biological criteria but at the right distance.

In the first chapter on Morphology and Structure, much of the information is drawn from nematodes other than free-living forms. This has introduced some patchiness and has resulted in such important sections as those on the sense organs, excretory system and cryptobiosis being weaker than the other more restricted parts of the book. References are quoted but they are not necessarily the most relevant; they do not always demonstrate a synthesis made by the author before their selection. The book is eminently readable and the few typographical errors and mis-spelled names are more distracting than misleading. The book is informative rather than scholarly. Dr Nicholas has chosen a chatty style which narrates the subject rather than one that provokes the reader to think beyond these pages. Typical of this are his useful chapters on taxonomy and methods of handling and culturing.

There are over 1000 references but only 20 are quoted after 1971 and none after 1973. This has resulted in certain topics, in which rapid growth has occurred, already being dated; it is, however, more contemporary than any other competing text.

Nematodes are being widely used as model metazoans by geneticists, behaviourists, gerontologists, and developmental biologists. This is the best book available to give these researchers and their students in allied disciplines a 'worm's-eye view' of the nematodes. ☐



Male fiddler crab (*Uca maracoani maracoani*), Trinidad

Fiddler crabs

R. G. Hartnoll

Fiddler Crabs of the World: Ocypodidae—Genus Uca. By Jocelyn Crane. Pp. xxiii+736. (50 plates.) (Princeton University: Princeton, New Jersey, November 1975.) £43.70.

WITH over seven hundred large pages, and weighing in at only a shade under 3 kg, this is a truly impressive book at first sight. It is a pleasure to report that this favourable opinion is reinforced by a study of the contents. This monograph covers all the known species of *Uca* in respect of taxonomy, functional morphology and behaviour. To a great extent it is based on many years of the author's own work in various regions of the world, and as a consequence the different topics are integrated to an unusual degree.

The first and larger part of the book is the systematic section within which each of the 62 species of *Uca* is dealt with in turn. For each one there is a full morphological description together with an analysis of its differences from related species, followed by details of behaviour, distribution and type material. I was relieved to find that the genus *Uca* was not fragmented here, for although large it has a distinctiveness and homogeneity which render it an excellent example of the generic concept. Recently Bott (*Senckenberg. biol.*, **54**, 315–325; 1975) has proposed the division of *Uca* into nine genera, but it now seems unlikely that this partition will be generally accepted. Dr Crane renders the genus manageable by introducing a new scheme of subgenera, and simplifies a number of taxonomic difficulties by a judicious use of subspecific categories. Her analysis of criteria for erecting subspecies is particularly interesting.

The second part of the book contains a series of chapters which collate and discuss, subject by subject, the information presented species by species in the first. There are excellent chapters on zoogeography, environmental relationships and functional morphology, but to me the most interesting are those on behaviour and evolution within the genus. Few large genera have been analysed in such detail with regard to these latter.

There are a number of appendices, of which the most useful are the keys to species in different geographical areas, and that providing practical advice on the observation, collection, transport and maintenance of these crabs. There are many high quality line drawings and photographs which amplify both the morphological and behavioural accounts. Overall this is a remarkably comprehensive review of a most interesting genus, and has been produced to a very high standard. It will be of great interest to carcinologists of a variety of disciplines, and it is only a pity that the economics of publishing must put it beyond the reach of most. ☐

Biology of man . . .

Cedric A. B. Smith

Human Variation and Natural Selection. (Symposia of the Society for the Study of Human Biology. Volume 13). Edited by D. F. Roberts. Pp. ix + 209. (Taylor and Francis: London, 1975). £4.50.

THIS book consists of a selection of papers read at meetings of the Society for the Study of Human Biology about 15 years ago, and published in previous symposia about that time. In spite of the lapse of time since then these papers still have freshness and relevance. A considerable amount of detailed knowledge has accumulated in the topics dealt with in many of the papers since they were written; but the basic ideas have not changed very much, even though the emphasis may now be different.

The first topic of importance essentially concerns the factors shaping the relative frequencies of various inherited characters in a natural population. There are contributions on that by L. S. Penrose, A. R. G. Owen, C. A. Clarke, P. M. Sheppard and T. Dobzhansky. They explain three main ways of maintaining variability in a population, namely by heterozygote advantage, by mutation counter-balanced by natural selection, and by natural selection favouring different types in different habitats. There are three main ways of introducing genetic variability for a limited time: genetic drift, and the response to changing natural selection, either because of a temporary change (for example, an epidemic) or a permanent shift in environment. Fifteen years ago we knew one clear case of heterozygote advantage, the sickle-cell polymorphism in Africa, described by Allison in a later paper in this book, and a number of cases of balance between mutation and selection. Although theory has been developed much further, observational knowledge remains substantially as before.

Another group of papers, by A. E. Mourant, A. C. Allison, N. A. Barnicot and S. M. Gartler, examines various Mendelian characters which show polymorphism, such as blood groups, haemoglobins, haptoglobins, transferrins and amino acids. Except for certain polymorphisms, such as that of abnormal haemoglobins, which seem to be related to the presence of malaria, these characters seem suitable for anthropological investigations designed to find which populations are most closely related. Later work has extended this list, especially as regards enzyme variability.

Drawing of a spectral tarsier. Taken from *Uniqueness and Diversity in Human Evolution: Morphometric Studies of Australopithecines.* By Charles E. Oxnard. Pp. viii + 133. (University of Chicago: Chicago and London, 1975.) £9.

There are also papers by A. C. Stevenson on "Biological studies of small communities". E. H. Ashton on "Rate of change in Primate Evolution", S. B. Holt on "Dermatoglyphic Patterns", and G. A. Harrison on "Pigmentation".

Each paper has had added to it a few paragraphs indicating more recent developments in the field. □

. . . and baboons

T. H. Clutton-Brock

Social Dynamics of Gelada Baboons. (Contributions to Primatology, Volume 6.) By Robin and Patsy Dunbar. Pp. viii + 157. (Karger: Basel, London and New York, 1975.) SFr.89; DM 85; $37.25.

To casual inspection, the social system of geladas closely resembles that of hamadryas baboons: the population is divided into stable harem units usually consisting of a single mature male, around three adult females and their offspring. Younger males join unisexual troops and both harems and all-male groups form bands which share a common home range. The takeaway message of the Dunbars' monograph is that superficially similar social systems may be the product of different behavioural arrangements. In the hamadryas, harem units are maintained by the chauvinistic activities of the male, who herds females and enforces group cohesion. In the geladas a more egalitarian situation prevails and harem units are maintained by strong social bonds between females.

The monograph provides a detailed but readable description of the anatomy of gelada social organisation. Its claim to cover group dynamics is less well justified. The study was of relatively short duration and few individuals could be recognised. As a result, virtually all interpretation of group dynamics is based on selected evidence. A more fundamental shortcoming (although one which has applied to many primate field studies) is the lack of theoretical orientation. This leads to a number of unfortunate effects: extensive description of trivial or obvious aspects of social behaviour, persistent attention to null hypotheses which are palpably false, and inadequate discussion of points of particular interest. The book will be of major interest only to primatologists. A stronger theoretical bent could have led to a study which was of much wider significance. □

Male gelada baboon

ARDEA Photographics

Molecular biology of RNA phages

J. Hindley

RNA Phages. Edited by Norton D. Zinder. Pp. viii+428. (Cold Spring Harbor Laboratory: Cold Spring Harbor, 1975.) n.p.

RNA Phages is the latest of the Cold Spring Harbor Monograph series and provides 400 pages of endeavour devoted largely to our understanding of the structure, replication, and translation of the phage genome. The RNA phages are among the smallest known viruses and since the techniques for RNA sequence analysis preceded those for DNA, they formed the logical choice for the new art of the sequencer. This emphasis is apparent in many of the contributions and adds a comfortable sense of reality to the descriptions of the various interactions which regulate the replication and translation of the viral RNA.

The fourteen chapters of this book provide a reasonably well balanced selection of current work and interest in this field. Invariably there are some omissions, and some are serious, for example the work of Weissmann *et al.* on the *in vitro* synchronised synthesis of both plus and minus RNA strands; and the extension of such methods in site-directed mutagenesis gets negligible attention. Similarly the important research of Porter *et al.* on the rebinding of $Q\beta$ initiator fragments to *Escherichia coli* ribosomes fails to get any mention whatever in spite of their particular relevance to the problem of ribosome recognition of initiator regions in phage RNA.

The first chapter provides an authoritative account of the physical properties of RNA phages and their RNAs, and the second contribution reviews the genetic studies which established the presence of three cistrons (complementation groups) in RNA phages.

One of the most informative features contributing to the study of RNA phages is the ability to compare primary RNA sequences with the amino acid sequences of the phage-specified proteins. The third chapter reviews our knowledge in this direction and clearly brings out the value of such work in pin-pointing the initiation triplets, the apparent non-random use of synonymous codons, the location and effects of amber mutations and the explanation of the 'read through' phenomenon found in phage $Q\beta$.

The fourth chapter surveys the physiology of phage attachments and penetration, and makes the point that much remains to be done in understanding these phenomena. Nearly 100 pages in the succeeding four articles are devoted to the replication of phage RNA. This makes fascinating reading and the main impression one is left with is the exquisite adaptation of the replicase complex, which contains both virus- and host-specified proteins, to the selective and controlled replication of the viral RNA. No less interesting is the elaborate control exercised on the translation of the viral RNA and this topic is discussed in the next three chapters. Again it is the level of organisation and sophistication achieved in these, the simplest of phages, which excites the wonder of the reader. The *tour de force* of the book comes in chapter thirteen in which Fiers presents the entire RNA sequence of the A-protein gene of phage MS2 and shows the value of such detail in grappling with the problems of gene organisation.

To complete the picture the morphogenesis of RNA phages, and the fact that *E. coli* is not unique in acting as host to RNA phages, are discussed in two informative contributions.

The clear message of this book is that the molecular biology of RNA phages have much wider implications into the general problems of replication and translational control, and it can be recommended to the student and specialist alike. □

Paracelsian chemistry

M. P. Crosland

The Chemists and The Word: The Didactic Origins of Chemistry. By Owen Hannaway. Pp. xiii+165. (Johns Hopkins University: Baltimore, Maryland and London, November 1975.) £6.50.

When did chemistry emerge as a distinct discipline? Hermes, Tresmegistos, Moses, Aristotle, Jabir, Paracelsus, Boyle, Lavoisier and Liebig have all been candidates with their respective supporters for the title of founder of chemistry. Even if we refuse to take the earlier names in this list seriously we cannot ignore a group of contemporary historians of science who have made great claims for Paracelsus and (more convincingly) for some of his followers. They have argued that the chemical philosophy of the Paracelsians in the sixteenth and seventeenth centuries was not only fundamental to the development of chemistry but to science generally. It sought to comprehend all natural phenomena and thus provided an alternative to both the traditional philosophy of Aristotle and the new mechanical philosophy of Descartes. Yet the obscurantism and secrecy of some Paracelsians have hardly helped to support this claim. Their apparently arbitrary use of language made any dialogue with outsiders extremely difficult. Dr Hannaway appreciates the relevance of the Paracelsians but admits that there was an essential difference between their aims and methods and that of a rational science. He therefore attempts a synthesis and tries to pin-point the beginning of the science of chemistry in a reaction to Paracelsianism. His hero is Andreas Libavius who first appears as the enemy of Paracelsian chemistry, seen as a "counter-culture". But it was the same Libavius who became the propagandist for a new chemistry, presented in a systematic and logical form.

A full discussion of the various strands of Paracelsianism would require a book of massive proportions and we can accept the author's decision to focus on one writer, Oswald Croll, as a representative of the Paracelsian school. This choice enables him to expose some of the deficiencies of the Paracelsians and to contrast their approach with that of Libavius. Hannaway suggests that chemistry emerged not so much from Paracelsian alchemy as from a more positivistic attitude of those who tried to present a new and rational science in textbook form. This is a plausible argument but the author goes further in claiming that the writing of one particular textbook, the *Alchemia* (1597) of Libavius constituted the "invention" of chemistry. It is easier to interpret the role of textbooks in science as providing a consolidation of a new approach rather than the main instrument of a "scientific revolution", and a detailed discussion of Ramism is included to help support this argument.

I would like to be able to recommend the book to any working chemist who felt that the didactic origins of his subject were worthy of some consideration. It would be fairer, however, to recommend the book rather as a contribution to the intellectual history of the sixteenth century. With its detailed textual analysis it is more a book for the specialist. Readers may not be convinced that the work of Libavius alone marked the beginning of 'real' chemistry but the discussion provides a persuasive reminder of the metaphysical and religious context of the emergence of early modern science. □

Reference work on rabies

G. S. Turner

The Natural History of Rabies. Edited by George M. Baer. Volume 1: Pp. xvi+454. $43.00; £21.50. Volume 2: Pp. xvi+387. $36.00; £18.00. (Academic: New York and London, September–October 1975.)

THESE two volumes provide a comprehensive central source of information on many facets of this ancient disease. They examine the molecular biology of the virus, the pathogenesis and pathology of rabies, its diagnosis, epidemiology and its prevention in man. The contributors of the 42 chapters have in many cases either been members of, or advisors to, the World Health Organisation (WHO) expert committee on rabies. Readers active in rabies research will recognise many familiar footprints in well trodden ground.

Whether the contents always justify the title of 'natural history' is arguable since this implies a continuing record of natural phenomena. Advances in rabies research seem to be discontinuous—much of the mythology was dispelled by Pasteur but more than 60 years elapsed before the successful application of cell culture methods enabled the virus to be seen for the first time, and also permitted the first reasonably accurate estimate of its size, the physicochemical and biological properties of which are described in part I. Similar methods, described in chapter 9, enabled mechanisms of infection and growth at the cellular level to be examined.

The section on the pathogenesis of rabies recalls arguments concerning the respective roles of neural and haematogenous spread of virus to the central nervous system (CNS). Evidence is also discussed for extraneural replication of virus before and after invasion of the CNS Latent and abortive rabies is reviewed here as well as the effects of interferon on infection. Contributors remind us, however, that the scanty histological changes observed in infected animal brain, contrast strikingly with the severe clinical signs observed in rabies, and that its pathogenesis remains "a complicated and little understood series of events".

The section on laboratory diagnosis details techniques which are already described elsewhere (see WHO monograph series No. 23, *Laboratory Techniques in Rabies*). Surprisingly the passive haemagglutination test for rabies antibody does not appear here.

Almost half the second volume is devoted to epidemiology. Individual chapters provide abundant information on rabies in each of many wild and domestic animals in both natural and experimental conditions. Wildlife data concerns several species indigenous only to the new world. No doubt the omission of global epidemiology reflects difficulties in acquiring information from underprivileged countries in which rabies is endemic.

The chapters devoted to the control of rabies in dogs, cats and other domestic animals seem to prefer vaccination to other means, Although vaccination is undeniably effective it is not a control method likely to be favoured in England at the moment. Included in the methods reviewed for the control of wildlife rabies are population reduction, vaccination, the use of gametocides and more recently the use of anticoagulants for destroying vampire bats. The methods mostly suggest directions for future research rather than immediate solution of this intransigent problem.

The final chapters deal with rabies in man, its prevention, first aid treatment, diagnosis and clinical manifestations. Recent optimistic hopes of cure of the overt disease by aggressive intensive care are also mentioned. Here too, details are given of the passive immunisation of man with anti-rabies serum as well as a highly critical review of human, postexposure vaccine therapy and the difficulties of assessing its efficacy. An appendix gives a guide to specific treatment.

Not every contribution is a model of stylistic or verbal excellence and the occasional mistake has escaped the proof reader. This is probably inevitable in a work of this magnitude and in no way detracts from its value as the best and most practical reference text on the subject that has appeared in recent times. □

Endocrine system in perspective

K. Fotherby

Comparative Vertebrate Endocrinology. By P. J. Bentley. Pp. xi+415. (Cambridge University: Cambridge, London and New York, January 1976.) Cloth £12; Paperback £4.95.

ENDOCRINOLOGY is a fascinating subject and to those of us who deal mainly with human endocrinology this fascination is increased by taking a broader view and looking at the way in which the endocrine system has evolved. For this purpose this textbook is ideal. It presents the subject matter in a readable way emphasising the differences between species from a functional aspect. It not only contains a wealth of information concerning the endocrinology of the various species but also contains more than enough basic information concerning the biosynthesis, metabolism and mode of action of the hormones for the book to be read and understood without the necessity of referring to a textbook of basic endocrinology.

In addition to chapters on the comparative morphology of endocrine tissues and the chemical structure and polymorphism and evolution of hormones, there are chapters dealing with the relationship between endocrinology and nutrition, calcium metabolism, the integument, osmoregulation, and reproduction. The text is illustrated with many excellent diagrams.

Although there are species differences in the morphology of the endocrine tissues, and in the chemical structure and biological and immunological behaviour of the hormones, many of these variations are such that they can often be placed into categories corresponding to the major systematic groups of vertebrates. These species differences suggest an orderly evolutionary change. The pathways of hormone synthesis, mechanisms of secretion and mode of action seem to be similar in all vertebrates although the nature of the stimulus responsible for the secretion of a particular hormone may vary according to the physiological role in which the hormone may be involved.

The longest chapter in the book is that devoted to reproduction. This is not surprising since the reproductive process shows a wide diversity of morphological and physiological characteristics, and the latter requires the co-ordination of many different events which are controlled by a number of different hormones. In spite of the wide variation in the morphological and physiological aspects of reproduction, the nature of the hormones involved varies little. The gonadal steroid hormones have the same structure in all vertebrates. More variation is shown by the gonadotrophins; and it is of interest that in most tetrapods the pituitary secretes two gonadotrophins, luteinising hormone and follicle-stimulating hormone, whereas in some vertebrates e.g. fishes, only a single gonadotrophin is secreted.

Although written as a textbook for graduate and undergraduate courses in comparative endocrinology, it should be read by all interested in endocrinology. It will be useful as a reference book for research workers, and the availability of a paperback edition may ensure a wide sale for this excellent book. □

All you need to know about H–2

Hilliard Festenstein

Biology of the Mouse Histocompatibility-2 Complex: Principles of Immunogenetics Applied to a single system. By Jan Klein. Pp. xii+620. (Springer: Berlin and New York, 1975.) DM97.60; $42.

During the past decade, the science of immunogenetics as applied to the major histocompatibility system, previously regarded as a somewhat esoteric area of scientific endeavour, has come into its own. Its rate of development has been unprecedented and it has provided new insight into such diverse biological problems as transplantation and cancer immunology at one end of the spectrum to those which are not even immunological at all—like hormonal control and the genetics of infertility—at the other end of the spectrum It represents the key to the understanding of antigen recognition, cell interaction, embryonic development and differentiation, and processes involved in the pathogenesis and manifestation of a variety of diseases. It has become important not only for the basic scientist but also for clinicians—rheumatologists, neurologists, nephrologists, obstetricians, endocrinologists, to mention but a few.

The major histocompatibility system is the most complex and polymorphic system geneticists have had to cope with and the more that is known about it, the more important it seems to become. Jan Klein's exhaustive treatise on the immunogenetics of H–2 is thus a very welcome and timely arrival It starts with an introduction dealing with the history of transplantation immunogenetics and the geneology and origin of the inbred and congenic laboratory mouse strains; there follow detailed descriptions of the methods and the current status of H–2 serology In the section dealing with histocompatibility, there is a short introduction to transplantation immunology followed by a discussion on the methods of histocompatibility testing and effects, comparing those of the H–2 system with various others—the erythrocyte (Ea) alloantigen loci, Ly, virus-associated alloantigen loci and non-H–2 histocompatibility loci

The section on the principles of genetic analysis, recombination and mutation in the H–2 complex and the genetics of the H–2 linked loci will be of particular value to those researchers entering the field; it contains a clear account of the genetic terminology and approach basic to an understanding of this science There is also a comprehensive section on the biochemistry of the H–2 gene products. The book is reasonably up to date and even includes discussions on the recently discovered complement gene in H–2 and the Ia specificities, as well as the newly described *X* locus. It ends with a short speculative chapter on the function and evolution of the H–2 complex; and there is a chronological table of the major events in the history of the H–2 system which is interesting and puts the author's own contributions into perspective. The references are an invaluable part of this book and will provide researchers with a rapid and comprehensive list of the major publications in this fascinating and new field.

This book will probably find a place on the shelf of every laboratory seriously engaged in the study of immunogenetics. □

Indispensible guide to tropical pollution

C. M. Yonge

Tropical Marine Pollution. (Elsevier Oceanography Series, 12.) Edited by E. J. Ferguson-Wood and R. E. Johannes. Pp. ix+192. (Elsevier Scientific: Amsterdam, Oxford and New York, 1975.) Dfl.65; $26.95.

We may be grateful for the original idea of the late E. J. Ferguson-Wood resulting in the production of this book under the final editorship of R. E. Johannes, who is also responsible for writing much the most important sections.

Although temperate seas have been the initial sufferers from pollution, the basically more susceptible tropical waters are all too rapidly becoming similarly afflicted. And what may be effective preventive measures in the former regions may not be applicable in the tropics. In so many different ways involving chemical and physical characters, community structure and biological processes, responses to pollution in the tropics differ significantly from those in temperate waters.

The second and longest chapter comprises the fullest available study of pollution and degradation of coral reef communities Writing with a great wealth of experience, Dr Johannes covers every aspect of the problem from the effects of sedimentation to those of dredging, from those of bad land management to those of sugar mill discharge and of sewage outflow, the latter so dramatically demonstrated at Kaneohe Bay to the north of Honolulu where I once collected from immaculate reefs. He finally discusses effects of oil and thermal pollution, and those of abnormal salinities. These last are produced by desalination plants, an analysis by R. H. Chesher of the impact of one at Key West forming the final chapter.

What is known about the impact of man on mangroves—it is estimated that some of those defoliated during the Vietnam war may take a century to recover—is succinctly reviewed by W. E. Odum and R. E. Johannes. There is a most useful account by J. C. Zieman of the effect of pollution on tropical eel grass communities, aptly described as "nurseries, food producers and stabilisers of the sea floor." The same author also collaborated with Ferguson-Wood in a description of the effects of thermal pollution by a power station most unsuitably sited in Biscayne Bay, Florida and involving the destruction of both sea grass beds and mangroves.

Although there is much of value in all chapters, those contributed by Dr Johannes are of over-riding importance greatly enhanced by his personally assembled list of references occupying 28 pages. This is a short and expensive book but is contains a wealth of information valuable to all, but surely indispensable to those confronted by the almost daily growing problems of pollution in tropical seas. □

Multidisciplinary approach to pollution

N. W. Moore

Pollutants and Animals: A Factual Perspective. By F. Moriarty. Pp. 140. (Allen and Unwin: London, September 1975.) £5.65.

This short book is a lucid account of the facts which have to be taken into account by those who study the effects of pollutants on living organisms. Probably more is known about the pollution effects of the organochlorine insecticides than any other chemical group, and so Dr Moriarty uses the organochlorines as the example on which to base his pertinent conclusions. About 80% of the book is about these compounds and the chemically related polychlorobiphenyls (PCBs), the remaining 20% being devoted to the effects of heavy metals, and a brief general review of pollution in air, water and on land. Radioisotopes are covered in two pages. At first sight the subject matter of the book seems unbalanced, but the advantages of using the organochlorines as an example outweigh this disadvantage.

Pollutants and Animals is accurate, clearly written and very readable Technical terms such as axon, isomer and isotope are defined and so it can be read by the informed layman as well as by scientists with a professional interest in pollution research and control, or in teaching or learning about pollution. Dr Moriarty shows how ideas have progressed in recent years, and, by pointing out significant gaps in knowledge, also succeeds in putting over the authentic 'feel' of doing research in this field. Studies which should be extended include those on the possible biological effects of pesticide metabolites, the behaviour of DDT in mud, the extent to which DDT is converted into DDE and transformed to PCBs in the physical environment, and laboratory studies on the interactions of different pollutants on fish.

Dr Moriarty's comments on the limitations of the LD$_{50}$ test are salutary for those who rely too much on this particular indicator of hazard. The desirability of obtaining more residue data when toxicological tests are made, is another practical requirement to which Dr Moriarty draws attention.

Conventional wisdom has it that organochlorine insecticides always become concentrated in food chains. In his critique of the pioneer work of Hunt and Bischoff at Clear Lake, Dr Moriarty shows how that hypothesis has had to be modified in the light of subsequent research. Similarly, it is commonly believed that populations of birds of prey have declined as the result of sublethal effects of organochlorines. Dr Moriarty, in a perceptive review of this very complicated subject, shows how lethal and sublethal effects have varied in their relative importance between different species.

This book should be of great interest to those concerned with the organisation of science. It demonstrates not only the desirability, but the necessity of relating chemistry, toxicology and population dynamics in order to provide the scientific base for pollution control. The multidisciplinary team of which Dr Moriarty was a distinguished member, was a casualty of the split of the Nature Conservancy. Some way must be found of supporting similar teams in the future. Anyone reading this excellent book will come to appreciate why. □

Food from the sea

G. E. Fogg

Marine Photosynthesis: With Special Emphasis on the Ecological Aspects. (Elsevier Oceanography Series, 13.) By E. Steemann Nielsen.) Pp. ix+141. (Elsevier Scientific: Amsterdam, Oxford and New York, 1975.) Dfl.52.00; $21.75.

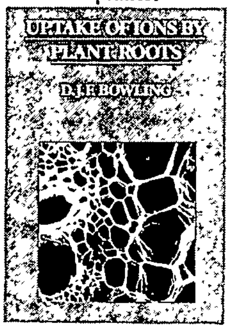
PROFESSOR Steemann Nielsen has contributed more than any other person to our knowledge of photosynthesis in the sea. His introduction in 1952 of the radiocarbon technique gave us a simple and sensitive means, which has been very widely used, for measuring the rate of photosynthesis in natural waters; and his laboratory experiments have deepened our understanding of the manner in which the photosynthetic activity of phytoplankton organisms varies in response to conditions in the sea. In this book, the first to be devoted to a kind of photosynthesis which provides at least half the Earth's supply of food materials, he brings together these contributions and sets them against the background of modern ideas about the mechanism of the photosynthetic process and its evolutionary history.

This background is sketched in the first two chapters; there follow discussions of underwater daylight, the units in which irradiance should be expressed, the kinds of photosynthetic organisms in the sea, the effects of various factors on their photosynthetic activity, the interrelationships of photosynthesis and respiration, and physiological adaptation to irradiance and temperature. The later chapters deal with photosynthesis *in situ,* and the primary production of the sea and its importance to man. It is a pity that in this account the author should have confined himself rather strictly to presenting his own work and avoided discussion of controversial matters such as the importance of extracellular products of photosynthesis.

Several independent groups of investigators now believe that they have demonstrated that healthy populations of natural phytoplankton frequently release as much as half of their photosynthetic product directly into the surrounding water. This much is briefly mentioned but after a longer discussion of the errors which may arise in the determination of extracellular products of photosynthesis the reader may be left with an impression, which the facts do not actually justify, that this important phenomenon is no more than an experimental artefact. Similarly, there is insufficient consideration of the implications of experiments by other workers on temperature adaptation.

Nevertheless, this is a wide-ranging and authoritative account which will be valuable and stimulating to students and research workers alike. □

MUTATION RESEARCH
Problems, Results and Perspectives
C. AUERBACH
April 1976: 528 pages: 86 line illustrations: 412 11280 9: hardback: £10.50
This book is intended for the senior-undergraduate and the postgraduate or research worker who wants either a review of the whole field of mutation or information about a specific problem within it. The book incorporates results on all types of organism: from prokaryotes and eukaryotes to animals and plants.



UPTAKE OF IONS BY PLANT ROOTS
D. J. F. BOWLING
March 1976: 222 pages: 4 pages of plates and 54 line illustrations: 412 12000 3: hardback: £6.50
This book provides an up-to-date assessment of our knowledge and understanding of mineral ion uptake by plant roots. The book offers an integrated approach covering movement of the ions in the soil and uptake into the root as well as transport in the xylem.
STATISTICAL ANALYSIS OF SPATIAL PATTERN
M. S. BARTLETT
February 1976: 100 pages: 412 14290 2: hardback: £3.50
The statistical analysis of spatial pattern and dependence has important applications in many areas of biology, geography and other sciences using quantitative methods. This monograph presents some of the relevant techniques, including methods only recently developed and not hitherto available in book form.

Biological problems of the deep sea

N. B. Marshall

Physiological Aspects of Deep-Sea Biology By A. G. Macdonald. Pp. xi+450. (Cambridge University: Cambridge and London, October 1975.) £18.50.

MONOGRAPHS of the Physiological Society " . . . review and assess important and neglected areas of physiology". The physiological aspects of this monograph are centred largely on the effects of hydrostatic pressure, which is certainly an important and neglected area of physiology. After the early experiments of Regnard and Certes in the 1880s, little was done until the late 1920s and 30s, as may be seen by reference to Cattells' (1936) *Biological Review*. The more recent and considerable advances in our knowledge of the effects of pressure on organisms are evident in Symposium XXVI (1972) of the Society of Experimental Biology and in an American Symposium (1972) entitled *Barobiology and the Experimental Biology of the Deep Sea* (Univ. North Carolina). Dr Macdonald was a contributor to both symposia. Besides his concern with the effects of pressure on the activity and metabolism of oceanic animals, he has also been involved in the design of apparatus for recovering deep-sea animals without pressure change.

In his brief introduction to the physical nature and inhabitants of the deep sea, the author devotes most space to the few species of animals, such as the ostracod *Gigantocypris* and the pogonophoran worm *Siboglinum*, that have been used by physiologists. There follow chapters on the molecular, biochemical, and physiological aspects of high hydrostatic pressure. Between these chapters and one entitled Deep-Sea Bio-engineering there are two dealing with sensory physiology and buoyancy in the deep sea and deep-sea nutrition

In his competent reviews of the effects of pressure from the molecular to organ system level, it is clear from more than the bibliography that most of the author's research has been on whole animals. When dealing with molecular aspects, he concludes that high pressure is of considerable importance in the molecular biology of deep-sea organisms but adds these cautionary words: "The volume changes and pressure effects which have been described were largely derived from *in vitro* systems and we have eventually to tackle the functional, living state. It is conceivable that a great deal of pressure sensitivity may disappear when an isolated protein is returned to its physiological environment. It is equally possible that the pressure sensitivity of intact animals will be greater than their isolated parts through amplification processes at the kinetic and integrated levels of organisation." Later he remarks that ". . . the intact organism may possess compensatory mechanisms which are absent in an isolated organ. Experiments with intact animals will help to identify some of their pressure-sensitive components." These quotations also show that the author writes well (although he could be more of a 'which hunter').

Thirty years ago, Sir Frederick Russell foresaw that physiologists would be eager to study deep-sea organisms when proper facilities were available. That physiologists are now able to take their equipment to sea is abundantly plain in Dr Macdonald's review of sensory physiology and buoyancy. Perhaps the outstanding contribution of other sea-going physiologists towards a proper understanding of deep-sea nutrition has been to measure rates of metabolism. How, for instance, do the changing pressures and temperatures that are experienced during vertical migrations affect the rate of oxygen consumption of deep-sea animals? Recently, *in situ* respirometry of benthic communities and benthopelagic fishes has shown that the pace of deep-sea life is much slower than that in shallow waters. But deep-sea conditions can be simulated in the laboratory, and what can be achieved by high pressure systems is well reviewed by Dr Macdonald in his last chapter, which also deals with the physiology of deep-sea man and the roles of deep-sea vehicles and surface ships.

In a comprehensive book of this kind errors are bound to occur, but one that is presumably not due to the author concerns the caption of Fig. 1 21 on page 28. The photograph is not of a rat-tail (macrourid) but of a chimaerid species.

The book contains a full bibliography (up to 1975). The references for each chapter are kept separate but 'pressurised' together at the end of the book, which makes transfers from textual references to bibliographies irritating to the reader Finally, I agree with the publishers' statement that "The book will be of great value to all interested in marine physiology and the biological problems of the deep sea" but wonder how many of "all interested" will be able to buy it. ☐

α-Chain contacts in the polymerisation of sickle haemoglobin

Ruth E. Benesch, Suzanna Yung, Reinhold Benesch & John Mack

Department of Biochemistry, Columbia University, College of Physicians and Surgeons, New York, New York 10032

Rose G. Schneider

Department of Pediatrics, University of Texas Medical Branch, Galveston, Texas 77550

Five new double-mutant haemoglobins composed of β^S chains and α chains with different substitutions, which are located at the surface of the tetramer, have been prepared. Although all the hybrids are more soluble than deoxyhaemoglobin S, the individual differences between these molecules make it possible to evaluate several regions on the α chains for intermolecular contacts in the polymerisation of deoxyhaemoglobin S.

THE discovery that the aggregation of deoxyhaemoglobin S (HbS) involves the formation of tightly packed helical rods[1,2] shows that multiple contact points must cooperate in the formation of the individual helices as well as in the interaction between adjacent tubules to give tactoids[3]. Identification of these contact points is facilitated by investigating the behaviour of haemoglobins which, in addition to the β^6 valine mutation, have others elsewhere on the surface of the molecule. Only two of these have so far been investigated—HbC Harlem[4,5] and HbS Memphis—and in both cases the additional substitution diminishes the tendency to sickle[4-6]. This implicated β^{73} and α^{23} in contact formation between adjacent molecules. To widen this approach we have prepared five new double-mutant haemoglobins which carry the β^6 valine substitution together with an additional one on the α chains. This facilitates a direct comparison of the effect of changing specific residues on the α chain on the properties of haemoglobins carrying the β^S substitution.

Preparation of hybrid haemoglobins

Haemoglobin was prepared from fresh human blood as described previously[7]. The mutant haemoglobins used in this investigation are listed in Table 1. HbS was obtained from a single homozygous donor by exchange transfusion. It was isolated by chromatography on CM–Sephadex (C-50) using a salt gradient of 0→0.1 M NaCl in 0.05 M phosphate buffer, *p*H 6.7. All the other mutant haemoglobins were separated from the haemolysates on DEAE–Sephadex (A-50) with a *p*H gradient of Tris buffer[13]. After column chromatography the haemoglobin solutions were concentrated using Amicon or collodion membranes. The purity of the isolated mutant haemoglobins was checked by acrylamide gel electrophoresis[14].

Hybrid molecules containing two β^S chains and two α chains derived from the mutant haemoglobin were prepared by incubating the α-chain mutant haemoglobin with a twofold excess of HbS in 0.2 M acetate buffer, *p*H 4.8, for 4 h at 0 °C as described previously[15]. The hybrids were again isolated by chromatography on DEAE or CM–Sephadex. HbS alone was subjected to identical procedures to serve as a control.

The identity and purity of the hybrids was established by electrophoresis both of the intact hybrid haemoglobins[16] and of the individual polypeptide chains[17]. Desarg HbS was prepared as described for Desarg HbA[18]. One mol of (arginine+ornithine) was liberated per αβ dimer and the protein was homogeneous on acrylamide gel electrophoresis. The oxygen equilibrium curves of all haemoglobins, including the hybrids, were measured at 20 °C and *p*H 7.30 as described previously[19,20]. Solubility was determined as a function of ionic strength in phosphate buffer, *p*H 6.8, by a modification of Itano's method[21,22] both in the presence and absence of dithionite. This method was chosen, rather than gelation measurements because it requires much

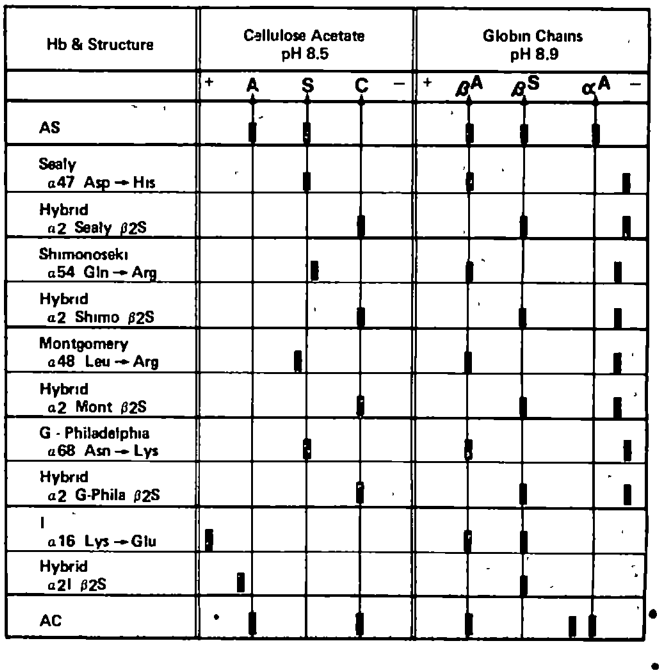

Fig. 1 Electrophoretic patterns of native and hybrid haemoglobins and their constituent globin chains on cellulose acetate. Tris-EDTA borate (TEB) buffer, *p*H 8.5, for haemoglobins; TEB buffer, *p*H 8.9, containing 2-mercaptoethanol and 6 M urea, for globins.

Table 1 Properties of mutant haemoglobins

Mutant haemoglobin	Structure	Ref.	% Total haemoglobin
Hb Sealy (hasharon)	$(\alpha^{47\ \mathrm{Asp} \rightarrow \mathrm{His}})_2\beta_2{}^A$	8	20
Hb Shimonoseki	$(\alpha^{54\ \mathrm{Glu} \rightarrow \mathrm{Arg}})_2\beta_2{}^A$	9	24
Hb Montgomery	$(\alpha^{48\ \mathrm{Leu} \rightarrow \mathrm{Arg}})_2\beta_2{}^A$	10	23
HbI	$(\alpha^{16\ \mathrm{Lys} \rightarrow \mathrm{Glu}})_2\beta_2{}^A$	11, 12	14
HbG Phila	$(\alpha^{68\ \mathrm{Asn} \rightarrow \mathrm{Lys}})_2\beta_2{}^A$	9	100*
HbSG Phila	$(\alpha^{68\ \mathrm{Asn} \rightarrow \mathrm{Lys}})_2(\beta^{6\ \mathrm{Glu} \rightarrow \mathrm{Val}})_2$	9	21

*The blood of this patient contained only HbG Phila and Hb H.
The latter was precipated quantitatively leaving HbG Phila in solution.

smaller amounts of material. Studies of chemically modified HbS have shown that these two methods give parallel results[23].

Characterisation of double-mutant molecules

Hybridisation between HbS and the α-mutant haemoglobins can be represented by the following equation:

$$\underset{\alpha\ \text{mutant}}{\alpha_2{}^X\beta_2{}^A} + \underset{\text{HbS}}{\alpha_2{}^A\beta_2{}^S} \rightleftarrows \underset{\text{Hybrid}}{\alpha_2{}^X\beta_2{}^S} + \underset{\text{HbA}}{\alpha_2{}^A\beta_2{}^A}$$

The electrophoretic mobilities of all the native and hybrid haemoglobins are shown in diagrammatic form in Fig 1. Four of the mutant haemoglobins, that is, haemoglobins Sealy, Shimonoseki, Montgomery and G Phila, have the same charge as HbS. Therefore, only three components are isolated after hybridisation, that is, the hybrid and HbA in equal amounts and a fraction of intermediate mobility containing both HbS and unchanged α mutant. In the case of HbI, on the other hand, all four components of the hybridisation mixture can be eluted separately. The hybrid haemoglobins comprised from 15 to 20% of the total. The electrophoretic patterns of the constituent globin chains of both the native haemoglobins and the hybrids are also shown in Fig. 1. The α chains of the four haemoglobins that resemble HbS electrophoretically all move cathodically to α^A, but the α chain of HbI moves anodically to α^A. The mobility of the α^I globin happens to be the same as that of β^S, so that α^I and β^S form only one band. None of the hybrid haemoglobins showed any appreciable contamination with α^A or β^A globin chains.

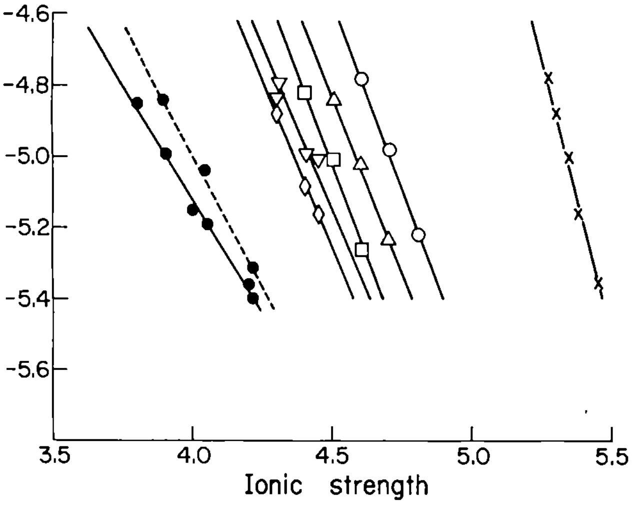

Fig. 2 Solubility of HbS and double-mutant haemoglobins. All measurements in potassium phosphate buffer, *p*H 6.8, at 25 °C. The solubility is given in mol of Hb tetramer per l of solution in the presence of solid phase. ●–●, S deoxy; ● – – ●, desarg S deoxy; ×, S oxy; ○, $\alpha_2{}^{\mathrm{Sealy}}\ \beta_2{}^S$ deoxy; △, $\alpha_2{}^{\mathrm{Shimo}}\ \beta_2{}^S$ deoxy; □, $\alpha_2{}^{\mathrm{Mont}}\ \beta_2{}^S$ deoxy; ▽, $\alpha_2{}^{\mathrm{G\,Phila}}\ \beta_2{}^S$ deoxy; ◇, $\alpha_2{}^I\ \beta_2{}^S$.

The structural and functional integrity of the hybrid tetramers was tested in several ways. (1) They bind oxygen cooperatively (n=2.4–2.6) and with a normal oxygen affinity. (2) HbS reisolated after hybridisation with HbA has the same solubility as the untreated protein. (3) In the case of one of the hybrids, that is $\alpha_2{}^{\mathrm{GPhila}}\beta_2{}^S$, it was possible to compare the tetramer prepared *in vitro* by hybridisation of HbG Phila and HbS with a naturally occurring one isolated from the blood of a patient who is heterozygous for HbG Phila and homozygous for HbS[8]. Since the natural and the synthetic hybrid gave the same result (Table 2) it can be assumed that the procedure for preparing the other hybrids has no effect on their solubility *per se*.

Solubility of mutant sickle haemoglobins

The effect of different substitutions in the α chain on the solubility of deoxyhaemoglobin S is shown in Fig. 2. Clearly all the double-mutant haemoglobins are significantly more soluble in strong salt than deoxyhaemoglobin S. This is in sharp contrast to the parent α-mutant haemoglobins which all have the same solubility as deoxyhaemoglobin A, that is their solubility is 10^{-5} M at an ionic strength of 5.70.

Since the most characteristic property of HbS is the large difference in the solubility of the oxy and deoxy forms, this value is used in Table 2 to compare the solubilising effect of the various α-chain mutations. Their influence on the solubility of the hybrid molecules must be due to interference with the polymerisation characteristic of deoxyhaemoglobin S because no solubilising effect of the α-chain substitution is found in the parent haemoglobin.

It is striking that a chemical modification of the α chains which favours the oxy conformation of haemoglobin[18], that is, removal of the C-terminal arginine residues, has little effect on the solubility of deoxyhaemoglobin S (Fig. 2).

The inhibitory effects of the different α-chain substitutions on the aggregation of HbS are not simply related to the alteration in charge. Thus, the Sealy and G Phila hybrids have the same charge and a very different solubility while the HbI and G Phila hybrids are almost equally soluble, but differ by six charges per tetramer.

It therefore seems that the synthetic hybrids represent a new approach to locating contact points provided by the α chains in the polymerisation of deoxy HbS. Such information is essential to restrict the number of possible orientations of the tetramers within the helix[24–27].

Fig. 3 Schematic model of the haemoglobin molecule showing the locations of the amino acid substitutions.

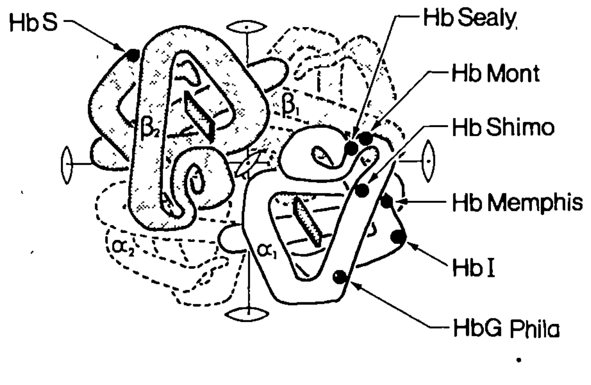

Table 2 Effect of deoxygenation on solubility

Haemoglobin	Position of α substitution	Ionic strength at which the solubility is 10^{-5} M Oxy	 Deoxy	 (Oxy–deoxy)
$\alpha_2{}^{A}\beta_2{}^{S}$		5.33	3.90	1.43
$\alpha_2{}^{\mathrm{Sealy}}\beta_2{}^{S}$	47	5.28	4.70	0.58
$\alpha_2{}^{\mathrm{Shimonoseki}}\beta_2{}^{S}$	54	5.28	4.58	0.78
$\alpha_2{}^{\mathrm{Montgomery}}\beta_2{}^{S}$	48	5.43	4.48	0.95
$\alpha_2{}^{\mathrm{G\ Phila}}\beta_2{}^{S}$ (synthetic)	68	5.50	4.42	1.08
$\alpha_2{}^{\mathrm{G\ Phila}}\beta_2{}^{S}$ (natural)	68	5.50	4.42	1.08
$\alpha_2{}^{I}\beta_2{}^{S}$	16	5.50	4.35	1.15

The positions of the α substitutions are shown in Fig. 3. It should be noted that all of them are on or near the surface of the molecule. It is clear, however, that there is considerable variation between the effect of the different substitutions on polymerisation. The largest increase in solubility is observed with $\alpha_2{}^{\mathrm{Sealy}}\beta_2{}^{S}$ with a substitution in the CD bend. Therefore, an intermolecular bond is probably located at this position. Moreover, the magnitude of the effect makes it likely that this bond is responsible for a large portion of the contact energy in this region. Conversely, the small increase in solubility due to the replacement of α^A by α^I chains suggests that here the substitution breaks only one of many bonds which participate in this contact region. This is in agreement with the conclusions reached by Levinthal *et al.*[28]. Figure 2 shows that the hybrids with α chains from haemoglobins Sealy and Montgomery have significantly different solubilities, although the substitutions are on adjacent loci (α47 and α48). Inspection of the three-dimensional model of haemoglobin reveals, however, that although residue 47 is on the surface of the molecule pointing outwards, residue 48 is oriented in the opposite direction.

The α mutants available to us have only permitted the preparation of hybrids with substitutions as far as the E helix (Fig. 3). We hope that gifts of α mutants with substitutions elsewhere on the α chain will make it possible to explore contact points in the remainder of this chain.

Bacterial cloning of plasmids carrying copies of rabbit globin messenger RNA

T. H. Rabbitts

MRC Laboratory of Molecular Biology, Hills Road, Cambridge CB2 2QH, UK

DNA copies of rabbit globin mRNA have been inserted into the plasmid mini-ColE1. After addition of poly(dT) tails, the plasmid was used to prime the copying of mRNA by reverse transcriptase. Mini-ColE1 carrying globin sequences were denatured and annealed with mini-ColE1 tailed with poly(dA). Functional plasmids containing the synthesised globin sequences were isolated by transfection in E. coli.

IT has been demonstrated that eukaryotic DNA can be cloned in bacteria after insertion into plasmids[1–4] or bacteriophage genomes[5]. These experiments indicate that it should be possible to clone any eukaryotic gene in bacteria and identify those bacteria carrying the gene by screening procedures involving hybridisation with radioactive messenger RNA (mRNA). This cloned DNA will facilitate the study of the sequence organisation and structure of eukaryotic genes. At present, bacterial cloning of defined eukaryotic protein-specifying genes has only been achieved with the multiple-copy histone genes[6]. The greatest proportion of genes, however, are found as single copies in the eukaryotic genome (for review see ref. 7).

Unless substantial purification of such genes can be achieved *in vitro*, cloning of individual plasmid-gene chimaeras (made from unfractionated eukaryotic DNA) will be difficult since specific clones are likely to be present in the population at the

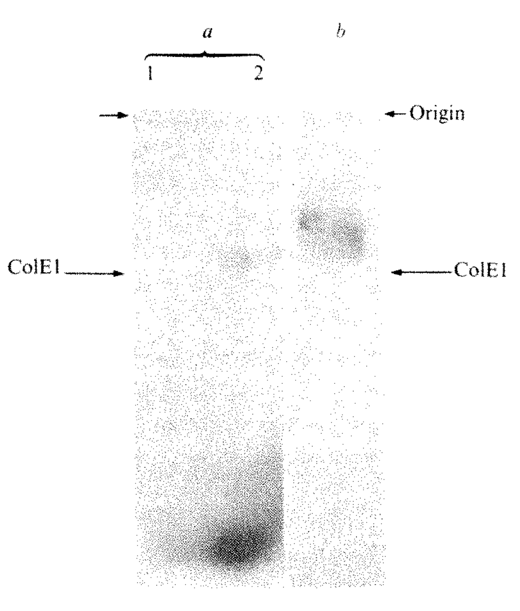

Fig. 1 Analytical Agarose gel electrophoresis of terminal transferase and reverse transcriptase activity with mColE1 DNA. *a*, 0.5 μg intact mColE1 DNA (panel 1) or 0.5 μg *Eco*RI-digested mColE1 DNA (panel 2) were incubated with 1 μCi ^{32}P-dTTP (New England Nuclear, 100 Ci mmol^{-1}) and 2.5 μg terminal transferase (P.L. Biochemicals, Lot No. 34421, specific activity 5,260 U mg^{-1}) in 10 μl reaction volume containing 100 mM potassium cacodylate (*p*H 7), 7.5 mM potassium phosphate (*p*H 7), 8 mM $MgCl_2$, 2 mM 2-mercaptoethanol. After 1 h at 37 °C, the reaction was terminated by addition of EDTA to give 10 mM and sucrose was added to 20% (w/v): the mixture was loaded on a 1% Agarose (w/v) vertical slab gel. Electrophoresis was for 1 h at a constant current of 40 mA. (The gel buffer was 20 mM sodium acetate, 40 mM Tris-acetate (*p*H 8.3), 0.2 mM EDTA.) An autoradiograph of the gel was made using Kodak Auto-Process X-ray film. Unreacted ^{32}P-dTTP appears (near the anode) at the bottom of the autoradiograph. *b*, 2 μg mColE1 DNA tailed with poly(dT) (prepared as in legend to Fig. 2) plus 1 μg rabbit globin mRNA were incubated in 50 μl containing 50 mM Tris-HCl (*p*H 8.3), 20 mM dithiothreitol, 6 mM $MgCl_2$, 60 mM NaCl, 500 μM dATP, dCTP, dGTP, dTTP, 1 μCi ^{32}P-dCTP, 2.5 μg actinomycin D and 0.16 μg reverse transcriptase (specific activity 29,316 U mg^{-1}). After 2 h at 37 °C the reaction mixture was diluted with an equal volume of 0.6 M NaCl, 0.02 M sodium acetate (*p*H 5) and passed over a small column (in a 1-ml plastic pipette) of Sephadex SP-50 to remove the unreacted nucleotides. The breakthrough peak was precipitated with ethanol (−20 °C, 18 h). The precipitate was dissolved in gel buffer, electrophoresed and the gel autoradiographed as in Fig. 1*a*. The anode is at the bottom of the gel.

level of 1 cell in 10^6. Methods for isolating clones such as the modified sib selection procedure used to identify bacteria carrying plasmids with histone genes[6] is unattractive for low frequency genes since the number of screening selections would need to be very large. A report by Rougeon *et al.*[8] has demonstrated the insertion of double-stranded DNA copies of rabbit globin mRNA into the plasmid pCR1. Using different methods from those described by Rougeon *et al.*[8], we have inserted double-stranded complementary DNA copies of rabbit globin mRNA into the plasmid mini-ColE1 (mColE1)[9]. The method involves a minimum of manipulations and should be suitable for producing such plasmids from any mRNA containing poly(A). The procedure is a modification of the A–T tail method[10,11] and utilises poly(dT) tails, added to mColE1, as primer for reverse transcriptase copying of globin mRNA into DNA. Double-stranded globin DNA is produced by repair *in vivo* of the single-stranded complementary DNA (cDNA) in the plasmid.

Preparation of plasmids containing globin DNA

The plasmid mColE1 possesses a single site for cleavage by the restriction endonuclease *Eco*RI (ref. 9). Digestion of the plasmid with this enzyme therefore yields a uniform population of linear molecules with an identical point of breakage. It has previously been shown that the enzyme terminal transferase adds nucleotides to 3′-termini of double-stranded DNA molecules[10–12] but that the efficiency of the process is greatest in the presence of a free 3′-OH group. Nevertheless, the ability of terminal transferase to add dT-residues to the unmodified ends of *Eco*RI-digested mColE1 was tested. A sample of mColE1 digested with *Eco*RI was incubated with terminal transferase plus ^{32}P-dTTP. The products were analysed by Agarose gel electrophoresis (Fig. 1*a*). The enzyme adds dT residues to the DNA to produce a heterogeneous size range of elongated molecules (Fig. 1*a*, panel 2). Intact circular plasmid DNA shows no change when incubated with terminal transferase (Fig. 1*a*, panel 1). The size range of the poly(dT) tails was rather difficult to control, however, and this heterogeneity is presumably due to the poor and unsynchronised initiation of elongation.

The ability of the mColE1 molecules carrying poly(dT) tails to act as primer for reverse transcriptase copying of globin mRNA was tested. This transcription would be analogous to the conventional preparation procedure of cDNA from mRNA (for example see ref. 13). Fig. 1*b* shows that a further elongation of the mColE1 resulted from the reverse transcriptase activity. Thus DNA copies of globin mRNA had been added (covalently attached) to the mColE1 by reverse transcriptase.

These observations showed that a population of plasmid molecules terminated by segments of globin DNA could easily be prepared and led to the development of a procedure for the cloning of plasmids carrying these globin sequences. The general protocol for this preparation is given in Fig. 2. The procedure consisted of five steps. (1) Circular mColE1 was digested to completion with *Eco*RI; (2) the digested plasmid was tailed with either poly(dT) or poly(dA); (3) the plasmid tailed with poly(dT) was used to prime the synthesis of cDNA using globin mRNA as a template; (4) the plasmid molecules containing cDNA were further tailed with poly(dT); (5) the resultant population from step 4 was mixed with plasmid molecules tailed with poly(dA) and the mixture denatured and annealed. Transfection was carried out with *Escherichia coli*. Colicin-resistant clones were plated on nutrient agar and grown overnight at 37 °C. *E. coli* clones containing globin plasmids were finally screened by hybridisation.

The annealing procedure was carried out in two parts. First, plasmid DNA from step 4 (that is, carrying globin DNA and a further poly(dT) tail) was mixed with an excess of plasmid DNA tailed with poly(dA). This mixture was denatured and annealed at high temperature and high DNA concentration to allow specific hybridisation of the plasmid DNA strands. Second, the DNA mixture was diluted to about 5 μg ml^{-1} before incubation at 37 °C to facilitate hybridisation of the poly(dA) tail of one strand with the poly(dT) tail present at the end of the globin DNA segment on the opposite strand. Such dilution of the DNA is known to facilitate intramolecular hybridisation of poly(dA) and poly(dT) (that is circularisation) rather than intermolecular hybridisation[14]. Although plasmid circularisation was not demonstrated directly, it was found that production of transfectant *E. coli* was absolutely dependent on the final 37 °C annealing step. Since the reverse transcription was carried out in the presence of actinomycin D, only single-stranded globin DNA would be synthesised. It is possible that the transfection efficiency could have been improved by repair *in vitro* of the single-stranded region and subsequent *in vitro* ligation. Since globin-plasmids could be produced without such *in vitro* steps, however, repair and ligation of the plasmids was allowed to occur *in vivo*.

Identification and characterisation of bacteria carrying globin plasmids

The first stage in the identification of individual clones containing globin plasmids was growth of the transfected cells in the presence of colicin. Only cells carrying mColE1 plasmids

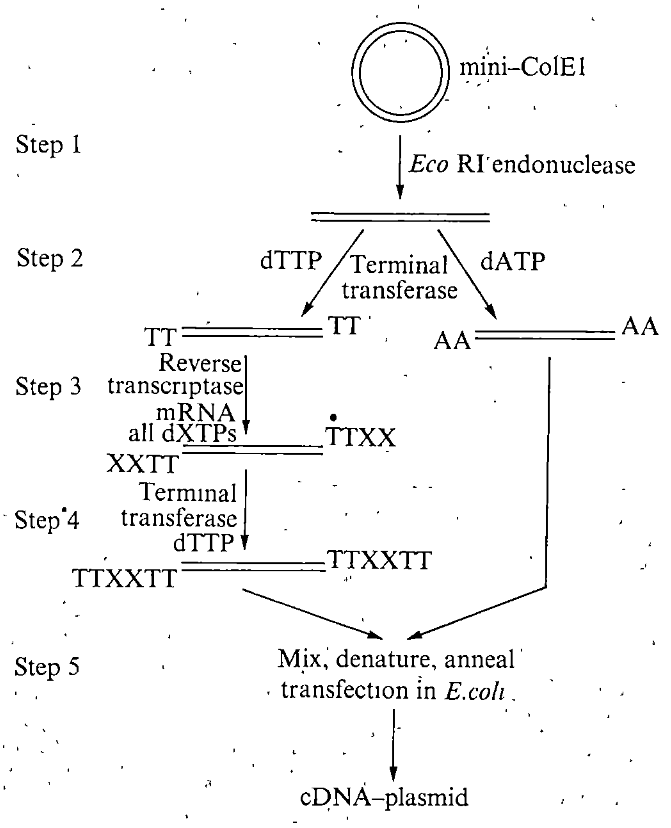

Fig. 2 General scheme for production of globin plasmids. Step one: mColE1 was prepared by the procedure described[15] and *Eco*RI was prepared by the method of Yoshimori[16]. mColE1 DNA (20 μg) was digested with *Eco*RI (the quantity of enzyme necessary was previously determined by digestion of λ phage DNA) in 100 μl of 10 mM Tris-HCl (*p*H 7.5), 10 mM $MgCl_2$, 10 mM 2-mercaptoethanol for 2 h at 37 °C. The reaction was terminated by freezing. Step two: two aliquots of 50 μl from the *Eco*RI digestion mix (10 μg DNA) were added to 50 μl containing 100 mM potassium cacodylate (*p*H 7), 7.5 mM potassium phosphate (*p*H 7), 8 mM $MgCl_2$, 2 mM 2-mercaptoethanol. dTTP was added to one aliquot and dATP to the other to give 0.3 mM. The tube containing dTTP also contained 10 μCi ^{3}H-dTTP (New England Nuclear) so that the labelled plasmid DNA could easily be monitored in subsequent steps. 10 μg terminal transferase were added to each mixture and the tubes were incubated at 37 °C for 1 h. Again the mixes were frozen to terminate the reaction. At this stage, an analytical Agarose gel was routinely carried out to check the efficiency of the transferase reaction. Step three: the mColE1 tailed with poly(dT), prepared in step 2 (10 μg DNA), was incubated in a 300-μl volume containing 20 μg rabbit globin mRNA (prepared by oligo(dT) chromatography of rabbit reticulocyte polysomal RNA[17]), 5 μg actinomycin D, 10 μCi ^{3}H-dCTP (New England Nuclear, 28 Ci $mmol^{-1}$), 500 μM dATP, dCTP, dGTP and dTTP in the same buffer as described in the legend to Fig. 1*b*. Reverse transcriptase (1 μg) was added and the mixture incubated at 37 °C for 2 h. The mix was further incubated with 10 μg pancreatic ribonuclease (previously boiled to remove contaminating deoxyribonuclease activity) for 30 min at 37 °C, extracted once with an equal volume of phenol and passed over a small column of Sephadex SP-50 (in a 1-ml plastic pipette) in 0.3 M NaCl, 10 mM sodium acetate (*p*H 5). One-drop fractions were collected and the position of the DNA monitored by scintillation counting of 1-μl aliquots. The peak fractions were pooled and precipitated overnight at −20 °C by the addition of two volumes of ethanol. (Note: XTP refers to equal quantities of each nucleotide triphosphate.) Step four: the ethanol-precipitated mColE1 containing globin DNA sequences (prepared in step 3) was spun down, dried *in vacuo* and dissolved in 50 μl of 100 mM potassium cacodylate (*p*H 7), 7.5 mM potassium phosphate (*p*H 7), 8 mM $MgCl_2$, 2 mM 2-mercaptoethanol and 0.3 mM dTTP. Terminal transferase (6 μg) was added and the mix incubated at 37 °C for 1 h. Step five: after 1 h incubation in step 4, 50 μl (10 μg) of mColE1 tailed with poly(dA) (prepared in step 2) was added to the reaction mixture and the volume was increased to 250 μl with the salt concentration adjusted to 100 mM NaCl, 10 mM Tris-HCl (*p*H 8), 10 mM EDTA. The solution was boiled for 5 min and incubated at 70 °C for 30 min, after which 2.75 ml of the above buffer were added and incubation continued for 5.5 h at 37 °C. Finally the solution was extracted once with an equal volume of phenol and precipitated overnight at −20 °C by the addition of 2 volumes of ethanol in the presence of 50 μg *E. coli* tRNA carrier. The final dried pellet was dissolved in 300 μl of 30 mM $CaCl_2$, 10 mM NaCl, 0.5 mM EDTA, 10 mM Tris-HCl (*p*H 8) (transfection buffer).

Competent cells were prepared (as described by Cohen *et al.*[18]) from an overnight culture of *E. coli* C600 $r^- m^-$ (a gift from Dr Noreen Murray). Approximately 1.2 × 10^8 competent cells were pelleted and suspended in 300 μl of solution containing the annealed mColE1 population. (Control transfections consisted of 1 μg native mColE1 in 300 μl transfection buffer or 300 μl transfection buffer with no DNA.) The bacterial suspension was held on ice for 60 min, heated at 42 °C for 2 min and held on ice again for 60 min (with an occasional shake). 0.7 ml 2 × TY medium (1.6% (w/v) tryptone, 1% (w/v) yeast extract 0.5% (w/v) NaCl *p*H 7.4) was added and the bacteria incubated at 37 °C for 45 min. Sufficient colicin was added to kill 1.2 × 10^8 cells (the dosage was previously determined) and the suspension incubated for a further 30 min at 37 °C. The cells were then pelleted, resuspended in 0.3 ml 2 × TY medium containing half the above quantity of colicin and plated on nutrient agar plates overnight at 37 °C.

should be resistant. Colicin treatment of bacteria, however, does not result in the full extinction of all non-plasmid containing bacteria and further, the annealing procedure will lead to the presence of plasmids tailed only with poly(dA) and poly(dT). The identification of clones carrying globin plasmids was facilitated by hybridisation as follows. Sixty-four randomly chosen colicin-resistant clones were grown in 1-ml cultures. Eight separate pools of eight clones were made and these pools were grown overnight in 100-ml cultures. DNA was prepared from these cultures and tested for the presence of globin-plasmids by hybridisation with globin ^{3}H-cDNA (prepared by normal reverse transcription). Table 1*a* shows the results of this initial screening: of the eight pools tested, half showed the ability to hybridise ^{3}H-cDNA and thus the presence of globin plasmids. The percentage of cDNA hybridised in each case was around 30–40% of the total cDNA recovered. Since the ^{3}H-cDNA used to assay for positive clones was a mixture of α-and β-globin sequences, 40% hybridisation approaches the proportion of the ^{3}H-cDNA representing the α- or β-globin sequence. Identification of individual positive clones was carried out simply by growing the eight individual clones of any positive pool in 100-ml cultures, preparing DNA from these cultures and identifying the positive clone(s) by cDNA hybridisation. For example, Table 1*b* shows the identification of one clone containing a globin plasmid from the eight pooled clones of the initial culture number *C*. It seemed that in this pooled culture *C*, only one clone actually contained a globin plasmid; thus, about 7% of the clones resistant to colicin actually contain globin plasmids. Most of the remainder of colicin-resistant clones (amounting to about 10 times as many clones as in a mock-transfection) are presumably due to plasmids formed from the reannealing of strands tailed with poly(dA) and poly(dT) but without added globin sequences.

The globin plasmid identified above was used in further characterisation studies. To determine whether the globin plasmid contained sequences for α or β globin, plasmid DNA was hybridised with either ^{3}H-cDNA prepared from the original mRNA (a mixture of α- and β-globin sequences) or with ^{3}H-cDNA prepared from mRNA originating from the rabbit reticulocyte post-ribosomal supernatant (this mRNA is enriched in α-globin mRNA[20]). The total cDNA population was found to hybridise with the globin plasmid to around 47% whereas the α globin enriched cDNA hybridised only about 22% (Table 2). Since β-globin sequences probably predominate in the total mRNA population but are relatively depleted in the α-enriched mRNA, the DNA in the plasmid seems to be the complement of β-globin mRNA. Furthermore, when annealed with unmodified mColE1, ^{3}H-cDNA of total globin and α-enriched globin only bound about 9% and 4% respectively to the hydroxyapatite (Table 2). This percentage is the amount of ^{3}H-cDNA consistently found to bind to hydroxyapatite in the absence of hybridisation. Thus there are no sequences in

a, After overnight growth of transfectant *E. coli* on nutrient agar plates in the presence of colicin (see legend to Fig. 2), 64 colonies were randomly selected for growth in 1 ml of 2 × TY broth. Eight pools of eight 1-ml cultures were made in 100 ml 2 × TY, grown to $A550 = 0.9$ and chloramphenicol added to a concentration of 200 μg ml^{-1}. Growth was continued overnight at 37 °C. The cells were collected and cleared lysates prepared as described[15]. DNA was precipitated for 1.5 h at 4 °C after addition of NaCl to give 750 mM and polyethylene glycol 6,000 to give 15% (w/v). The precipitates were drained, dissolved in 1 ml 50 mM NaCl and digested at 37 °C for 30 min with 10 μg pancreatic ribonuclease; 5 μg proteinase K (Merck) was added to each tube and digestion continued for 30 min at 37 °C. At the end of this time, 10 μl 10% SDS were added, plus 1 ml 2 M NaCl, 10 mM Tris-HCl (*p*H 8). The DNA was extracted 3 times with equal volumes of phenol and chloroform (1:1 ratio). The final aqueous phase was sonicated for 2 × 30 s and the DNA precipitated by the addition of two volumes of ethanol (−20 °C for 2 h). The precipitates were dried and dissolved in 0.2 ml water, placed in a small siliconised tube with 2,000 c.p.m. ^{3}H-globin cDNA (prepared by conventional oligo(dT) priming of mRNA as in ref. 19: s. a. 6 × 10^6 cm^{-1} μg^{-1}) and sodium phosphate buffer (*p*H 6.8) to give 0.24 M (total volume 0.3 ml). These mixtures were boiled for 5 min and incubated for 15 h at 70 °C. The hybridisation was assayed by hydroxyapatite fractionation as described[19]. A control hybridisation tube containing 100 μg sonicated mColE1 DNA and ^{3}H-cDNA was processed to determine background binding of ^{3}H-cDNA in 0.4 M phosphate on hydroxyapatite fractionation. *b*, The individual clones of culture *C* were grown in 100 ml culture as described for *a*. DNA preparation and hybridisation (against 10,000 c.p.m. ^{3}H-cDNA) were also as in (*a*).

mColE1 DNA which hybridise with ^{3}H-globin cDNA.

The globin plasmid described will contain tracts of poly(dA) and poly(dT). Therefore, it was necessary to eliminate the possibility that the hybridisation experiments were detecting hybrid formation between the poly(dA) of the plasmid and the poly(dT) tract known to be present at the end of ^{3}H-cDNA[19]. Two control hybridisation experiments were carried out. The globin-plasmid DNA was annealed with mouse immunoglobulin light-chain ^{3}H-cDNA. This cDNA will contain only poly(dT) tracts in common with sequences present in the globin plasmid. Table 2, line 6 shows that 9.6% of this cDNA binds to the hydroxyapatite after annealing with the globin plasmid compared to 5.6% binding after annealing with unmodified mColE1 DNA. Thus the poly(dT) tracts of the ^{3}H-cDNA do not seem to be involved in hybridisation described. Furthermore, the ability of ^{3}H-globin cDNA to hybridise with the globin plasmid in the presence of tenfold excess of unlabelled poly(dT) competitor was examined. Table 2, line 2, shows that about 45% hybridisation occurs in the presence of poly(dT), therefore the hybridisation of the ^{3}H-cDNA is essentially unaffected by the presence of the poly(dT). This observation confirms that the hybridisation observed was due to DNA sequences complementary to globin mRNA present in the plasmid. The length of the globin segments in the plasmids is as yet unknown. It is likely, however, that the population as a whole shows a similar heterogeneity to the cDNA population made by conventional reverse transcriptase copying of mRNA. Thus an individual plasmid may contain a sequence anywhere from 50 residues to the entire length of the globin mRNA.

This paper describes the insertion of DNA copies of rabbit globin mRNA into the plasmid mColE1 and subsequent amplification by cloning in *E. coli*. These DNA copies are probably partial copies of the globin mRNA and represent the successful synthesis of part of the globin gene. A similar synthesis has also been described elsewhere[8]. The method should be applicable to any poly(A)-containing RNA or RNA to which poly(A) can be added *in vitro*, so that a large supply of the sequence can be made available. It is hoped that the ability to clone globin sequences in bacteria will facilitate isolation, by hybridisation procedures, of those regions from the chromosomal DNA involved in control of globin gene activity. For example, the plasmid DNA could be covalently linked to cellulose to provide a basis for hybridisation/chromatographic purification of the complementary regions from nuclear DNA. The principal advantages of this method are the large quantity of DNA available, plus the important point that the plasmid contains double-stranded DNA which will allow purification of both strands of the chromosomal DNA in a single step.

In addition, manufacture of double-stranded copies of messenger RNA in mColE1 will make sequencing of such

Table 2 Hybridisation properties of purified globin plasmid

	DNA hybridised	^{3}H-cDNA type	c p.m. hybridised (%)
(1)	Globin plasmid	Total globin	49.2
(2)	Globin plasmid	Total globin (in presence of poly(dT))	45.1
(3)	mColE1	Total globin	9.8
(4)	Globin plasmid	α-Enriched globin	22.7
(5)	mColE1	α-Enriched globin	3.9
(6)	Globin plasmid	Mouse Ig	9.6
(7)	mColE1	Mouse Ig	5.6

Globin plasmid DNA was prepared as described for the mColE1 DNA (Table 1) All DNA stocks were sonicated for 1 min before use. ^{3}H-cDNA was prepared from rabbit reticulocyte 9S mRNA (total globin cDNA) from rabbit reticulocyte post-ribosomal 9S mRNA (α-enriched cDNA) and from mouse myeloma MOPC21 light chain mRNA (mouse Ig cDNA) as described[19]. In each hybridisation tube, 2 μg of DNA were annealed with 10,000 c.p.m. ^{3}H-cDNA for 16 h at 70 °C in 300 μl 0.24 M sodium phosphate buffer (*p*H 6.8) after boiling for 5 min (Tube 2 included 10 μg poly(dT) (P.L. Biochemicals)). After annealing, the mixes were diluted with 3 ml 0.12 M phosphate containing 100 μg *Micrococcus* DNA and fractionated on 0.5 gm hydroxyapatite (BioRad HTP) as described[19] % c.p.m. hybridised represents the percentage of the total recovered counts in the 0.4-M fraction from the hydroxyapatite column.

species easier by application of the rapid sequencing methods now emerging[21]. In fact, it is conceivable to clone any available RNA species (for example, eukaryotic ribosomal RNAs) by first adding poly(A) to the RNA[22,23] and then inserting DNA copies in mColE1: the inserted DNA copies would be more amenable to sequence studies than the native RNA itself.

I thank Dr J. W. Beard for supplying reverse transcriptase, Dr C. Milstein for discussion and Mr A. Forster for technical assistance.

Addendum

Although the experiments described in this paper were, in the main, carried out before publication of the US National Institutes of Health Committee report on containing experiments with recombinant DNA, the guidelines suggest that the containment facilities used for such experiments should be mentioned in publications. It thus seems relevant to report that containment equivalent to P2 level was used initially for these experiments. Classification of this particular experiment under the NIH guidelines is rather difficult but nevertheless since publication of the guidelines, work has been carried out in conditions satisfying P3 containment.

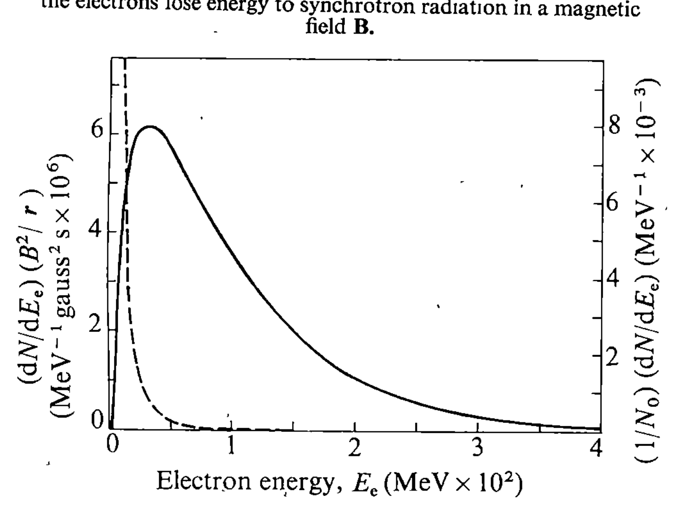
Annihilation of matter and antimatter and the cosmic X-ray background

IN cosmological models where matter and antimatter occur symmetrically in the Universe[1–5], their annihilation is likely to take place also at the present time. At the annihilation of a proton and an antiproton, ~ 1.6 negative electrons and an equal number of positrons, each with an energy of ~ 10–100 MeV are produced (Fig. 1), together with γ rays and neutrinos[6]. The initial electron energies can be expected to decrease gradually because of their interaction with cosmic magnetic fields, plasmas, and electromagnetic radiation. As a result of these interactions synchrotron radiation, bremsstrahlung, and inverse Compton radiation are all emitted. When optical photons are scattered against the relativistic electrons, X rays are produced by the inverse Compton effect. This mechanism may be an important source of cosmic X rays. Our purpose here is to study how efficient this X-ray mechanism can be in intergalactic space (where most of the annihilation electrons are expected to be found) and to see whether it can offer an explanation to the cosmic X-ray background observed (see refs 7–9).

Fig. 1 ——, Energy spectrum of electrons (negative and positive) directly-produced by proton–antiproton annihilation. The spectrum is normalised by means of the total number of electrons N_0 formed. — — —, Stationary energy spectrum of annihilation electrons $\mathrm{d}N/\mathrm{d}E_e$ multiplied by B^2/r. The spectrum is obtained for a constant rate of annihilation r when the electrons lose energy to synchrotron radiation in a magnetic field **B**.



For the sake of clarity we shall consider a simplified model of the X-ray mechanism assuming:

(1) That the annihilation of protons and antiprotons occurs at a constant rate giving rise to relativistic electrons with a production spectrum according to Fig. 1, with a maximum close to 30 MeV.
(2) That the energy of the electrons decreases continuously, primarily from synchrotron losses, so that a stationary energy spectrum is obtained for the electrons.
(3) That the primary optical radiation in intergalactic space (with which the annihilation electrons interact and produce X rays) consists mainly of galactic light having an intensity of $S_{10} = 1.4$ ($m_v = 10$) star degree^{-2} (ref. 10) and a spectrum with the shape of a black-body distribution at a temperature $T_{ph} = 6 \times 10^3$ K.

For assumptions (1) and (2), Ekspong *et al.*[6] have estimated the stationary energy spectrum of the annihilation electrons (Fig. 1). A considerable concentration of electrons towards small energies can be noticed in the graph. It should be mentioned that the shape of this spectrum is unchanged if one includes energy losses from inverse Compton scattering of the electrons against black-body radiation of low energy.

Korshak[11] has calculated the spectrum of the inverse Compton radiation produced by one electron of energy E_e interacting with black-body photons of temperature T_{ph} and density n_{ph}. He finds

$$P_C(\nu) = 1.24\, \sigma_T c h n_{ph} F(\nu/\nu_C) \text{ erg s}^{-1} \text{ Hz}^{-1} \qquad (1)$$

provided $E_e \gg m_e c^2$, $\beta E_e \gg h\nu \gg kT_{ph}/\beta$, $(\beta = v/c \simeq 1)$.

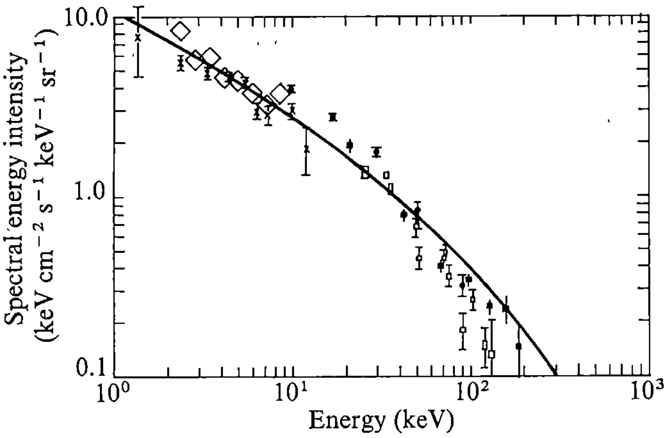


Fig. 2 Spectrum of inverse Compton radiation resulting from scattering of galactic light on annihilation electrons which decrease in energy because of synchrotron radiation (solid curve). The inverse Compton spectrum is compared with measured intensities of the cosmic X-ray background in the energy interval 1 keV $\lesssim h\nu \lesssim 10^2$ keV (ref. 9). The experimental points are from: ●, OSO III; ◇, LLL; ×, ASE; □, Leiden-Nagoya; ■, GSFC-OSO V.

$\sigma_T = 6.65 \times 10^{-25}$ cm^2 is the Thomson cross section, ν is the frequency of the scattered photons, and

$$\nu_C = (4kT_{Ph}/h)\,(E_e/m_e c^2)^2.$$

The function $F(\nu/\nu_C)$ reaches its maximum value of 0.254 at $\nu \simeq \nu_C$ and is $\simeq 1.65\nu/\nu_C$ for $\nu/\nu_C \ll 1$ and

$$\simeq (\nu/\nu_C)\exp(-\nu/\nu_C) \text{ for } \nu/\nu_C \gg 1$$

By integrating numerically the spectrum defined by equation (1) over the stationary energy distribution of the relativistic electrons (dashed curve in Fig. 1) we can estimate the spectrum of the inverse Compton radiation in our model, which is shown in Fig. 2, together with the measured intensities of the cosmic X-ray background in the interval 1 keV $\lesssim h\nu \lesssim 10^2$ keV (ref. 9). As is clear from Fig. 2, the inverse Compton spectrum agrees well with the observed spectrum in this interval.

It should be noted that except for the total intensity there is no adjustable parameter in this derivation. For photon energies > 1 MeV, the inverse Compton spectrum starts to deviate appreciably from observational data[7]. The maximum photon energy of the inverse Compton radiation that can be produced by our mechanism is well above 10 MeV.

The intensity of the inverse Compton radiation is proportional to the density of the primary photons and to the density of the relativistic electrons. Furthermore, the intensity depends also on the size of the volume which the electrons occupy. With the radius of the volume being $R = 10^{10}$ light yr $= 10^{28}$ cm and the primary radiation consisting of galactic light as assumed in (2), the intensity in Fig. 2 is obtained for a mean electron density $n_e \simeq 10^{-9}$ cm^{-3} in the energy interval 10 MeV $< E_e < 10^2$ MeV. This electron density is about two orders of magnitude smaller than the mean atom density of galactic material throughout the Universe.

The electrons which are necessary to produce the cosmic X-ray background will of course also give rise to other types of electromagnetic radiation. One of these is the synchrotron radiation whose intensity and frequency is influenced by the magnetic field **B**. To obtain a stationary spectrum for the electron energies of interest, $E_e \gtrsim 1$ MeV (as assumed in (2)), the magnetic field must be so strong that the decay time (τ_s) arising from synchrotron losses

$$\tau_s = \frac{5.1 \times 10^8}{B^2}\,\frac{1}{1+E_e/m_e c^2}\ \text{s} \qquad (2)$$

(B in gauss) is at least less than the age of the Universe, being $\sim 10^{10}$ yr $= 3 \times 10^{17}$ s. Thus, the magnetic field must be $\gtrsim 2 \times 10^{-5}$ gauss.

With a magnetic field of this strength, the intensity of synchrotron radiation in the radio band produced by the annihilation electrons necessary to generate the X rays, would be higher than experiment allows[12–14]. The solution of this problem may be that the annihilation electrons are created locally in quasars and galactic nuclei[15], where the magnetic field is sufficiently strong to cause a rapid decay in the energy of the electrons. This could also lead to absorption of the γ rays formed by annihilation, so that their flux does not become unacceptably high[16,17]. The annihilation electrons, on the other hand, escape into intergalactic space where they become uniformly distributed and where they produce the X-ray background by interacting with optical photons.

We have for simplicity disregarded effects of cosmological evolution, but, nevertheless, our description may be adequate in a framework such as the Klein–Alfvén metagalactic theory. A more detailed discussion has to wait for general development of the symmetric cosmology.

We thank Professor H. Alfvén for suggesting this problem as well as for a number of discussions.

X-ray observations of GX17+2 and GX9+9 by Aryabhata

X-RAY observations on GX17+2 and GX9+9 were made using the proportional counter telescope on board the first Indian satellite 'Aryabhata'. We present these results, which enable us to start discussing source mechanisms for these objects.

The proportional counter had an effective area of 15.4 cm^2 and was fitted with a 0.0635-mm beryllium entrance window. The counter was filled with a gas mixture of Ar, CO$_2$ and He in the pressure ratio of 0.9 : 0.095 : 0.005 to a total pressure of 1 atm. Cylindrical aluminium collimators defined a field of view of 12.5° FWHM for the counter. The telescope was mounted with its look direction along the spin axis of the satellite. The details of the payload are being published elsewhere[1].

Observations on GX17+2 and GX9+9 were made by the proportional counter telescope in the thirty-first orbit, before the spacecraft was spin stabilised, when it was performing a slow spin around an axis different from the spin axis. Sighting of GX17+2 occurred at 110 d 8 h 9 min 8 s (UT), followed by that of GX9+9. The identifications of

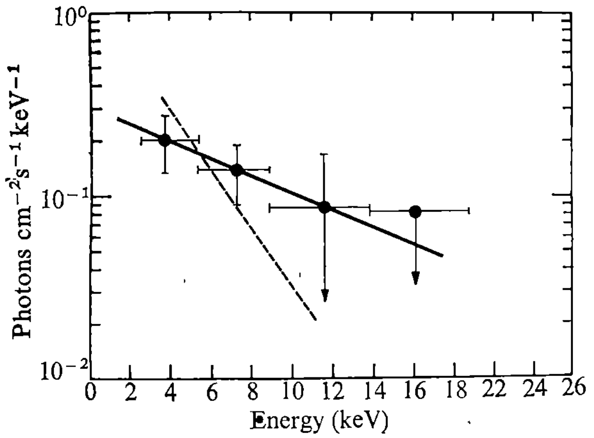

Fig. 1 Spectrum of GX17+2 obtained from Aryabhata observations. The dashed line represents the estimated temperature from the Lawrence Livermore group (42×10^6 K). The solid line represents our temperature (108×10^6 K).

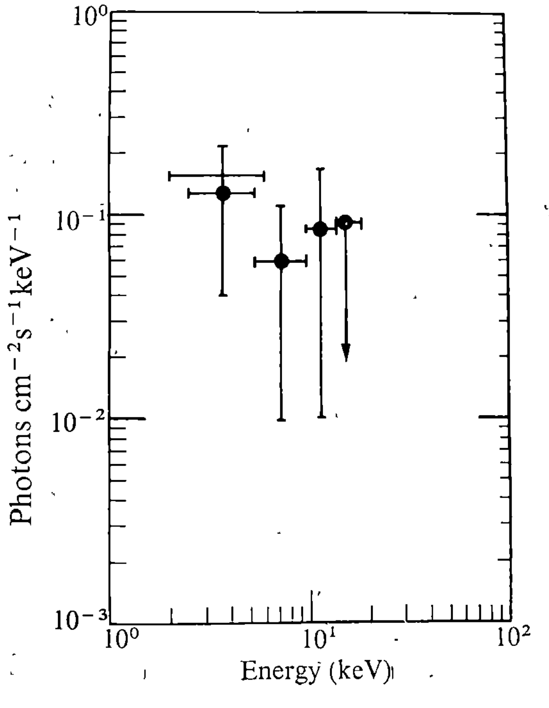
GX17+2 and GX9+9 were based on the available positional data on these sources[2–4]. Data were obtained in four pulse height intervals over the energy range of 2.5–18.75 keV. The contributions of the two sources to the observed counting rates were derived after making allowance for the background effects as deduced from the examination of the nature of counting-rate profiles and their known geomagnetic dependence. Further, in the case of GX17+2, it was necessary to take into account contributory effects from GX+13.5 which was partially in the field of view for part of the observation time. These corrections were based on the available data[2] on this source, and the effect so estimated was ~ 20%. The photon spectra for GX17+2 and GX9+9 were derived after correcting for the efficiency of the counter and the telescopic response of the detector. The spectra so deduced for these sources are shown in Figs 1 and 2.

The spectrum of GX17+2 can be fitted to an exponential function in the present case, and yields a characteristic kT value of 9.31 ± 0.3 keV. If the X radiation arises from bremsstrahlung in a hot plasma, the equivalent temperature of the emitting body was $(108\pm4)\times10^6$ K at the time of observation.

Fig. 2 Spectrum of GX9+9 obtained from Aryabhata observations. ——, Uhuru; ●, Aryabhata.



GX17+2 is one of the relatively intense X-ray sources in the Scorpius–Sagittarius region. Observations on this source[5–7] had provided information primarily on its position rather than detailed emission features. The first set of detailed observations[8] were made by Uhuru detectors in late 1970 and early 1971 and revealed the variable character of X-ray emission besides establishing the exponential nature of the spectrum. Rocket-borne observations by the Lawrence Livermore Laboratory (LLL) group (R. W. Hill *et al.*, unpublished) have provided confirmation of the thermal nature of its emission. It seems that the source exhibits variations over a wide range of temperatures from 25×10^6 to 155×10^6 K. A closer analysis of the temperature–emission flux relationship in the 2–7 keV energy range leads, however, to no definite correlation between these two parameters. Further, when we consider all the existing data on this source, no definite conclusion can be drawn about the existence of a two-state emission character for this source as suggested by Tananbaum *et al.*[8]. The source seems to be similar in its properties to Sco X-1 as deduced from the comparison between radio and X-ray observations[9], but the lack of optical data on the source is a serious constraint to further analysis.

The spectral distribution of GX9+9 seems to be governed by a power law function with an exponent value of ~ 1.2, and is suggestive of a non-thermal mechanism for X-ray emission. In the energy interval of 2.5–10 keV, the integrated energy flux is $(0.57\pm0.3)\times10^8$ erg cm^{-2} s^{-1}. The flux obtained by Bradt *et al.*[3] in a rocket flight in 1967 was 0.25×10^{-8} erg cm^{-2} s^{-1} in the energy range 1.5–6 keV, whereas the same group[4] reported a flux of $\sim0.77\times10^{-8}$ erg cm^{-2} s^{-1} in the 1.5–8 keV energy interval from a subsequent observation in 1968. Comparison of the energy fluxes obtained from our observation and the two earlier rocket observations, after normalising to the same energy interval of 1.5–8 keV, leads to the suggestion that X-ray emission from GX9+9 is variable.

This work was supported by the Department of Space, Government of India. The launching of Aryabhata was made possible through the joint cooperation between the Indian Space Research Organisation and the Academy of Sciences, USSR.

Reliability of sunspots as tracers of solar surface rotation

NEW methods of measuring solar rotation have produced significantly different rotation speeds to those derived from sunspots[1,2]. Spectroscopic measurements of Doppler displacements give a so-called plasma rotation velocity of 13.76° d^{-1} (sidereal) at the solar equator[3] as against 14.38 ° d^{-1} (sidereal) from sunspot proper motion velocity[4,5]. Other techniques of measuring solar rotation lead to differences in the differential

Table 1 Sunspot properties and derived solar rotation velocities

	Spot SPO3703	Spot SPO3707	Spot SPO3710
Central meridian passage (UT)	Oct. 7.3 1975	Nov. 10.6 1975	Nov. 19.9 1975
Heliographic latitude	+32.5 °	+3.5 °	−7.0 °
Number of days observed during passage	13	9	11
Proper motion rotation (synodic) (degree d^{-1})	12.66±0.10	13.36±0.10	13.12±0.10
Proper motion rotation (sidereal) (degree d^{-1})	13.65±0.10	14.35±0.10	14.11±0.10
Plasma rotation (sidereal) (degree d^{-1})	12.47±0.15	13.16±0.20	13.61±0.20
Velocity difference (proper motion−plasma) (m s^{-1})	+140±20	+170±30	+60±30

rotation from a strong variation of the solar rotation with latitude for sunspots[4] and photospheric plasma[3] to hardly any variation at all for coronal holes[6]. Our understanding of these differences is very poor. It is therefore appropriate to obtain additional accurate solar rotation measurements with as many different techniques as possible and to check the validity of the assumption that the proper motion of tracers, like sunspots, correspond to the actual motion of matter on the solar surface. We report here the result of plasma rotation velocity measurements inside sunspot umbrae and their relation to the rotation velocities derived from spot proper motions. We find that plasmas inside and outside the spots rotate at similar rates, and conclude that sunspots make poor tracers.

The spectrographic measurements consist of sequences of spectra of the sunspot umbrae in the neutral titanium line at 571.39 nm. This line has been selected because of the following favourable properties[7]: (1) it has no Zeeman splitting; this makes it possible to locate its wavelength very precisely, independent of instrument polarisation properties: (2) it is strongly enhanced in sunspot umbrae with respect to the surrounding penumbra and photosphere; this changes in apparent lineshifts resulting from stray light from the atmosphere instrument and seeing: (3) it falls in a window between the numerous absorption lines introduced in the spectrum by an iodine absorption tube. The sunspot is imaged through this absorption tube, which is placed just in front of the spectograph slit. The numerous weak but very sharp iodine absorption lines provide a very stable wavelength reference for the Ti I line[8]. Since the iodine absorption spectrum is observed simultaneously with the sunspot spectrum (using light originating in the spot), effects arising from different spectrograph conditions, which often limit the accuracy when using emission reference lines, are eliminated. The spectra were recorded on Kodak SO-392 film with a dispersion of 96.9 mm nm^{-1} with an exposure time of ~ 2 min. The Sacramento Peak Observatory 16″ coronagraph was used to image the Sun, on the scale of ~ 8″ mm^{-1}.

Fig. 1 Difference in line-of-sight velocity for observed plasma velocity ($V_D{}^0$) and as derived from the sunspot proper motion ($V_D{}^{pm}$). The zero point for $V_D{}^0$ has not yet been determined, and is therefore not indicated. One division on the ordinate corresponds to 100 m s^{-1}. Error bars correspond to 1 s.d. The curvature of the data for the SPO3710 spot is probably the result of the third term in equation (1) indicating an upflow of ~125 m s^{-1} in the umbra.

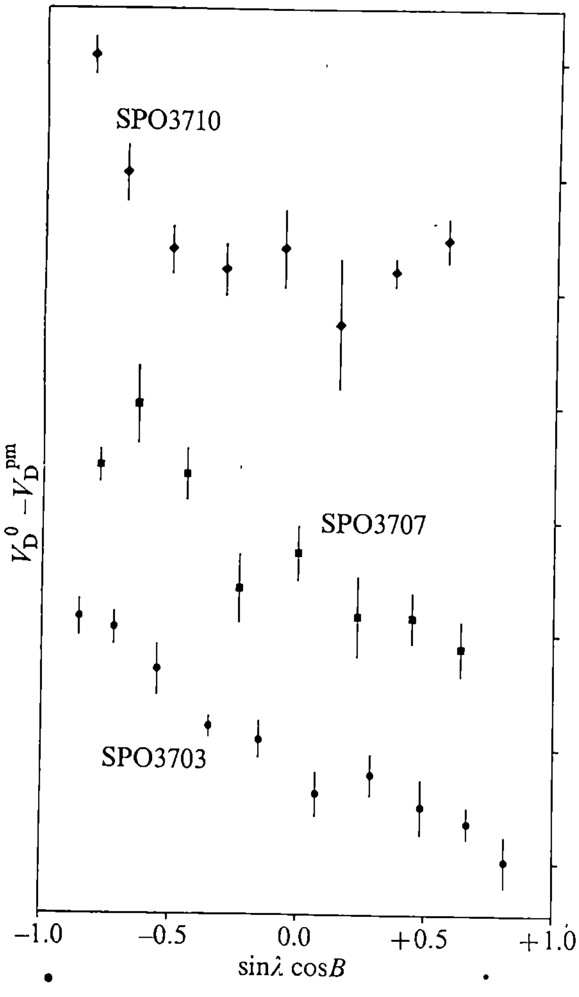

Table 1 lists the three sunspots for which rather complete coverage was obtained while the spot moved from the solar E–W limb. Two spots belong to the old cycle, one to the new. For each of the spots 60–100 spectra were obtained and analysed. The Ti I line could be located with respect to the nearby iodine lines with an accuracy 0.1 pm, corresponding to a Doppler velocity of ~ 50 m s^{-1}. Observations of the proper motion of the sunspots were made at the Sacramento Peak Observatory and at the NOAA Space Environmental Forecasting Center in Boulder. Table 1 also lists the synodic and sidereal rotation velocities derived from these proper motions. The latitude drift of the spots was very minor, $\lesssim 2$ ° during the spot passage across the solar disk (or $\leqslant 20$ m s^{-1}). After correction for the rotation and orbital velocities of the Earth the line of sight velocity V_D for a point on the Sun with heliographic longitude λ and latitude β may be shown to equal

$$V_D = V_\lambda \sin\lambda \cos B + V_\beta \cos\theta' - V_h \cos\theta \qquad (1)$$

where V_D is positive for a velocity away from the observer, (V_λ, V_β, V_h) are the velocity components on the Sun in positive longitude, latitude and height directions, B is the heliographic latitude of the centre of the solar disk, θ is the angle between the observed point on the Sun and the Earth as seen from the centre of the Sun and θ′ is the same as θ, but for a point in the opposite hemisphere at the same longitude, λ, but 90 ° away from the observed point. The last two terms in equation (1) are symmetrical around the central meridian (λ = 0), whereas the rotation term is not. This allows the determination of the rotation to be quite independent of any other velocity field. Figure 1 displays the difference in the observed Doppler velocity $V_D{}^0$ and the velocity $V_D{}^{pm}$ as predicted by the spot proper motions (and equation (1)) as a function of sinλ cos$B$. It is quite obvious that the observed plasma rotation velocity is significantly less than the spot proper motion rotation velocity. Table 1 lists the resulting plasma rotation velocities (degree d^{-1}) and the velocity differences from the proper motion values (m s^{-1}).

The difference between the two rotation rates is quite surprising since it is generally believed that the magnetic fields on the Sun are 'frozen-in' the plasma so that the two rotation rates should have been the same. The difference also shows that spots are poor tracers for measuring solar surface motions. The faster rotation of the spots (found to be close to the average sunspot values[4]) must be the results of subsurface effects, perhaps indicating an increase of rotation rate with depth. The slower plasma rotation velocities for sunspots makes the spot plasma rotate at similar rates as the plasma outside sunspots[3]. It should be noted here that P. Foukal (unpublished) found the solar surface plasma rotation velocity to increase with magnetic field strength in the plasma. This effect obviously does not persist for the very high field strengths found in sunspots. Future work will include comparison of spot and non-spot plasma rotation rates, analysis of the data for V_β and V_h velocity components and observations of (V_λ, V_β, V_h) for a number of sunspots within the same sunspot group.

I thank L. B. Gilliam, E. Coleman and E. Johansen for the observations described here, F. Reesly from NOAA, Boulder, for measuring the sunspot coordinates and W. J. Wagner for comments on the manuscript.

Physical argument and hypothesis for Sun–weather relationships

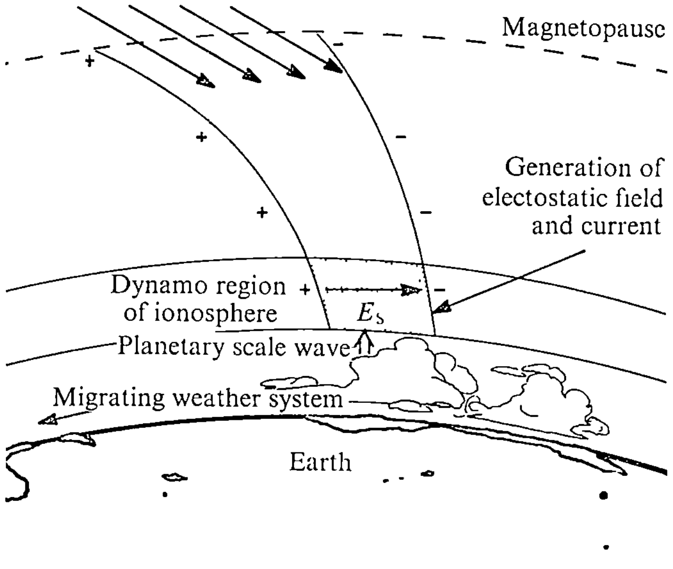
A GREAT deal of attention has been focused on the subject of Sun–weather relationships[1,2]. There is a clear need for physical processes and hypotheses to be brought forward and tested in this area. I propose here two theoretical schemes to account for some of the observed correlations; one is a physical argument suggested earlier[3], and expanded here, that the weather may generate electrical effects in the ionosphere (which may in turn affect the magnetopause), and the other is an hypothesis that the total emissivity of the Sun (both particles and electromagnetic radiation) remains constant. I investigate the possible consequences of this hypothesis.

First, the physical argument. There is strong evidence that weather systems in the lower atmosphere can launch energy into the ionosphere and there generate winds on a planetary scale[4]. In the dynamo region of the ionosphere the winds can generate electric currents and therefore magnetic disturbance directly[5]. Moreover, new electrostatic fields can be generated by the wind, which can be up to one order of magnitude greater than the wind dynamo fields[5]: their magnitude can be as great as 50 mV m^{-1} at the ionosphere. When there is good conductivity along the geomagnetic field, these fields can be mapped throughout the magnetosphere. If these new electrostatic fields occur on magnetic field lines connected to the magnetopause, solar wind plasma can be moved by the $\mathbf{E}\times\mathbf{B}$ drift into the magnetosphere[3]. The plasma so caught in the magnetosphere can be a source of energy for subsequent magnetic disturbance of direct solar wind origin. It should be unnecessary to state that there is continual interplay in this fashion between winds in the ionospheric dynamo region and the magnetopause, no matter what their origin. A field of 50 mV m^{-1} at the ionosphere could cause a field of $\sim$ 1.5 mV m^{-1} at the magnetopause because of the reduction in strength of the magnetic field there. This electric field is comparable in order of magnitude with that measured near the magnetopause by Aggson (see ref. 6). To drift solar wind plasma across the magnetopause one must have a component of electric field perpendicular to **B** and parallel to the magnetopause. Even if the angle between the electric field transmitted from the ionosphere and the normal to the magnetopause were as high as 85°, the drift speed of solar wind plasma across the magnetopause (where the magnetic field is assumed to be of strength $\sim$ 50 nT) would still be 2.6 km s^{-1}. Given a solar wind[7] of density 10 cm^{-3} and speed of 300 km s^{-1} and an area of capture of (30 Earth radii)^2, an input of energy to the magnetosphere of 7×10^{17} erg s^{-1} would be produced. This is comparable with the consumption of energy in the thermosphere from moderate magnetic disturbance[8,9].

In giving a physical interpretation to the correlations between magnetic disturbance and the weather in the lower atmosphere[10], one must further understand the migration path and the time constant of the weather systems. The complex wave communication time from the lower atmosphere to the very magnetopause may only be of the order of hours, but the time constant of weather systems of the order of days. It is entirely possible, then, that a primitive weather system while in polar regions could initiate magnetic disturbance in the above manner (see Fig. 1). This system could then migrate to middle latitude where it would seem to have followed, rather than initiated, the magnetic disturbance. This does not rule out the possibility that some (at this stage unknown) mechanism may allow magnetic disturbance to initiate some weather systems; on the other hand, the physical system propounded here could provide feedback to such an unknown mechanism. To test the foregoing theory, studies of correlations of magnetic disturbance and polar weather systems on or near magnetic field lines that connect to the magnetopause[11] should be performed.

We now present a new hypothesis. Note first that the solar 'constant' and the energy of emission of the solar wind near the plane of the ecliptic are similar when expressed in mass units through Einstein's well known relationship $E = mc^2$. The solar constant is[12] $\sim$ 1.9 calorie min^{-1} cm^{-2} $\sim$ 1.48×10^{-15} gcm^{-2}s^{-1}. The mean solar wind near the plane of the ecliptic at 1 AU from the sun has a density of 8 proton–electron pairs cm^{-3} and a radial speed of 320 km s^{-1}. This represents a mass flux of 4.3×10^{-16} gm cm^{-2} s^{-1}. The kinetic energies of the protons and electrons are not included in this estimate because they make only a small contribution. Of course helium and more massive ions may make up a substantial contribution to the mass flux also[7]. If the number density of helium reaches 25%, its mass flux then equals that of protons. A solar wind with ten proton–electron pairs per cm^3 and two helium ions per cm^3 and

Fig. 1 Modulation of solar wind capture by the weather



a speed of 633 km s^{-1} would equal, in mass flux, the solar 'constant'. It is possible that there is interplay between these two energy components at some fundamental level in the Sun.

Now the total energy (S) of emission of the sun may be written in mass units as

$$S = \int_0^{2\pi}\int_0^{\pi}\left[\int_0^{\infty}\frac{\varepsilon(\lambda)\mathrm{d}\lambda}{C^2}+\sum n_s m_s v+\frac{v}{8\pi C^2}[B^2+E^2+K]\right]\times$$

$$\times R^2 \sin\theta\mathrm{d}\theta\mathrm{d}\varphi$$

where $\varepsilon(\lambda)$ is the electromagnetic energy flux Å^{-1}; n_s, m_s, v the number density, mass and radial speed of a species s of particle; **B** and **E** the d.c. magnetic and electric field connected with the solar wind; K is the kinetic energy density associated with the thermal and organised motions of the solar wind particles; and R is radial distance from the centre of the Sun.

The most important of the terms of S in interplanetary space are those involving $\varepsilon(\lambda)$ and n_s, m_s, v. The theory of the solar wind[13] demonstrates the interaction of the parameters n_s, v and K in the lower reaches of the solar corona, where thermal energy density is converted to kinetic energy of expansion. There may be interplay between the terms involving $\varepsilon(\lambda)$ and those involving n_s, m_s and v at some levels in the Sun's outer layers perhaps somewhere in the chromosphere. I hypothesise that variability in S may be considerably less than variability of the component terms of S. The test of the possible constancy of the fundamental parameter S should be an added reason for an 'out-of-the-ecliptic-mission'.

This hypothesis has application to the modulation of the solar corona and to Sun–weather relationships and in particular to that involving interplanetary magnetic field sector structure[14].

On the first of these questions we note that extreme ultraviolet emission from the Sun may modulate the solar wind speed, as indicated below. In passing we note that the kinetic energy density flux of the solar wind ($\frac{1}{2}n_s\, m_s\, v^3$) is of the same order of magnitude as the combined extreme ultraviolet and ultraviolet flux at 1 AU from the Sun, that is, in the range 0.1–1 erg cm^{-2} s^{-1} (refs 7 and 15). There may be coupling between these fluxes. Indeed, recent X-ray images of the Sun show a relationship in space between depressions of X-ray intensity in the 3–32 Å and 44–54 Å band and increases in solar wind speed. Moreover, the depressions in X-ray intensities are related spatially to magnetic field structures on the Sun, being located between lines of polarity reversals[16]. We also note that magnetic structure in interplanetary space is mappable, to a good degree, with present knowledge, back to the Sun[17]. I suggest that the correlation of some weather systems and interplanetary magnetic field structure is traceable in physical origin back to the physical processes involved in the interplay of energy of solar wind at its origin, the magnetic field there, and the accompanying electromagnetic radiation. In terms of the hypothesis about S, this would mean that the weather modification associated with interplanetary sector structure is caused by a modulation of electromagnetic radiation (not necessarily restricted to the XUV range) emission from the outer layers of the Sun in specific regions in which the solar wind velocity and magnetic field structure are also altered. The possible occurrence of geomagnetic disturbance at an intermediate stage may be incidental and the weather modification can be traced more directly to the modulation of electromagnetic radiation at the Sun. Since it is now feasible technologically to look at a wide range of solar emissions with satellites, measurement of the comprehensive parameter S should be made, because it may be more basic to the understanding of Sun–weather relationships than the conventional solar constant. In the meantime it would be fruitful to search for a correlation in time of the conventional solar 'constant' and interplanetary sector structure. It should be noted that a correlation of time variations of intensities in the ultraviolet part of the solar spectrum with sector boundary crossings has already been noted[18].

I thank the NRC (USA) for the award of a Senior Postdoctoral Research Fellowship, Goddard Space Flight Center for hospitality, and La Trobe University, Australia for leave.

Early lunar magnetism

WE have applied a new method[1] for palaeointensity (ancient magnetic field) to three subsamples of a single, 1-m homogeneous clast (72215) from a recrystallised boulder of lunar breccia. Samples from the clast have been dated by ^{40}Ar–^{39}Ar (ref. 2), Rb–Sr (ref. 3) and U–Pb (ref. 4) methods to yield a date of 4.0×19^9 yr as the age of boulder assembly. The new method[1] has two desirable characteristics; first, its reliance on simulating the natural remanent magnetisation (NRM) directly with a thermoremanent magnetisation (TRM); second, it includes a built-in monitoring device which detects thermally-induced sample degradation (oxidation, sintering and annealing), a common occurrence in lunar samples. We therefore provide here the first credible evidence that the strength of the ambient magnetic field at the Taurus–Littrow region of the Moon must have been about 0.4 oersted, 4.0×10^9 yr BP.

Of the two main models for the origin of the lunar magnetic field—the iron-core dynamo[5] and the uniformly magnetised lunar silicate core[6,7]—the former more easily explains our observation of an average magnetic field of 0.4 oersted during early lunar history. But in view of the similarity between the size of this field and that deduced[8–10] from carbonaceous chondrites 4.4×10^9 yr old, we draw attention to a relatively little considered possibility: that such large fields were characteristic of, and emanated from, a pre-main sequence, T-Tauri stage Sun.

The details of our experiments will be published elsewhere. The NRM of lunar rock 72215 was found to be very stable[11], and the remanences carried by the desirably high coercivity

Table 1 Palaeointensity values from 72215

Subsample no.	N	H (oersted)	s.d. (02)	Range (oersted)
72215,56	7	0.55	0.10	0.74–0.44
,46	7	0.41	0.17	0.60–0.21
,93	8	0.28	0.07	0.37–0.18

range of 100–800 oersted were used to calculate palaeointensities. Table 1 lists three palaeointensity values, which are roughly 0.3, 0.4, and 0.5 oersted respectively. Within one standard deviation, the values 0.3 and 0.4 obtained from subsamples 72215,46 and 72215,93 do not differ significantly from each other. The value of roughly 0.5 oersted obtained from 72215,56 is, however, different and may be expected to represent the lunar palaeointensity during the formation of the boulder (4.0×10^9 yr BP); the mean palaeointensity of 0.35 oersted obtained from the other two subsamples may pertain to an older time. We prefer however, to adopt a more conservative attitude: that of calculating an average palaeointensity of 0.4 oersted from all the three subsamples, and assigning them all an age of approximately 4.0×10^9 yr. In the present experiment, for the first time, three subsamples from one rock (72215) have been heated to beyond their respective maximum blocking temperatures, and anhysteretic permanent magnetisation (ARM) curves before and after heating have shown that little change in the magnetic carriers took place during the heating. The deduced palaeointensities are based on comparisons of laboratory TRMs in a known field, with the NRMs acquired as TRMs during the assembly of the boulder.

Leaving aside other palaeointensity measurements involving approximate methods such as simulating the TRM of the lunar samples with an ARM (refs 12–14) or induced permanent magnetisation (IRM) (ref. 15), there are four determinations involving complete heatings to the highest blocking temperatures of lunar samples with approximate ages of 4.0×10^9 yr. Our measurements from the three subsamples reported here indicate a value of 0.4 oersted. The other reliable measurement[16], taken from a single piece of 62235,53 (dated at 3.9×10^9 yr) yielded a value of 1.2 oersted. A replotting of those data to meet criticisms[15] does not change the observed value by more than 20%. Thus, we need to find a source for a rather large, ancient lunar magnetic field at $\sim4\times10^9$ yr BP. The magnitude of this field could be as low as 0.4 oersted (our measurements) or as high as 1.2 oersted (Collinson *et al.*[16]). In either case, the required fields are approximately 10^4 times greater than present-day interplanetary or solar flare fields.

Sonnett and Runcorn[17] have outlined a rather ingenious mechanism, which could generate a lunar, iron-core dynamo, using inductive heating as a heat source, in a small accreting Moon. It meets one of the difficulties[15,18] of an operating dynamo in the young lunar core. The present state of knowledge in theoretical magnetohydrodynamics is, however, such that we cannot convincingly say whether such a small dynamo would be able to produce fields on the order of 1 oersted (see ref. 14). In our opinion, however, if we have to choose between a lunar core dynamo and the field of a permanently magnetised, lunar silicate core, once exposed to an even larger primordial field, the first alternative seems more preferable. Strangway and Sharpe[7] have calculated that a primordial field strength of 10 oersted would have been needed to produce that degree of magnetisation in the silicate core (with 3% by weight of iron) which would lead to an ambient palaeointensity of 0.02 oersted at the lunar surface. Such a low palaeointensity is indicated[19] by an apparently reliable thermal determination on a young (3.3×10^9 yr) lunar breccia, 15498,36. But using the latest value[20] of iron content for lunar interior (9% by weight) and our lunar palaeointensity of 0.4 oersted at 4.0×10^9 yr, the updated value of the postulated primordial solar field has to be as large as 75 oersted. Faced with this dilemma of generating 0.4 oersted (or as much as 1.2 oersted) at the lunar surface by invoking either a primordial field of 75 oersted uniform over 10^3 km, or a marginally plausible, central iron-core dynamo that can generate 0.4 oersted at the lunar surface, we prefer the latter model.

A third solution may be even more acceptable than those two. First, we draw attention to the apparent coincidence between the range of 0.4 to 1.2 oersted for a lunar surface field at 4.0×10^9 yr BP, and the reported[8–10] range of 0.2–1.1 oersted for palaeointensities determined from carbonaceous chondrites approximately 4.4×10^9 yr old. The latter values are $\sim10^4$ times greater than the present interplanetary field, and if such a field were attributable to a pre-main sequence, T-Tauri stage Sun (with no sector structure of the solar field), it could indeed be the same large, early Solar System field postulated[21] to explain the smaller solar angular momentum of that time. Could the lunar surface at 4.0×10^9 yr BP not, in fact, have recorded the same early field? Alternatively, the ambient solar field could have decayed from 1 oersted at 4.4×10^9 yr BP to, say, 0.1 oersted at 4.0×10^9 yr BP. The apparently higher (0.4–1.2 oersted) ambient field at the lunar surface would then be attributable to an amplification of the 0.1-oersted field by 'dusty' plasma dynamos operating on the lunar surface, and generated by the intense collisions[22,23] which seem to have gone on at the lunar surface till 4.0×10^9 yr BP (ref. 24).

There is one apparently strong objection to this hypothesis. Lunar rocks aged $4.0–3.2\times10^9$ yr old have been found to be magnetised. Thus, it is commonly assumed that the same source of the lunar surface field had to operate continually over the given time range. We do not agree with that contention, and point to a possible recorded drastic decrease in the lunar field after 4.0×10^9 yr BP. The palaeointensity[19] of 0.02 oersted at 3.3×10^9 yr BP is the single reliable, thermally determined value, at present available for those younger times. Future palaeointensity studies may confirm such a low (by two orders of magnitude) value, and thus point to quite a different source for the lunar field, such as the magnetohydrodynamic amplification of a 0.002-oersted ambient solar field, or even the presence of an older underlying crust, magnetised at an earlier time. Regarding the latter, it should be recalled that station magnetometer readings as large as 0.003 oersted produced locally by the magnetised crust were measured by the Apollo-16 astronauts[25]. So far as the present work is concerned, we believe to have presented credible evidence for a large magnetic field during early lunar history which could most easily come from a pre-main sequence T-Tauri Sun. In as much as we do not have to invoke an external field that was both dipolar and uniform over the Moon as a whole, our conclusion here does not invalidate the suggestion[26] that the global lunar magnetic anomaly record could not be attributable to an external, uniform, dipolar field.

Radiocarbon evidence for deglaciation in north-western Himalaya, India

SINCE the publication of the first post-glacial pollen diagram from Toshmaidan (74°31′E, 33°56′N, ~ 3,120 m OD) in the Kashmir Valley by one of the authors[1], the age of the pollen sequence has been a bone of contention[2–4]. The organic deposits overlie a sequence of bluish-grey buttery clay and crushed rock, and were suggested[1] to date from the last deglaciation. The pollen sequence was divided into eight stages, and showed a cold–warm–cold climatic sequence, which was similar to previous findings on post-glacial climate[5]. Here we present radiocarbon dates on these deposits, and these confirm our previous work.

In early June 1973, an expedition to Kashmir was organised to obtain radiocarbon dates of the inorganic–organic interface, as well as the sedimentary sequence in the mire, at Toshmaidan, and a position stratigraphically close to the original point was selected for collecting samples. The samples dated were subjected to pollen analysis for correlation with the original pollen diagram from the site.

The results of the radiometric dating are shown in Table 1. All but one sample were dated at between ~ 9,500–15,000 b.p., showing that the sedimentation of the organic deposit at Toshmaidan started long before the Neolithic period. The samples which were pollen analysed showed that all samples predating 9,500 b.p. belonged to the time of the first four pollen stages (*a–d*) (Table 1). The next sample above, however, correlated with the seventh stage (*g*) of the pollen sequence, and gave a date of 2,790 ± 160 b.p. As none of the samples showed any similarities with stages *e* and *f* it was suggested that there was an erosional break between samples PRL-**2(B)** (2,790 ± 160 b.p.) and PRL-**3** (9,650 ± 245 b.p.) which correlated with stages *g* and *d* respectively. The gap of nearly 7,000 yr between the radiocarbon dates from the above two samples (Table 1) confirmed the presence of the break in sequence. Because of this disconformity in the sequence it is not possible to calculate the rates of sedimentation in the whole sedimentary profile. This also means that pollen stages *e* and *f* in Singh's pollen diagram cannot yet be dated accurately. Nevertheless the dates for these stages cannot be outside the range set by PRL-**2(B)** (2,790 ± 160 b.p.) and PRL-**3** (9,650 ± 245 b.p.), and therefore the stages could still represent broadly the mid-postglacial time to which they had been assigned in ref. 1. Similarly stage *h*, the topmost stage, can now be considered to postdate 2,790 ± 160 b.p. Radiocarbon dates from samples comparable with stages *a–c* fall between ~ 14,000 and 15,000 b p. and with stage *d* between 9,500 and 11,000 b.p.

Terminal dates for the pollen stages all remain to be calibrated but it may not be possible to do so accurately without a detailed pollen analysis and fresh radiocarbon dating from the site.

The most significant point to emerge from the present study has been the evidence of deglaciation at Toshmaidan which is shown to have been in progress at ~ 3,120 m OD in Kashmir, ~ 14,000–15,000 yr b.p. This date, from the contact between inorganic and organic sediments, is in agreement with the dates generally associated with deglaciation following the last glacial period in several parts of the world[6]. The regional significance of the date for deglaciation from Toshmaidan will become clear as more dates become available from other parts of the Himalayan region. In the global context, the date of deglaciation from Kashmir broadly falls in line with dates obtained from similar elevations in New Guinea[7] and Ruwenzori, Uganda[8] in the tropics. There are, however, no available sites providing information on age of deglaciation situated at similar latitude and altitude as Toshmaidan, and, as a result, exact parallels have not yet been found.

Eastern Greenland basalts and their supposed plume origin

IT has been suggested[1,2] that the eastern Greenland flood basalts had their origin in plume activity centred about a triple junction of which Kangerdlugssuaq (Fig. 1) is the failed arm. The suggestion is reviewed here in light of the petrological characteristics and spatial distribution of the basalts.

The main outcrop of lavas is on the Blossville coast in the 450 km between Kangerdlugssuaq and Scoresby Sund, though scattered, less well known outcrops are found along the 800 km of coast between Kialineq and Shannon Isle. The lavas were extruded during an early stage of the opening of the North Atlantic from sources on the seaward side of the present outcrops. They thin inland from the coast, where estimates[3] of their thickness in the neighbourhood of Ryberg Fjord indicate a maximum of 9 km Though Nielsen[4] has suggested that thickness estimates may be overgenerous because of a failure to take into account faulting, we do not believe that the figures are significantly in error. The base of the pile is submarine and the upper 6 km comprises dominantly, but not exclusively, subaerial flows. Allowing for several kilometres of thinning between Kangerdlugssuaq and Scoresby Sund, and taking into account basalts on the coastal shelf, the present volume along this 450 km of coast is estimated as approximately 6×10^5 km^3.

Palaeontological dating using marine microfossils of the submarine base of the lava pile in the Kangerdlugssuaq–Ryberg Fjord area[3] and marine horizons in the top of the pile at Kap Dalton[5], shows that the effusive activity occurred in latest Palaeocene time over a very restricted time interval, the best estimate of which is approximately 3 Myr. It may be that the activity took place within one geomagnetic reversal[3], and if that is so then even 3 Myr may be an overestimate.

Using the best available estimate of 3 Myr, however, the volume of basalts erupted each year in this one area of flood basalts is 0.2 km^3, well in excess of the estimated maximum discharge of the Icelandic plume model[6], and as shown in the reconstruction of the North Atlantic (ref. 7, and Fig. 2) the actual extent of the flood basalts must have been much greater. Particularly intense activity is indicated and there is no evidence in the lava pile of regional evolution with time from alkaline to tholeiitic (of the sort found, for example, at the Afar triple junction[12]).

Analyses of subaerial basalts from a typical section in the area of Wiedemann Fjord (Table 1) show a content of large ionic lithopile elements (LIL) characteristic of 'hot spot' basalts, as distinct from relatively LIL-depleted mid-ocean ridge basalts[8]. Published analyses of subaerial basalts from the area of Scoresby Sund[9], are comparable. Schilling[10,11] has suggested that 'hot spot' basalts typically have a lanthanum-samarium enrichment factor $(\text{La/Sm}_{\text{EF}})>1$ and he has presented analyses from Scoresby Sund which show this feature[11]. The Wiedemann Fjord analyses likewise show a $\text{La/Sm}_{\text{EF}}>1$, and also the light rare earth pattern typical of 'hot spot' basalts (Fig. 3). Schilling and Noe-Nygaard[11] have shown that the Lower and Middle Series basalts of the Faeroe Islands also have $\text{La/Sm}_{\text{EF}}>1$ and are comparable with the Scoresby Sund basalts, though, as they pointed out, Scoresby Sund in the Atlantic reconstruction is significantly distant from the Faeroes.

Tholeiitic basalts with these characteristics are typically found at oceanic hot spots such as Iceland, or occur late in the process of crustal thinning, as in the Afar region[12,13]. They show no evidence of continental crustal influence in their chemistry and satisfy the criteria of volume and compositional homogeneity indicative of basalts generated directly by mantle fusion. The Greenland basalts overlie continental crust but their chemistry and the low pressure regime necessary for their voluminous generation by direct mantle melting[14,15] indicate that they were erupted from the embryonic ocean forming offshore from the present outcrop after thinning of the continental crust. The evidence is that this part of Greenland never attained any significant elevation above sea level before or during the effusive activity[3,5], and it is not difficult to envisage the lavas spreading on to the continental crust and thinning away from their source area.

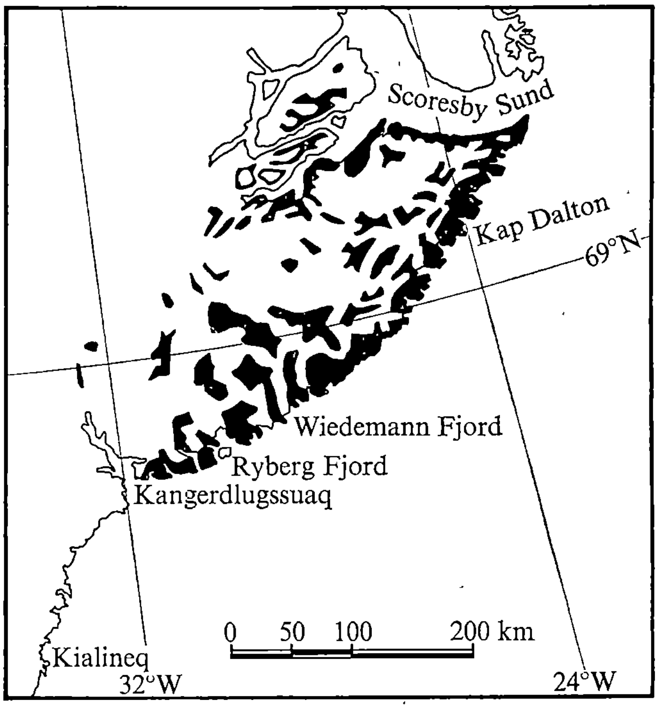

Fig. 1 Localities and basalt distribution between Kangerdlugssuaq and Scoresby Sund.

The original plume hypothesis of Morgan[16] postulated plumes of the order of 150 km diameter rising from the deep mantle. As developed by Schilling[10] and Vogt[17] for Iceland, a much larger plume of geochemically undepleted mantle, 200 km in radius, rises beneath Iceland and provides material which spreads preferentially away beneath the mid-ocean ridge. Geochemical anomalies of decreasing magnitude are found up to 400 km away from Iceland[10] (that is, up to three times the plume radius from its centre), beyond which normal (relatively depleted) mid-ocean ridge lavas become dominant. Schilling[10] attributed the systematic variation in rare earth and minor element concentrations, which he documented along the Reykjanes Ridge axis, to the mixing of relatively undepleted (plume) and depleted (asthenosphere) materials or their partial melt products (though later developments[18,19] have shown that the variations may be step-like rather than gradational). Flow rates away from the plume beneath the mid-ocean ridge have

†Average of 37 analyses from Scoresby Sund.

been estimated[17] at 10–20 cm yr^{-1}, and 5–7 Myr must have elapsed for the geochemical anomalies to reach the furthest distance from the plume at which they can be detected. If the plume model is applied to Greenland 55 Myr BP, then the distribution of the basalts would likewise indicate preferential movement of the plume material along the developing lithospheric weakness from which the lavas erupted. If a plume of the large 200-km radius and flow characteristics suggested for Iceland was centred about Kangerdlugssuaq, then several million years would be expected to elapse between the initiation of magmatic activity over the plume and the build-up of the voluminous extrusions actually found along the length of the coast. The evidence, however, suggests that chemically similar, undepleted magmas erupted in large volumes simultaneously between Kangerdlugssuaq and Scoresby Sund, the whole effusive activity occupying approximately a mere 3 Myr. On the plume hypothesis, an escalation in plume intensity or an unlikely increase in dimensions to something double that for Iceland would be necessary.

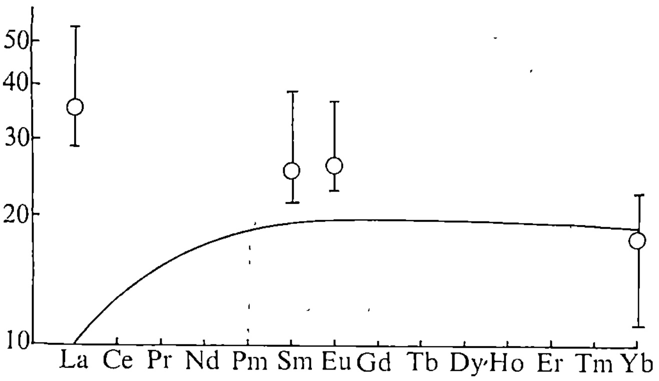

Fig. 3 Pattern of chondrite normalised, selected rare earths for Wiedemann Fjord basalts, showing average and spread (analyst J. E. Whitley). Lower line, chondrite normalised, mid-ocean ridge average pattern[22].

It is concluded that in their spatial and temporal characteristics the eastern Greenland flood basalts do not easily conform to the model of a narrow plume beneath continental crust. The rise of a discrete mantle blob, as opposed to a long lived plume (see ref. 11), a model which offers an explanation of sudden chemical changes with time, has similar difficulties of dimensions and timing when applied to the eastern Greenland–Faeroes situation. A convective system of wide lateral extent, or perhaps the linking of several lithothermal systems into a major convection system[20,21] seems preferable. Nevertheless the problem of separate magma sources for hot spot and mid-ocean ridge basalts, or the alternative of appealing to phlogopite stability and disequilibrium melting[15], still remains.

We thank N. J. Soper and C. Downie for discussions.

Late-glacial and postglacial sedimentation in the Peris-Padarn Rock Basin, North Wales

BOREHOLES sunk in the Llyn Peris Trough, North Wales, have revealed considerable thicknesses of Quaternary deposits, including glacial lake rhythmites, sands and gravels, together with substantial amounts of organic lake mud and wood debris peats rich in pollen and macrofossils. Preliminary sedimentological and palaeontological analysis and radiometric dating indicates that the sedimentological record extends from the period of ice wastage in the valley heads into the Christian era.

The gravels, sands, silts and peats were deposited in a rock basin produced by glacial overdeepening of the Cambrian shales, slates and gritstones. The lowest lithostratigraphical unit consists of laminated lacustrine clay-silts which are locally sandy and gravelly They are glacilacustrine rhythmites predominantly of diatactic type and, so far, they have proved to be barren of pollen and macroscopic organic remains. They exceed a thickness of 27 m (borehole EP7: Fig. 1) and they rest on rock-head at about 35 m OD in the vicinity of borehole EP4. In thin section, both coarse and fine laminae can be seen to contain an appreciable amount of clay-sized material, the range of grain size in the coarser layers (1–10 μm) being about one order of magnitude larger than in the finer laminae. Grain counts of the relatively few clasts with long axes greater than 0.2 mm revealed a predominance of feldspars, muscovite, quartz with some grains of magnetite, chlorite and partly altered biotite The finer material in the coarser layers and the material in the finer layers was found to be dominantly of quartz with feldspars, muscovite and some chlorite. The finer laminae include a notable amount of very fine grained clay mineral. Analysis of this clay mineral component by X-ray diffraction showed a dominance of muscovite, chlorite and kaolinite, in addition to

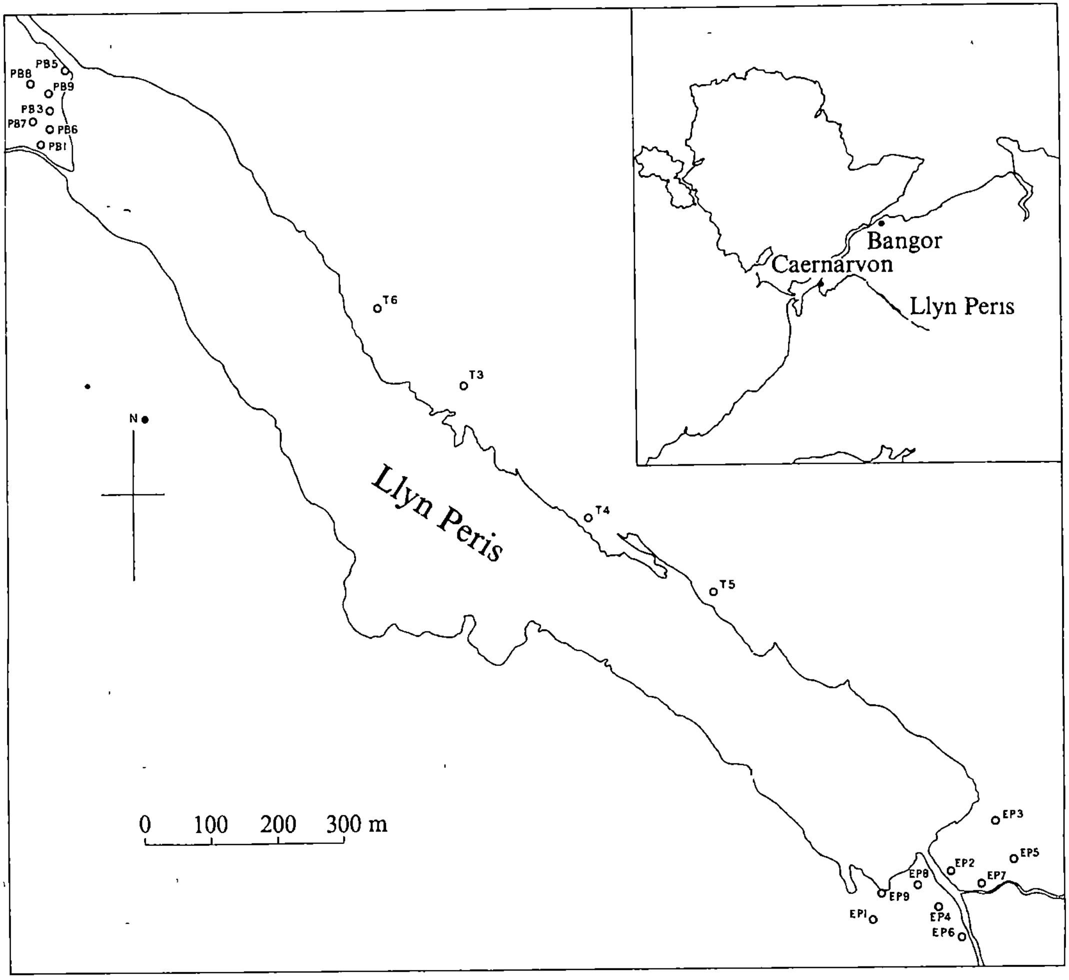

Fig. 1 Location of Llyn Peris and sites of boreholes.

quartz. The kaolinite has a high crystallinity index, indicating a clastic origin, attributable to the grinding action of ice. There is little amorphous clay and little difference in the clay mineralogy of the coarse and finer layers. The microfabric of the silts and clays is being investigated using the scanning electron microscope.

Although severely disturbed in local areas because of overburden from slate quarries, the rhythmites make up a regular series of plane beds with only occasional discontinuities caused by local penecontemporaneous erosion and minor faulting.

Varve counting methods have been applied to the total length of the rhythmites in borehole T3. The mean thickness of rhythmite sets (which are assumed to represent deposition over 1 yr, and thus to be true varves) is 12 mm (range 2–50 mm), the number of coarse and fine couplets within each varve varying from 1 to 8. Given that the rythmite sets are true varves, the results suggest that accumulation extended over a period of 738 yr, or 850 yr if an estimate is included for gaps in the core.

At the head of Llyn Peris and in the large fan at Pont-y-Bala separating Llyn Peris from Llyn Padarn, the rhythmites are overlain by beds of glacifluvial origin. These sediments range in size from very coarse cobble and pebble gravels to thin layers of fine and medium sand associated with the rhythmites and the overlying organic deposits. The constitution of the gravels is dominated by the local bedrock types, the slates and shales giving high average flatness values in all grades, and moderate to high roundness values. Clasts of medium gravel grade and larger show faceted forms. In the case of the grits and vein quartz that is probably attributable to glacial grinding. The medium sand grade, probably the most susceptible to edge rounding, is moderately to well rounded. The greatest thicknesses of sand and gravel are found in the large fan at Pont-y-Bala, which comprises interlayered sands, gravels, rhythmites and peats.

The sands and gravels are the products of periodically high discharges of meltwater streams which issued from the Peris Glacier above the lakehead and from waning cirque glaciers above Pont-y-Bala[1]. This gravel fan is of particular interest. As it is interbedded with rhythmites, it evidently began to accumulate well before the final vestiges of ice disappeared from the adjacent cirques and higher valley heads. The interbedding of the sand and gravels with peat indicates that the fan continued to grow well into the postglacial period. Thus, fan growth imposed a progressively rising water level on the Llyn Peris Basin.

Complete bores and bulk samples of the organic layers (earlier obtained by shell and auger rig) have been examined from sites at both ends of Llyn Peris. Macroscopic examination has revealed three distinct suites of organic deposits.

The Pont-y-Bala suite consists of discontinuous wood peat lenses, between 0.5 m and 2 m thick, interbedded with gravels. Borehole PB6 traversed three such lenses (Fig. 2). The wood, which is of *Betula/Alnus* type, is highly compressed and distorted. This feature, together with the high mineral content of the peat, suggests that the material has been rafted into the Pont-y-Bala fan from adjacent slopes. The East Peris suite from the head of the basin is much more impressive. Borings have revealed organic deposits up to 20 m thick buried by 10–12 m of sands and gravels. Material from the EP7 borehole at depths between 10 m and 30 m (Fig. 3) is highly variable, comprising organic lake muds, wood and debris peat with well preserved

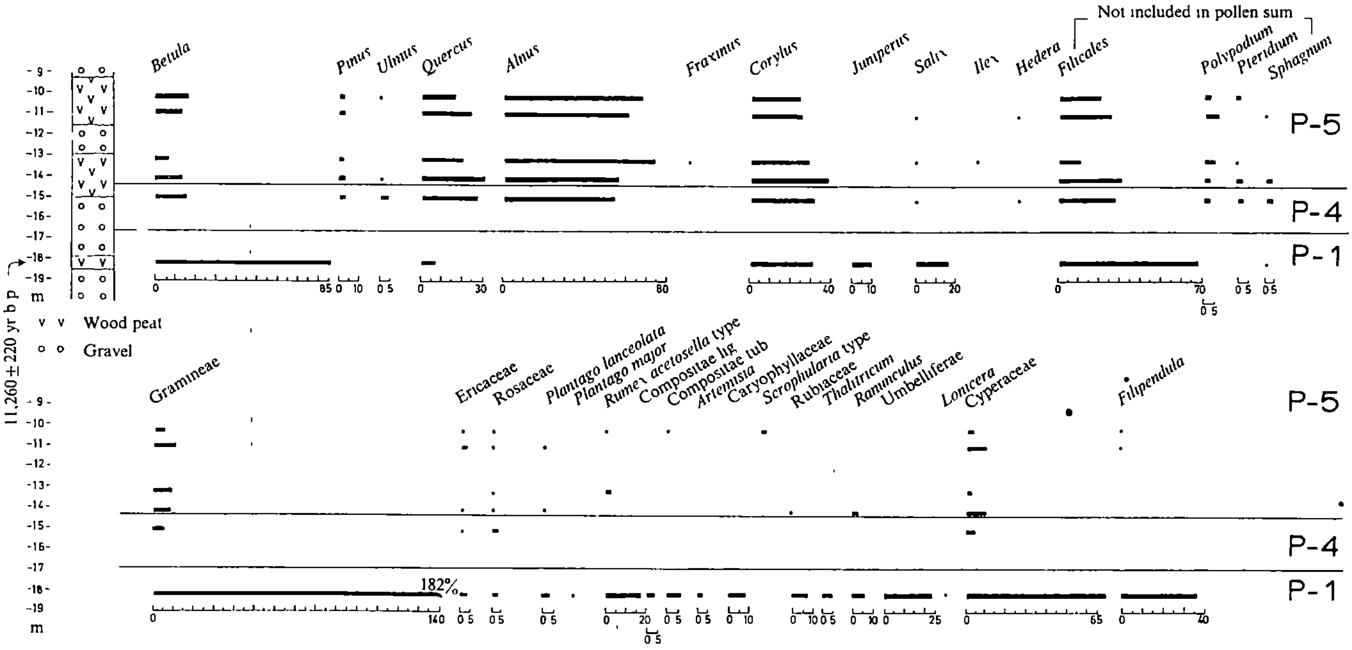

Fig. 2 Tree and non-tree pollen expressed as percentages of total tree pollen for PB6 at depths of 9–19 m

leaves, and sand and gravel partings. These deposits indicate accumulation *in situ* in a marginal lacustrine environment with a rapidly rising water table. The Central Peris suite of organic deposits is not discussed in detail here. This suite lies beneath Llyn Peris and beneath the Dinorwic slate tip, which has extended out into what was formerly the lake. They comprise fine-grained, dark-grey organic lake muds and silts, typical of a deep lacustrine environment.

Figures 2 and 3 show the pollen diagrams from boreholes PB6 and EP7. The sampling interval was determined by the availability of bulk samples from those cores. Six pollen assemblage zones, Peris 1–6, have been recognised, and their characteristics are summarised in Table 1. They are listed in what is assumed to be chronological order, although the sequence in PB6 is interrupted because of the discontinuous nature of the deposits.

The earliest assemblage, Peris 1 has a late Weichselian date of 11,260±200 yr b.p. (Table 1, B-555), and has similarities with the late-glacial floras described from Cwm Dwythwch and Nant Ffrancon[1].

The assemblage suggests a fairly open environment, as the proportions of pollen of light-demanding plants are high. It is likely that scrub of birch and willow was fairly widespread in the basin. If the theory of rafting is correct some of this material may have originated in the Cwm Dwythwch area, as this lies immediately above the Pont-y-Bala fan. Figure 3 shows the full sequence of pollen assemblage zones (Peris 2 to Peris 6), and these exhibit the standard changes which are associated with the develop-

Table 1 Characteristics of Peris pollen assemblage zones

Pollen assemblage zone	Representative samples	Characteristics	Affinities and dating†
Peris 1 *Betula/Filipendula/Rumex* assemblage	PB6 18.55 m	*Betula* >80% AP.* *Filipendula* >30% AP. *Rumex* >10% AP Gramineae >150% AP. AP* values relatively low. Wide variety herb pollens.	Late Weichselian 11,260±220 yr b.p.
Peris 2 *Betula/Pinus/Corylus* assemblage	EP7 29.5 m	*Betula* >50% AP. *Pinus* >30% AP. *Corylus* >100% AP. Herbaceous types well represented but reduced in variety compared with Peris 1.	Flandrian chronozone F I 9,400±200 yr b.p. (start zone)
Peris 3 *Pinus/Ulmus* assemblage	EP7 28.0–28.95 m	*Pinus* >40% AP. *Ulmus* >10% AP. *Betula* <30% AP. *Corylus* <60% AP. *Alnus* rising. Low representation of herbaceous types.	Flandrian chronozone F II
Peris 4 *Alnus/Quercus/Ulmus* assemblage	PB6 15.0 m EP7 23.75–28.0 m	*Alnus* >60% AP. *Quercus* >20% AP. *Ulmus* >5% AP. Low representation of herbaceous types	Flandrian chronozone F II
Peris 5 *Alnus/Quercus* assemblage	PB6 9.4–14.5 m EP7 15.45–22.8 m	*Alnus* >60% AP. *Quercus* >25% AP. *Ulmus* <2% AP. Low representation of herbaceous types. Representation of *Betula* increases at expense *Quercus* at top of zone.	Flandrian chronozone F III
Peris 6 Gramineae/*Plantago lanceolata* assemblage	EP7 13.72–10.6 m	Gramineae >75% AP. *Plantago lanceolata*> 5% AP. A wide variety of herb pollen types represented.	Flandrian chronozone F III 1,750±100 yr b.p. (end zone)

* AP, Arboreal pollen.

† Radiocarbon dates provided by Department of Geology, University of Birmingham.

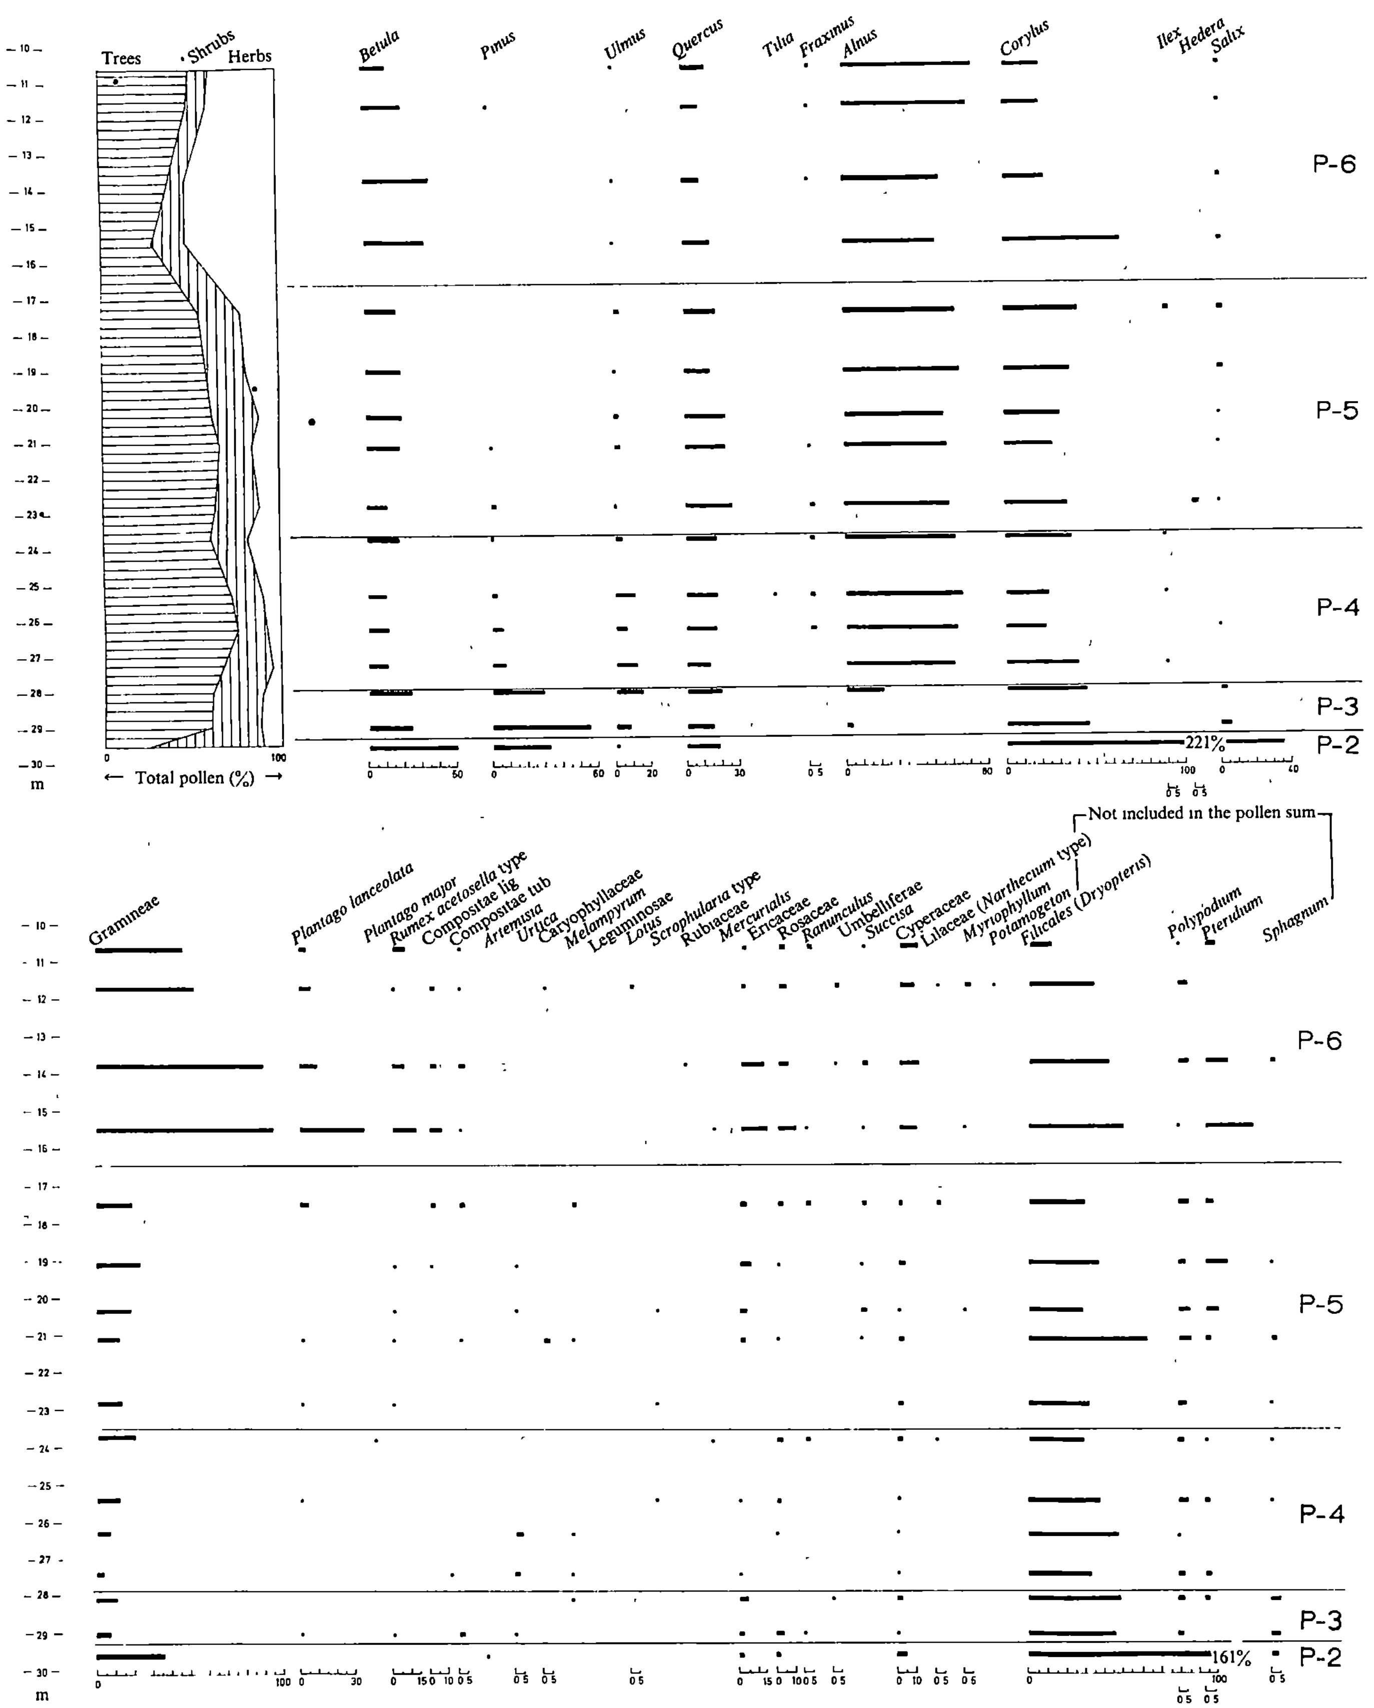

Fig. 3 Tree and non-tree pollen expressed as percentages of total tree pollen for EP7 at depths of 10–30 m.

ment of Flandrian vegetation in the British Isles. Material from Peris 2 has a radiocarbon date of 9,400±200 b.p. (Table 1, B-554). The high percentages of *Corylus* pollen typical of this assemblage occur at many sites in the British Isles in Flandrian chronozone Ib (ref. 2). The woodland canopy in the basin was becoming closed at this stage, although some open areas clearly persisted. Stands of pine existed, with birch and hazel scrub being widespread. Peris 3 is characterised by an increase in *Pinus* pollen at the expense of *Betula*. Pine must have come to dominate the woodlands of the basin in this zone, but oak and elm were spreading and alder was already present in the area.

Mixed oak forest became well established in the Peris-Padarn basin during Peris 4. The expansion of *Alnus* which marks the opening of this zone, is usually assumed to correlate with the FI/FII chronozone boundary around 7,000 yr b.p. The stratigraphical evidence suggests that dense alder carr grew at the eastern end of Llyn Peris at that time, probably extending all around the lake and partly up the slopes as the assemblage is also represented in the rafted material from Pont-y-Bala. The canopy seems to have been very dense with few herbaceous plants surviving. The *Ulmus* decline horizon, assumed to date from around 5,000 yr b.p. (ref. 3) has been used to separate the Peris 4 and Peris 5 assemblage zones. Apart from the decline in elm in the area the forest composition does not seem to have changed markedly. In contrast, the high proportions of pollen of Gramineae and herbs in Peris 6 are indicative of man's interference with the vegetation on a large scale. *Plantago lanceolata* is a herb particularly associated with pastoral farming activities, and it seems probable that the inception of this zone dates from the Bronze Age. Organic material from the top of the zone has a radiocarbon date of 1,750 ± 100 yr b.p. (200 AD: B-556).

The sequence of vegetation history follows the pattern already established for western Britain. Further detailed analyses of these and other cores from the area should allow the reconstruction of a complete picture of the ecological development of the basin. Particular attention will be paid to establishing the nature and scale of man's activities in this highland area.

Two features of the deposits of this basin are of outstanding interest. The first is the very great depth of peat, of the order of 20 m, which has accumulated in 9,500 yr at the East Peris site. This can only be accounted for in terms of a very rapidly rising water table which must have been governed by the growth of the alluvial fan at Pont-y-Bala. The second feature of particular interest is the 10 m of gravel which buries these East Peris deposits—gravel which has accumulated in the basin since 200 AD. Certainly, catastrophic events must have been involved in its deposition. It seems that disruption of the vegetation cover on the steep hillsides triggered this wave of sedimentation. Whether this was the product of climatic oscillation or early man is still to be determined.

We thank the Central Electricity Generating Board and Binnie and Partners, Consulting Engineers for allowing access to the core material on which this study is based.

Relationships of Middle and Upper Pleistocene hominids from sub-Saharan Africa

IT has long been common to refer to the Broken Hill (Kabwe) and other later Pleistocene African hominids as representive of a "Neaderthaloid" population in the sub-Sahara In the first account of the Rhodesian skull, Smith Woodward[1] notes similarity to the "Neanderthal or Mousterian race", and this theme has been repeated, with qualifications concerning the extent to which African Neanderthals actually resemble their European relatives[2-4]. Brose and Wolpoff[5] lump all African and Eurasian specimens under the heading "Neanderthal". Following Mourant[6], a few recent studies[7,8] have cast doubt on the interpretation; these are based on measurement and use distance statistics which show separation between African and European materials but provide little information about important anatomical differences involved. I report here morphological evidence of the distinctiveness of Broken Hill and its relationships to other African remains. Examination of original fossils from Hopefield (Elandsfontein), Florisbad and the Omo as well as Broken Hill reveals a pattern quite unlike that of Neanderthal crania from Europe.

The Rhodesian skull roughly resembles Neanderthals and other archaic *Homo sapiens*, in that the facial skeleton is large below the massively developed supraorbital torus, the braincase low, and the occiput rather more sharply angulated than in modern man Broken Hill, however, is extreme in supraorbital development, and the torus is absolutely thicker than in comparable later Pleistocene material (Table 1). Frontal flattening is marked, in spite of some keeling in the midline. The frontal is also relatively narrow as noted by Mourant[6], so that torus exaggeration produces lateral flare of the anterior temporal lines, and the temporal fossae are deep. These characteristics are not matched in European specimens, and Neanderthals generally have a supratoral sulcus (ophryonic groove) backed by a prominent, more bulbous frontal region "Classic" Neanderthal crania also have extensive flattening of the parietal vault near bregma, while there is lateral swelling of the braincase towards asterion With some variation, there is rearward extension of the occiput to form a bun-like structure. Although the Rhodesian cranium has limited parietal flattening along the posterior course of the sagittal suture, characteristic asterionic bulging of the vault is not apparent, and this part of the braincase seems poorly filled by comparison. Greatest breadth is in the supramastoid region rather than higher on the parietals as in most Neanderthal specimens. Viewed from the side, the occiput is nearly vertical above a strongly developed torus, so that actual bunning of the bone is slight. This has been overemphasised in discussions in which Broken Hill is labelled an African Neanderthal.

Striking aspects of the Rhodesian face are its biorbital width and extreme length, especially below the nasal opening. But this face has been shown to be less projecting at nasion and subspinale than various Neanderthals measured[9]. Inspection reveals relative flatness of the maxillary frontal processes and the walls below the orbit, whereas in European crania there is obvious retraction of the zygomatic arch relative to the facial midline. Broken Hill has some alveolar prognathism, but only here does protrusion begin to approach that recorded for Neanderthal remains.

There are such departures from "classic" Neanderthal morphology in other African skeletons, though there has been little effort to document them systematically. Parallels between the Rhodesian and Hopefield fossils have been emphasised[2,10] and these are most obvious in the frontal region. Torus form is certainly similar. The Hopefield parietals are slightly more rounded laterally, but maximum breadth is still low, near the mastoids (which are missing). The base is also broken away, but the form of the occiput seems to be like that of Broken Hill, even if a torus is not so well developed. A fossil with similar morphology is Eyasi I, though this represents a smaller individual, perhaps a female. A cast in the British Museum (Natural History) shows the supraorbital torus to be less robust than in the southern skulls, but in overall appearance Eyasi I is strikingly like Hopefield.

The Omo skeletons[11] now provide more information from East Africa, and Omo II has a few traits not seen in Broken Hill. The Omo II frontal bone is substantially broader than

Parietal chord	111	109	119			
Occipital chord	87		106	101		
Occipital angle (degrees)	40‡		34	35		

All measurements were taken on original specimens. Techniques and definitions are discussed ref. 24.

*The Dreyer reconstruction of Florisbad has been disassembled, and the measurements listed are those which can be obtained from the separate frontal and facial parts. Until a new reconstruction is attempted, dimensions of the orbit and nasal opening cannot be reliably reported.

†Supraorbital torus development is difficult to quantify, and my measurements do not correspond exactly with others reported (for example, ref. 2). One reading is taken in the centre of the orbital margin, though this is not always the point of maximum thickness. The second measurement is taken close to the frontomalar suture, to gauge the extent of lateral attenuation of the torus.

‡These measurements make use of reconstructed landmarks.

§Values obtained by doubling a reading to the midline.

the Rhodesian specimen and quite flat, lacking a supratoral sulcus. The supraorbital margin is intact for only about 4 cm from the left frontomalar suture, and here torus development is slight; however, thickening of the bone towards the centre of the orbit suggests more massive construction in the middle of the face. Outcurving of the anterior temporal lines is not marked, and the temporal fossae are not deep as in Broken Hill and Hopefield. But the skulls are similar in side view, and the vertex lies well forward near bregma. Behind this point, the Omo profile drops evenly away for about half the parietal arc length and then dips again, though the resulting step-like contour is not as obvious as in Broken Hill. There is slight keeling of the parietals in the midline, and there is none of the lambdoid flattening characteristic of European Neanderthals. Instead the parietal wall falls sharply from the temporal line to the mastoid, so that the sides of the cranium are almost concave above the massive mastoids and supramastoid crests, and there is no bulging of the parietals at asterion. Occipital curvature is comparable with that of Broken Hill and Hopefield, but the facial skeleton is missing.

Omo I is less complete but has been termed more modern in appearance. Certainly the back of the occiput is higher relative to the reduced nuchal plane, and the entire bone seems less flexed than that of Omo II. Prominent but localised raised areas of muscle insertion on the nuchal surface are misleading, however, and absolute differences in curvature are small (Table 1) The vault is higher and has a more rounded parietal profile from behind Several frontal fragments cannot be fitted to the parietals but suggest a flattened forehead not unlike that of Omo II.

Given these features of the Omo skulls, several hypotheses regarding their affinities deserve examination. Leakey[12] views the Omo material as separate from "Neanderthaloids" such as Broken Hill and Hopefield This may be reasonable if only the frontal is considered, but obvious similarities in total pattern between Omo II and the southern remains cannot be ignored. Other workers see a major division within the Omo assemblage and prefer to set only Omo I apart, as more modern than Omo II as well as Broken Hill Statistical results[8,13] which seem to support this are based on few measurements or on reconstructions, however, and it is questionable whether a firm case for two lineages in East Africa can be made on the evidence available. An alternative suggestion[8] that Omo I is sampled from a more recent segment of the lineage also containing Omo II cannot be verified geologically[14].

While there is uncertainty about Omo I, the remaining sub-Saharan crania including Omo II are not only long and low in outline but distinctive in more specific ways. Frontal flatness (whether or not associated with extreme supraorbital development), an anteriorly placed vertex coupled with a step-like sagittal contour, near vertical parietal walls above a massive and broad cranial base, and an angulated occiput are all features of a braincase poorly filled by modern standards. The rear of the skull, which lacks asterionic expansion and shows no real occipital bun, is not like that of European Neanderthals, nor is the Broken Hill face, which is broad and devoid of projection in its upper parts. Surely these African hominids are better referred to as archaic than as Neanderthal-like[15], and this term also describes the mandibles usually assigned to the later Pleistocene[16]. A formal subspecific designation as *Homo sapiens rhodesiensis* now seems justified on morphological as well as geographic grounds. Recent revisions of dating support this view and suggest that the African material is substantially earlier than the Würm age appropriate for European specimens Klein[17] argues for a Middle or earliest Upper Pleistocene date at Broken Hill, and the bulk of the Hopefield fauna is also likely to be Middle Pleistocene[18] An aspartic acid racemisation age for a femoral fragment in the Broken Hill assemblage is reported as 110,000 yr (ref. 19), and there is a Th/U date of 130,000 yr for member I of the Kibish Formation in which the Omo skulls were found[20].

If a later Middle Pleistocene age can be accepted for this material, comparisons with other earlier African fossils are more convincing. Leakey[21] notes resemblances of Broken Hill and Hopefield to hominid 9 from bed II at Olduvai, but this important find has never been described fully. Hominid 9 is about equal in length to the Rhodesian skull and exceeds it in maximum breadth across the base by 5 mm It is also lower and more rugged in general morphology, and inion lies well above the horizontal plane The occiput is more strongly curved, and the extensive nuchal surface merges evenly on to the broad posterior faces of the pyramidal mastoid processes. That this heavy flattened cranium is easily distinguished from Broken Hill is not surprising, if the Olduvai hominid is roughly 0.9–1.0 Myr in age[22]. But there are points of definite similarity, particularly in the frontal region. Torus development and postorbital constriction are marked on hominid 9, though the straight brow is not quite so thick as that of Rhodesian man There is also general resemblance in occipital proportions to the later skulls, especially Omo II, although this braincase is more rounded at the back and bears modern looking mastoids. Since the functional significance of such craniofacial likeness is uncertain, the issue of relatedness must be approached with caution. But, the still archaic skulls of *Homo sapiens rhodesiensis* can be regarded as somewhat expanded, higher versions of the Olduvai vault, and the populations sampled at Broken Hill and in the Omo are probably evolved from local groups of early Mid-Pleistocene *Homo erectus.*

Where some individuals (for example, Omo I) depart from the archaic morphology of Broken Hill, there is a suggestion of continuity with more recent hominids. The Florisbad frontal exceeds even that of Omo II in breadth, and brow ridges must be more comparable in size with the (incomplete) Omo structures than with those of Rhodesian man Glabellar protrusion is similar to Omo I. The Florisbad forehead is, however, not as evenly flattened anteriorly, and in torus form and temporal fossa depth this specimen rather recalls the architecture of Broken Hill and Hopefield. Even if Florisbad is correctly dated at 39,000 yr (ref. 23), it is far from fully modern in construction. Facial fragments should provide more information, and fresh study will tie Florisbad more firmly into the succession of later Pleistocene African populations.

I thank B. Hendey, R. E. Leakey, M. D. Leakey, J. J. Oberholzer, C. Stringer and M. Tessema for access to fossil material. M. H. Day commented on a draft of the manuscript, and the work was supported by a grant from the National Science Foundation.

A spatial approach to insect population dynamics

THERE are two aspects of the regulation of animal numbers: first, how the numbers in a population are controlled around a mean level over a number of generations and second, how this mean level is determined. Studies on the dynamics of insect populations leading to the construction of life tables are frequently confined to a particular location where the fecundity and mortality of successive generations are estimated[1-3], and this approach emphasises the first aspect. Varley[1] appreciated the value of obtaining permanent traces of the insects as they passed from one instar to another (galls, emergence holes, exuviae), since such direct counts of the numbers entering an instar avoided the time-consuming and inaccurate process of integrating successive estimates of population size[4]. The traces are analogous to a natural accumulative trap. Beaver[5] and Danks[6] used this 'trace' method for bark beetles and various solitary Aculeata. Freeman[7] extended the trace method to accumulated generations at each of several sites, an approach which emphasises the second aspect of population dynamics.

Our studies in Jamaica on the population dynamics of solitary aculeates commenced with the wasp *Sceliphron assimile* Dahlbom[7-9]. This sphecid builds mud cells, in each of which a single egg is laid[7]. Thus the number of cells constructed by a female constitutes a long-lasting record of her fecundity. Instars which die within cells constitute a similar record of mortality, whereas emergence holes simply measure adults emerged. Moreover, the predators, parasites and competitors can be identified by traces of their entry into or exit from the cells, or by the cast exuviae or faecal pellets within them. The traces thus represent data accumulated for many successive generations[8].

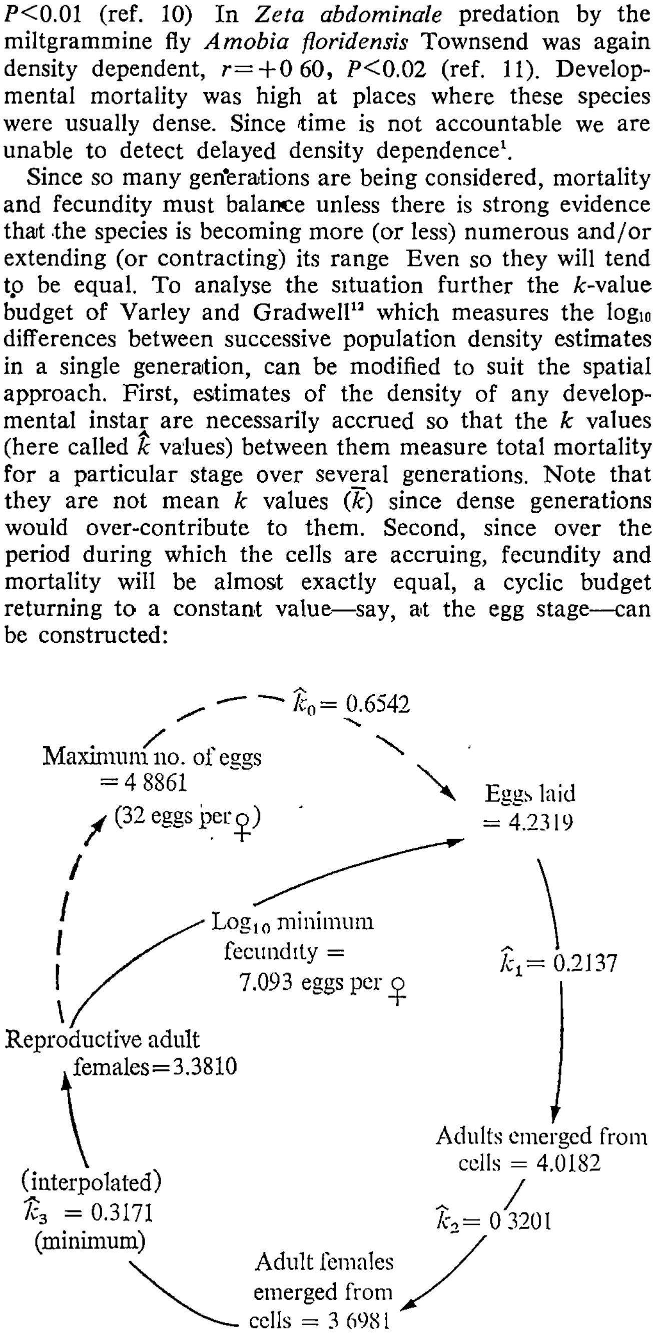
In temperate countries the alternation of summer and winter tends to regulate the synchrony of generations, but in the tropics this is frequently not so and the concept of generation loses much of its value. Although *S. assimile* breeds at a reduced rate between January and March and some prepupae diapause, during the rest of the year about five to six overlapping generations occur. Disused cells accumulate with very small losses for at least seven years or some 40 such generations. Cells belonging to different generations or years cannot be accurately separated. Thus their study and dissection at any site provide data which although not generation(time)-specific are location(space or place)-specific, since we could not expect the pattern of fecundity and mortality relating to so many generations to be very different from any other equal or longer period. Note, however, that the variation of fecundity, mortality and migration with time cannot be assessed.

It is a relatively short task to dissect a large sample of cells from a particular locality, and from this to construct a retrospective place-specific life table. Many localities can be investigated and compared, and thus the spatial pattern in population dynamics can be more simply explored since the temporal one is suppressed. Also, life tables from many localities can be summed to produce one which is a species-specific character for an entire population and therefore of similar status to a human life table for a particular nation.

The major problem in this work is to relate the density of the disused cells at any site to that of the living animals on which mortality factors have been operating. The former are naturally the sum of the latter, but errors would arise if cells had been accruing at one site for a longer period than at another, or if the disappearance rate of disused cells was greater at one site than at another. The numbers of living and disused cells of *S. assimile* were correlated[8] ($r = +0.96$), but errors can be further reduced by sampling at comparable sites—for example, rejecting sites where cells have been accruing for only a year or two. Although specifically unaccountable errors must be present, we estimated[10] in *Pachodynerus nasidens* (Latr.) their magnitude to be about ±20%, which is relatively small compared with the range of density of disused cells (about 1–1,000 m^2).

Within the limitations of our method, density-dependent mortality with respect to place is well established in our tropical aculeates. *Melittobia ?hawaiiensis* (Eulophidae), (formerly recorded as *M. chalybii* Ashmead) is the chief parasitoid of solitary Aculeata in Jamaica. The correlation coefficients of percentage mortality caused by it on the density of the following Aculeata were: *Sceliphron assimile*: $r=+0.84$, $P<0.0001$ (ref. 8); *Zeta abdominale* (Drury), (=*Eumenes colona* Saussure): $r=+0.72$; $P<0.01$ (ref. 11); *Pachodynerus nasidens*: $r=+0.52$, $P<0.01$ (ref. 10) In *Zeta abdominale* predation by the miltgrammine fly *Amobia floridensis* Townsend was again density dependent, $r=+0.60$, $P<0.02$ (ref. 11). Developmental mortality was high at places where these species were usually dense. Since time is not accountable we are unable to detect delayed density dependence[1].

Since so many generations are being considered, mortality and fecundity must balance unless there is strong evidence that the species is becoming more (or less) numerous and/or extending (or contracting) its range Even so they will tend to be equal. To analyse the situation further the k-value budget of Varley and Gradwell[12] which measures the $\log_{10}$ differences between successive population density estimates in a single generation, can be modified to suit the spatial approach. First, estimates of the density of any developmental instar are necessarily accrued so that the k values (here called $\hat{k}$ values) between them measure total mortality for a particular stage over several generations. Note that they are not mean k values ($\bar{k}$) since dense generations would over-contribute to them. Second, since over the period during which the cells are accruing, fecundity and mortality will be almost exactly equal, a cyclic budget returning to a constant value—say, at the egg stage—can be constructed:



$\hat{k}_0 = 0.6542$
Maximum no. of eggs = 4 8861 (32 eggs per ♀)
Eggs laid = 4.2319
$\log_{10}$ minimum fecundity = 7.093 eggs per ♀
$\hat{k}_1 = 0.2137$
Reproductive adult females=3.3810
Adults emerged from cells = 4.0182
(interpolated) $\hat{k}_3 = 0.3171$ (minimum)
$\hat{k}_2 = 0.3201$
Adult females emerged from cells = 3 6981

Fig. 1 A cyclic budget for *S. assimile* in Jamaica (see text). $\hat{k}_0$, Loss of fecundity; $\hat{k}_1$, developmental mortality; $\hat{k}_2$, loss to males, $\hat{k}_3$, pre-reproductive mortality/migration of females.

Figure 1 traces the fate of 17,059 ($\log_{10}=4.2319$) eggs laid during some 40 generations The sex ratio was equivalent to about 47.8% females, and the remaining males are considered as a 'loss' to the species and therefore equivalent to a mortality factor. The pathway of maximum fecundity (broken line) would occur if all reproductive females laid the maximum number of eggs recorded for a single female. Minimum fecundity is the average number of cells per nest in Jamaica corrected for those cells in which no egg was laid[7]. Observations on marked females indicate that fecundity achieved was 10–15 eggs per reproductive female. $\hat{k}_0$ measures the maximum loss of fecundity due to the death of reproductive females before they have laid all their eggs. The budget has the important property that any missing $\hat{k}$ value (here $\hat{k}_3$) can be interpolated. Thus, if achieved fecundity was 12 5, $\hat{k}_3$ would rise to 0.5631 and $\hat{k}_0$ would fall to 0 4082.

Budgets for specific localities will contain an immigration–emigration factor and this will usually occur in the preproductive adult stage; but the one above is for Jamaica as a whole, and therefore we expect this factor to be small. Budgets for specific localities provide quantitative data on how population levels are achieved and their comparison may enable factors causing the specific population level to be identified, but they cannot reveal the mechanism of control Budgets for entire populations enable inferences about the life strategy of a particular species to be made.

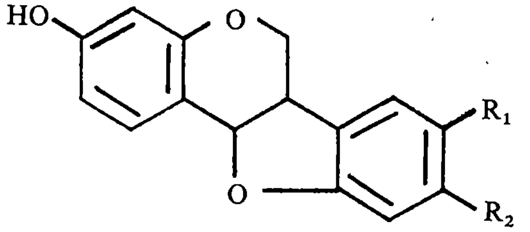
Phytoalexin induction as a new dynamic approach to the study of systematic relationships among higher plants

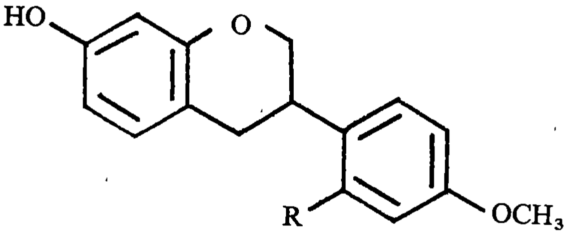
IT is well established that many higher plants respond to microbial invasion by the *de novo* production of organic substances called phytoalexins[1,2] These compounds are absent from healthy plants and are induced by the attacking microorganisms Although the role of phytoalexins in disease resistance is not yet entirely clear, considerable evidence suggests that they are of importance in the protection of higher plants from fungal colonisation Although few surveys have been attempted, there is clearly a taxonomic element in phytoalexin biosynthesis, in that different plant families accumulate chemically different types of compounds[3]. Thus, the Leguminosae in general produce isoflavonoids, the Solanaceae diterpenes, the Compositae polyacetylenes and so on[2]; anomalies are rare, for example, the furanoacetylene, wyerone acid, from *Vicia faba* (Leguminosae)[4] As lesser variations also occur within these families, there is the clear possibility of using phytoalexin induction as a tool in taxonomic studies. We report here the first successful application of this technique to the problems of classification at the generic and species level in the Leguminosae.

The first genus studied was *Trigonella*, a group of some 70 annual species, the best known member being the spice plant, *T. foenum-graecum* *Trigonella* is a taxonomically 'difficult' genus because it merges into the closely related *Medicago* and *Melilotus*[5]; indeed, some of its species have at one time or another been variously classified under these other two genera Young plants were grown from authenticated seed samples of 35 *Trigonella* species. Phytoalexins were obtained from detached leaves using the drop-diffusate technique[6]; conidial suspensions (about 5×10^4 spores ml^{-1}) of the non-pathogenic fungus, *Helminthosporium carbonum* in 0.05% aqueous Tween-20 were used as the phytoalexin inducer[7]. Control leaves were inoculated with deionised water containing Tween-20. After 48 h of incubation, the droplets (diffusate) into which the phytoalexin had diffused, were collected and the antifungal component(s) isolated and identified by direct comparison (thin-layer chromatography, ultraviolet and mass spectroscopy) with authentic samples. The fungitoxicity of compounds I, II, III and IV was determined in tests against the mycelial growth of *H. carbonum*.



I: $R_1=H$; $R_2=OCH_3$

II: $R_1=R_2=O—CH_2—O$



III: $R=OH$

IV: $R=OCH_3$

All 35 species produced one or more of five chemically related phytoalexins. Two of these were the known pterocarpans, medicarpin I and maackiain II while a third (compound TC-1) was provisionally identified as a new tri- or tetrahydroxy-pterocarpan. The others were the known isoflavans, vestitol III and sativan IV. All five compounds were absent from the control diffusates. Traces of three pterocarpan precursors, namely the isoflavone formononetin, the flavanone liquiritigenin and the chalcone isoliquiritigenin accompanied the above phytoalexins in a few species. The results of surveying all 35 species clearly indicate that *Trigonella* can be divided into three broad groups (Fig. 1); group 1, with medicarpin and maackiain; group 2, with medicarpin alone; and group 3, with medicarpin and vestitol. These groups were also divisible into several subgroups (Fig. 1). Thus, within the eight species of group 1, three produce medicarpin and maackiain in equal amounts, whereas the other five produce much more of the former than of the latter. Similarly in group 3, there is a division between the three species which synthesise medicarpin and vestitol and the eight which also produce sativan.

That phytoalexin studies allow *Trigonella* species to be placed within groups which are systematically meaningful is apparent from supporting morphological and chemical evidence. In particular, many species from group 2 show some morphological resemblance to *Melilotus*, a genus characterised by the production of medicarpin. Furthermore, a special chemical feature of *Melilotus*, namely the ability to release coumarin when tissue is macerated[8], is present in most (11 of 16) of the *Trigonella* species in this group (Fig. 1) but is otherwise absent from the genus. Also, the 11 species of group 3 have morphological affinities with members of *Medicago*; again there is a parallel in phytoalexin synthesis in that *Medicago* species generally produce those compounds characteristic of the third *Trigonella* group. It is perhaps significant that taxonomists have made several attempts to move one member of group 3, namely *T. platycarpos*, into *Medicago*[9].

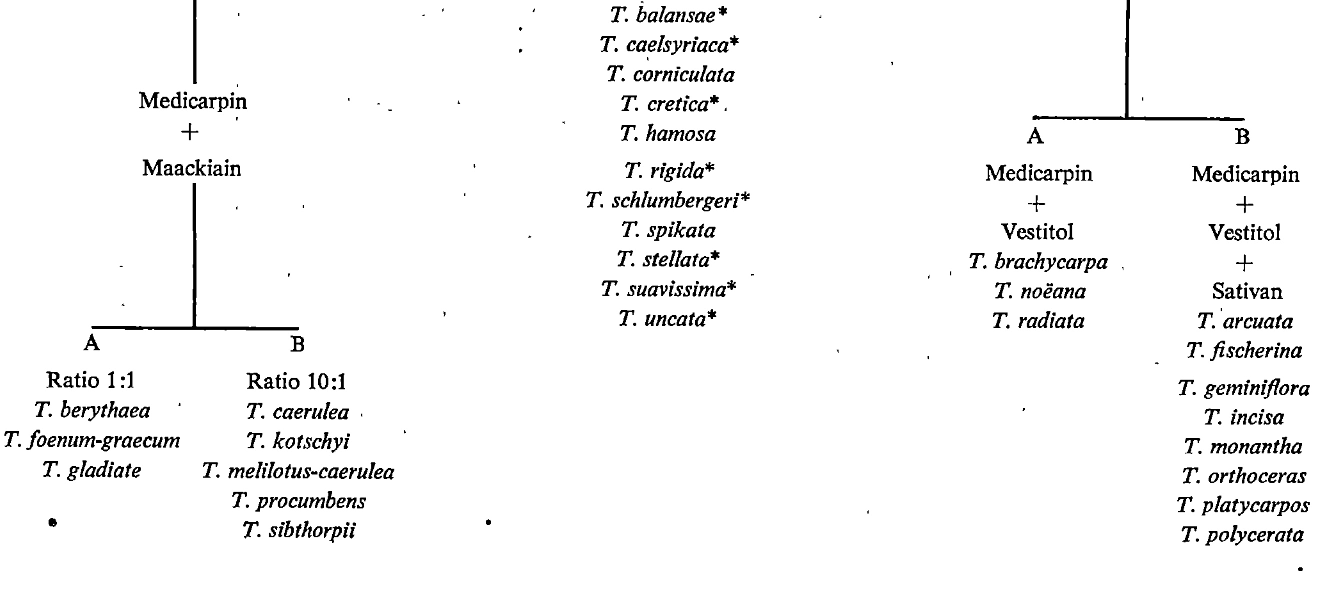


Fig. 1 Groupings of *Trigonella* species based on their phytoalexin production. *Coumarin producer.

The above results also have some bearing on evolutionary relationships between these taxa, in that several of the phytoalexins can be placed in a biogenetically developing series. Thus, medicarpin might be converted to vestitol, from which sativan could then be obtained by methylation. Production of maackiain is an evolutionary step of some significance as this chemically 'advanced' pterocarpan cannot be obtained directly from medicarpin[10]. At the same time is should be noted that both isoflavans (III and IV) are considerably more antifungal than are either of the pterocarpans. On this basis then, the three *Trigonella* groups fall into a series of increasing chemical advancement: group 2 → group 1 → group 3.

We report the present results because we believe that phytoalexin studies are generally applicable to systematic problems in angiosperms. We have successfully induced phytoalexin synthesis in twelve other leguminous genera and the results will be reported in detail elsewhere. Several known and new phytoalexins have been encountered in these genera, including resveratrol—a simple stilbene from groundnuts (*Arachis hypogaea*). Finally, we believe that phytoalexin surveys are economically important in that new naturally occuring compounds of potential value to crop protection may well be revealed.

Evidence of hormonal control of ovulation in tsetse flies

ODHIAMBO[1] and Saunders and Dodd[2] reported that the first fully developed egg in the tsetse fly (*Glossina pallidipes*[1] and *G. morsitans*[2]) is not released from the ovary into the uterus until the female has had mating experience. They observed that the component of the mating act causing ovulation was not insemination, and suggested that a mechanical factor is responsible for the initiation of ovulation[2]. It is difficult to see how a strictly nervous mechanism could account for the time lag between mating and ovulation (females mated 2–3 d after emergence usually ovulate 6–7 d later). Foster[3] found that the ablation of median neurosecretory cells (MNC) of the pars intercerebralis almost always inhibited ovulation in *G. austeni*. He noted, however, that surgical brain trauma also inhibited ovulation in control flies. Ejezie and Davey[4] found that the MNC undergo cyclic changes of net synthesis and release in *G. austeni* and attempted to correlate these phenomena with ovulation and larviposition. We describe here investigations of the control mechanism of ovulation in *G. morsitans morsitans*.

In our laboratory (24.5±0.5 °C, 65±5% relative humidity, 12 h light and 12 h dark and 100 lx at the level of experimental flies), females (fed on rabbit ears 6 d a week) are normally mated 2–3 d after emergence and ovulate 5–7 d later when they possess the first fully chorionated egg. But we found that if the females were prevented from mating until their first egg was fully chorionated (11–12 d after emergence, to be certain) and then were allowed to mate ('delayed' mated), they ovulated within 24 h of termination of copulation (Fig. 1).

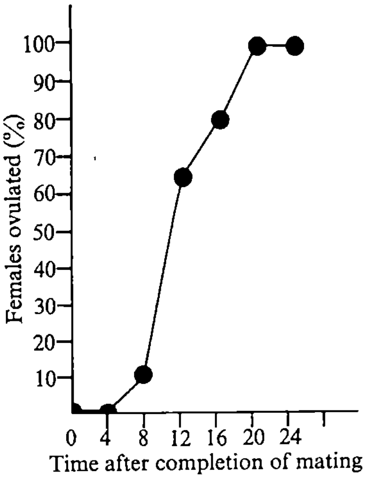

Fig. 1 Pattern of ovulation in delayed mated females. They were allowed to mate 12 d after emergence. Groups of 20 females were dissected 0, 4, 8, 12, 16, 20 and 24 h after termination of mating to determine whether ovulation had occurred.

A male could inseminate a female (while ovulated subsequently) when allowed to mate uninterrupted for a prolonged period—about 60 min. But brief copulatory acts of 20 min or less did not result in insemination or ovulation. To obtain conclusive data on the relationship of mating, insemination and spermatophore formation to ovulation, we allowed the female to experience multiple interrupted (manually separated) matings of shorter than normal duration (10–20 min) with several different males consecutively, which allowed her to accumulate a prolonged mating experience but prevented her from receiving sperm or sufficient male accessory reproductive gland (AG)

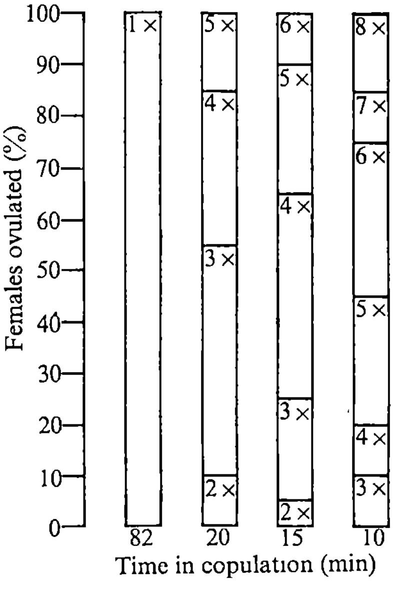

Fig. 2 Pattern of ovulation in females that experienced consecutive multiple matings of shorter than normal duration with fresh unmated males. Females (12 d old) were allowed to mate consecutively with two (2×) to eight (8×) males for 10, 15 or 20 min each by manually terminating each mating and allowing each female 30–100 min in copulation. Control females were mated with only one male (1×) and were not interrupted. Ovulation was checked 24 h after the last mating was terminated. Spermathecae were checked routinely to record any insemination. Each percentage is based on observations on 20 females.

secretion to form a spermatophore. Ovulation occurred in all females which spent 80–100 min copulating in several brief 'sterile' matings but the rate of ovulation declined with the decrease in copulation time (Fig. 2). Further observations of interrupted matings revealed that males could transfer some AG secretion during 10 min in copulation (unpublished work). To eliminate the effect of male AG secretion on ovulation, we removed the paired male AG, and, in some cases, the proximal part of the ejaculatory duct, and allowed the operated males to copulate with the virgin females. Twelve females which mated with the operated males for an average of 57 min ovulated, but five that mated for an average of 25 min did not.

There is no evidence of a male contact pheromone involved in induction of ovulation, as ovulation was demonstrated in virgin females which had no contact with males but into whose uteri one or two glass beads of about 300 μm diameter (about half the size of a spermatophore) had been inserted through the vaginal opening. A comparable effect is the sensory perception of artificial stimulation of the reproductive tract which results in ovulation in some vertebrates[5].

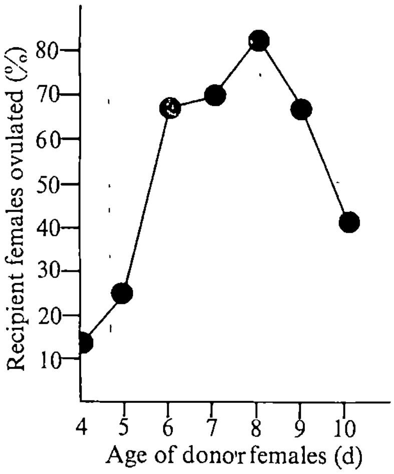

Fig. 3 Pattern of ovulation in virgin females after receiving haemolymph from the mated females of indicated age. Donor females were mated when 3 d old. Virgin recipients (n = 15–20) were 11–12 d old when they received haemolymph. Control virgin recipients (n = 10) received haemolymph from virgin donors. Ovulation was checked 48 h after the injection. Ovulation in controls = 0%.

We also removed the corpus allatum (CA) and corpus allatum–corpus cardiacum (CACC) of the female before or immediately after completion of mating. In either mating status the removal of CACC inhibited ovulation. Allatectomy of 9–12-d-old females did not interfere with the first ovulation.

Pursuing a different line of investigation, we induced ovulation in physiologically mature virgin females by injecting each of them with 0.5–0.8 μl haemolymph taken from 4–10-d-old mated (mated when 3 d old) females. Preliminary results show a correlation between the age of donor females at the time of transfusion and the percentage of recipients (n=15–20) showing ovulation (Fig. 3). Haemolymph from the virgin donors did not result in ovulation in virgin recipients (n=10).

We draw the following conclusions from these observations. (1) Ovulation is dependent on the physical component of copulation and (2) is independent of insemination and the transfer of male AG secretion or seminal fluid. (3) The duration of the mating act is critical in inducing ovulation. (4) The CC is important in the regulation of ovulation; (5) a blood-borne factor in the mated female is ultimately responsible for induction of ovulation, and (6) ovarian development itself may have a role in the control mechanism.

Our findings, together with earlier observations[1–4], suggest that afferent nervous impulses resulting from prolonged mating, and probably those resulting later from ovarian distension due to the presence of a fully developed oocyte, activate the MNC to release an ovulation-stimulating hormone into the haemolymph, probably through the CC. We suggest that this hormone ultimately induces ovulation.

We thank Professors Thomas R. Odhiambo, Vincent B. Wigglewsworth and Jan de Wilde for suggestions and Dr John Strangways-Dixon for reviewing the manuscript.

Growth regulation in chimaeras between large and small mice

AGGREGATION chimaeras between strains of mice differing in body size may be used to determine whether the regulation of growth is determined by the relative proportions of cells deriving from the constituent strains. Should this be so, several questions arise; is growth regulated by the proportions in the body as a whole, or is the cellular composition of particular organs (or tissues) more critical? If critical organs or tissues are established, is the regulation then a systemic property, or does the response of other organs and tissues depend further on their own cellular composition? We describe here preliminary findings which indicate the answers to some of these questions and suggest ways of answering the others.

Aggregation chimaeras were made, by methods described previously[1], between mice from strains selected for large (L) and small (S) body size, and between L and unselected control (C) mice; the history of the strains is given in ref. 2. Some C$\longleftrightarrow$C chimaeras are included for comparison. Fifty overt chimaeras, all from C-strain foster mothers, were distributed among the three classes in the numbers shown in Table 1. Overt chimaerism was detected by marking the constituent strains with contrasting coat colours, either albino or coloured. Coat colours and body size were used reciprocally in chimaeras between L and S and since there was no difference between the reciprocals, they were pooled. In chimaeras between L and C, the latter was always the albino component. The proportion of albino in the coat was scored as described in ref. 3. We do not include data from successful aggregations which later resulted in single coat colours, but those mice ruled out any general tendency for L cells to outgrow S cells, or vice versa. This is supported by the fact that the mean proportion of L in the coat, in chimaeras both with S and with C, is close to 50% (Table 1). All data reported here were recorded when the mice were 6 weeks old. All female body weights were adjusted to male equivalents, males being 20% heavier in these strains. The weights of the constituent strains were adjusted further by regression to litter sizes equal to those in which the chimaeras were born, the weights thus seeming greater than those published earlier[2].

Examination of the data revealed a positive regression of body weight on the proportion of the L genotype in the variegation score of the coat (Fig. 1), the corresponding correlations being 0.51 and 0.70 in S$\longleftrightarrow$L and C$\longleftrightarrow$L chimaeras, respectively. Cumulatively, there is no doubt about the significance of these regressions, and two conclusions follow. First, body size is linearly and directly proportional to the cellular composition of the coat of the chimaera. Second, since melanocytes themselves can hardly be determinants of growth, the observed correlation must reflect a fundamental correlation between the proportions of melanocytes in the coat and the corresponding proportions of L and S cells in whatever tissue(s) regulate growth.

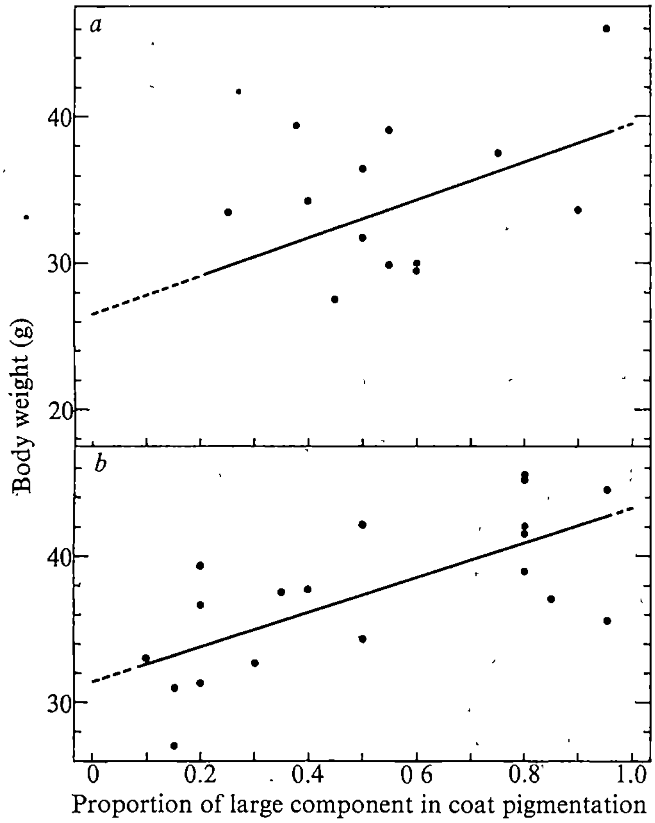

Fig. 1 Relationship between body weight and proportion of L component in coat pigmentation. Values of regression coefficients: in S⟷L (*a*), 13.0±6.9; in C⟷L (*b*), 11.7±2.9.

A critical observation from Table 1 is that S⟷L and C⟷L chimaeras are 2.5 times more variable in weight than C⟷C chimaeras, whose own variance is about the expected normal value. A source of variance in chimaeras between different strains, not present in other mice, is the variation between individuals in the proportions of the two cell types. For coat colour, this proportion varied between 0 and 1, and covered most of that range even if the single colours were excluded. If the same kind of variance in proportion applies to weight-controlling tissue, the inflated variance of weight is readily explicable. It is therefore important to estimate the variance of the proportions of cells in the weight-controlling tissue.

We now define the 'chimaeric genotype' (G) for growth in terms of the proportions of the two types of cells. Let

$$G = P\mathrm{L} + (1 - P)\mathrm{S}$$

where P is the proportion of large cells (L), leaving $(1 - P)$ small cells (S). In the other class of chimaeras, C is substituted for S. On rearrangement, this gives

$$G = \mathrm{S} + (\mathrm{L} - \mathrm{S})P = \mathrm{S} + DP$$

where D is the difference in weight between the constituent strains. G is thus a linear function of P, as implied by Fig. 1. Since S, for present purposes, is a constant,

$$\mathrm{var}(G) = D^2\,\mathrm{var}(P)\,,$$

where var(G) is the variance of G, and so on. Trivial reorganisation gives an expression for var(P)—the variance of proportions of cells in the growth-controlling tissue. D is directly observable and var(G) may be estimated, at least roughly, as follows. The variance in body weight of the C⟷C chimaeras does not contain any var(G), by definition, since G was defined in terms of the proportions of differing cell types; however, the variance of the C⟷C chimaeras will reflect all other sources of variation. Subtracting the variance in body weight of C⟷C chimaeras from that of the S⟷L chimaeras therefore provides a direct estimate of var(G) appropriate to that class. All the necessary data are available from Table 1, and using the expression derived above, we obtain estimates of 0.046 and 0.190 for var(P) in S⟷L and C⟷L chimaeras, respectively. Viewed slightly differently, these are the variances in the cellular composition of the growth-controlling tissue that would be necessary to explain the increased variance in weight found in chimaeras between different strains. Although we make no claims for the numerical accuracy of these estimates of var(P), the values found seem to be reasonable, and they correspond closely to the variance in the proportions of melanocytes, estimated from the coat by direct observation (see Table 1).

Table 1 Body weights and proportion of L component in coats

Constituent lines	L	C	S
Adjusted weights (g)	36.7	27.3	18.3
Chimaera type	S⟷L	C⟷L	C⟷C
n	12	19	19
Coat: proportion L	0.58	0.52	(0.28)*
variance	0.040	0.096	(0.075)*
Weight (g): mean	34.1	37.5	28.2
variance	25.7	26.8	10.0

* These values refer to the proportion of albino in coat.

Our results therefore establish that growth in chimaeras is a direct function of the proportions of cells from the two constituent strains, which in turn implies that growth regulation resides in the cellular properties of certain organs or tissues. Further, from consideration of the variances of the proportions of cells, it seems that the system of growth regulation needs be neither more complicated nor more extensive than that controlling the distribution of melanocytes in the skin. This indicates that the organs or tissues governing growth control may eventually be located, and to that aim we are marking constituent strains with variants of an enzyme that can be assayed quantitatively. The higher the correlation between body weight and proportion of L cells in various tissues, the more important will that tissue be in regulating growth. Equally, the systemic effect deriving from such tissue can be examined against the cellular composition of target organs, to see whether there is any local autonomy of size regulation

Evidence for a new diffusible element of mating pheromones in yeast

THE yeast *Saccharomyces cerevisiae* produces pheromones which seem to participate in the mating process[1,2]. Each of the two haploid mating types (*a* or α) produces a diffusible factor (called *a* factor or α factor, respectively) which causes cells of the opposite mating type to be retarded in the G_1 period of the cell division cycle[3–6]. The pheromones thus act to synchronise the cell cycles of mating cells before the formation of the diploid zygote. By a variation of the original assay for yeast mating pheromones[8,9], we have observed that cells of mating type *a* produce a new pheromone which inhibits action of the α factor.

The standard assay for the α factor requires the placing isolated *a* cells ('assay cells') near a source of α factor, for example, a heavy streak of α cells[8,9]. The α cells are unable to initiate new rounds of budding[2] and instead undergo the α-factor response, a characteristic shape change (see Fig. 1*c*, *d* and *e*). Continued exposure to α factor results in the further elongation of the *a* cell for at least 12 h, at which time cells furthest from the source of the α factor resume budding (ref. 4, and R. Chan, L. Hartwell and T. Manney, personal communication).

When a dense streak of *a* cells is placed between the α cells and *a*-assay cells (Fig. 2*a*), no α-factor response is observed in the *a*-assay cells (although the response is seen within the streak of *a* cells). Figure 1 shows the response of *a*-assay cells with (Fig. 1*a*) and without (Fig. 1*e*) interposed cells. The interposed cells therefore exhibit a barrier to the α-factor response and are said to have the Bar$^+$ phenotype. To determine whether the barrier effect is controlled by the mating type locus, we have examined the Bar phenotype of a number of different *a* strains, *a*/α strains, and two classes of α mutants (*ste*$^-$) which do not produce the α factor (ref. 7 and J.M.H. and I.H., unpublished). All of the *a* strains tested here are Bar$^+$, and all the *a*/α strains are Bar$^-$. Although the barrier phenotypes of the *a* strains and the *a*/α strains are clearly different, it has been observed that assay cells in the presence of an *a*/α barrier recover from α-factor inhibition more quickly than controls where no barrier is present. This may indicate the partial expression of the Bar function in *a*/α diploids. (Analogous observations have been made by T. R. Manney (personal communication).) Interestingly, the α strains carrying *ste*$^-$ mutations inseparable from the mating type locus (classes 1 and 2) differ in their Bar phenotype. It is thus clear that the mating type locus itself regulates the barrier effect.

To determine further the relationship between the barrier effect and genes involved in mating, we examined the Bar phenotype of *a* cells carrying mutations which block mating (*ste*$^-$). Six of the *a ste*$^-$ are Bar$^+$, and three are Bar$^-$ (see Fig. 1*b* and *c*). The barrier effect therefore seems to be under the control of genes essential to mating. Since all of the *a ste*$^-$ mutants tested were insensitive to the α factor (ref. 7, and unpublished), there is no correlation between the Bar phenotype and α-factor response. The sterile mutant of class 10 behaves in some respects, including its Bar phenotype, as an *a* mutant (see Table 1). It should be noted that the existence of Bar$^-$ strains (*a*/α, α *ste*$^-$, and some *a ste*$^-$) argues against the notion that the barrier effect is attributable to a nonspecific effect of the growth of cells in the barrier streak (Table 1).

The barrier effect could involve the adsorption of the α factor by the *a* cells within the barrier streak. Another possibility (not exclusive of the first) is that the barrier cells produce a 'diffusible barrier', that is, a diffusible inhibitor. To test that possibility, we rearranged the geometry of the standard α-factor assay so that the *a*-assay cells were placed between heavy streaks of α and *a* cells (the 'N technique', see Fig. 2*b*) Under such an arrangement, the assay cells furthest from the *a* streak responded to α factor, whereas those closest to the *a* streak did not. The presence of the *a* streak was not essential for the inhibition of the α-factor response. Rather, *a* cells seem to excrete an inhibitor into the agar. This diffusible effect can be seen by allowing a streak of *a* cells to grow on an agar slab for 6 h at 30 °C. The *a* cells should then be removed by cutting the agar (see Fig. 2*b*). The standard α-factor assay should then be carried out on the slab thus obtained using *a*-assay cells at varying distances from the α cells. As controls, the assay should be carried out in parallel on untreated agar, and on agar 'treated' by growth of an *a ste*$^-$ strain which is Bar$^-$ (strain S111). As before, the *a* cells nearest to the α cells will respond to the α factor in all

Table 1 Ability of different strains to exhibit barrier and diffusible effects on response to α factor.

Strain*	Mating type	Barrier effect	Diffusible effect	*a* factor†
39, 73, 75, 94, X5–39	*a*	+	+	NT
S107, S111	*a ste*$^-$	–	–	NT
S110	*a ste*$^-$	+	–	NT
S108	*a ste*$^-$	+	NT	NT
VAB2 (class 3), VW9 (class 7)	*a ste*$^-$	+	+	+
VAB1 (class 5), VU3 (class 15)	*a ste*$^-$	+	+	–
VY3 (class 13)	*a ste*$^-$	–	–	+
VC73 (class 10)	( )‡	+	+	NT
VC2 (class 1)	α *ste*$^-$	–	–	NT§
VB3 (class 1)	α *ste*$^-$	–	NT	NT§
VP1 (class 1)	α *ste*$^-$	+	NT	NT§
VN33 (class 2)	α *ste*$^-$	–	–	NT§
X14, X16, X17	*a*/α *ho*/*ho*	–	–	NT
X47	*a*/α *HO*/*ho*	–	–	NT
X10–1B	*a*/α *HO*/*HO*	–	–	NT

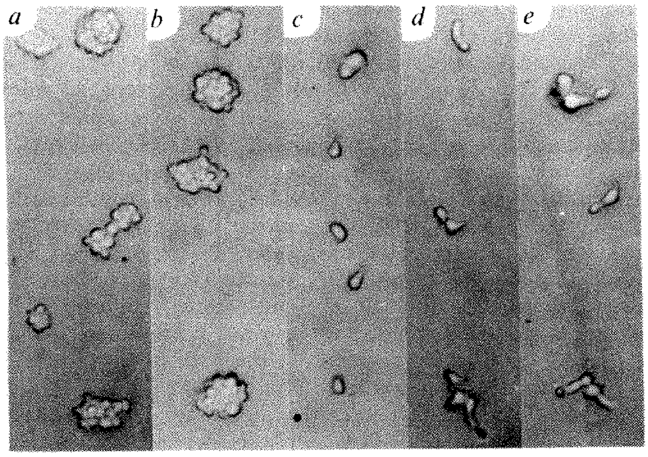
In most cases the *a*-assay cells were strain 73 (*a-ilv*3–X) and the α-factor source cells were strain 70 (α *thr*3–10).

*Strains 73, 75, 94, X5–39 and X10–1B are described in ref. 10. S107, S108, S110, and S111 are sterile mutants isolated from X5–39, and carry mutations *ste*107, 108, 110, and 111, respectively (unpublished). The V series sterile mutants are described in ref. 7.

†Ref. 7.

‡VC73 was isolated from an α parent and does not produce the α factor[7]. It mates with α cells 1% as efficiently as do wild-type *a* cells (unpublished).

§These mutants do not produce the α factor.



75 (a^+) S 110 (a ste^-, Bar$^+$) S 107 (a ste^-, Bar$^-$) X-14 (a/a) Control (No barrier)

Fig. 1 The α-factor response by *a*-assay cells (strain 73) in five separate barrier tests photographed after 12 h incubation at 30 °C. The strain designations below each panel refer to the barrier cells. Arrangement as in Fig. 2*a*. Growth of assay cells in (*a*) and (*b*) is the same as in the absence of α cells (data not shown) and indicates the absence of α-factor activity. The production of morphologically aberrant cells in *c*, *d*, and *e* is the normal response to the α factor exhibited by *a* cells. The α-factor source was strain 70.

cases. The α cells further from the α streak, however, will not exhibit the α-factor response on agar treated previously with *a* cells. On untreated agar or on agar treated by the growth of the *a* ste^- strain, all of the *a*-assay cells will exhibit the α-factor response. This indicates that *a* cells produce a diffusible inhibitor of the α-factor response.

To test whether the inhibitor acts on α cells (for example, on α-factor synthesis or release), we looked for inhibition in the absence α cells when the α factor was present in the agar. The α cells were grown on an agar slab (Fig. 2*b*) for 6 h, and were then removed by cutting away an agar slab. The slab was cut in half horizontally (Fig. 2*b*) to give slabs A and B. A dense streak of *a* cells was laid down on slab A, and a streak of *a* ste^- Bar$^-$ (S111) was laid down on slab B. The α-factor response by *a*-assay cells placed on slab A was considerably less than the response on slab B. The diffusible inhibitor can, therefore, act in the absence of α cells.

The relationship between the Bar$^+$ effect and the diffusible inhibitor was examined by testing a number of strains for the diffusible inhibitor by the N technique (Fig. 2*b* and Table 1). No Bar$^-$ strains (a/α, *a* ste^-, or α ste^-) exhibited a diffusible effect. All the strains tested which showed a diffusible effect were Bar$^+$ but not vice versa. We observed one case in which a Bar$^+$ strain (S110) did not show the diffusible effect. Further analysis of this mutant and characterisation of more *a* ste^- mutants will be necessary in order to determine the relationship between the barrier effect and the diffusible inhibitor.

Therefore, *a* cells are able to block in some manner the action of the α factor. The ability of strains to exhibit a barrier effect is controlled by the mating type locus and by genes essential for mating, suggesting that it may be a normal component of the mating process. The observation that class 1 sterile mutants differ in their Bar phenotypes provides further evidence for the complexity of the mating type locus. At least part of the barrier effect is mediated by a diffusible factor. This factor does not necessarily act on the synthesis or release of the α factor by α cells since its action is seen in the presence of the α factor. The inhibitor, thus, may act directly on *a* cells to modify their response to the α factor itself. The production of the inhibitor does not require induction by the α factor. Finally, the inhibitor seems to be distinct from the *a* factor since some strains which are *a*-factor deficient produce the inhibitor and vice versa (Table 1).

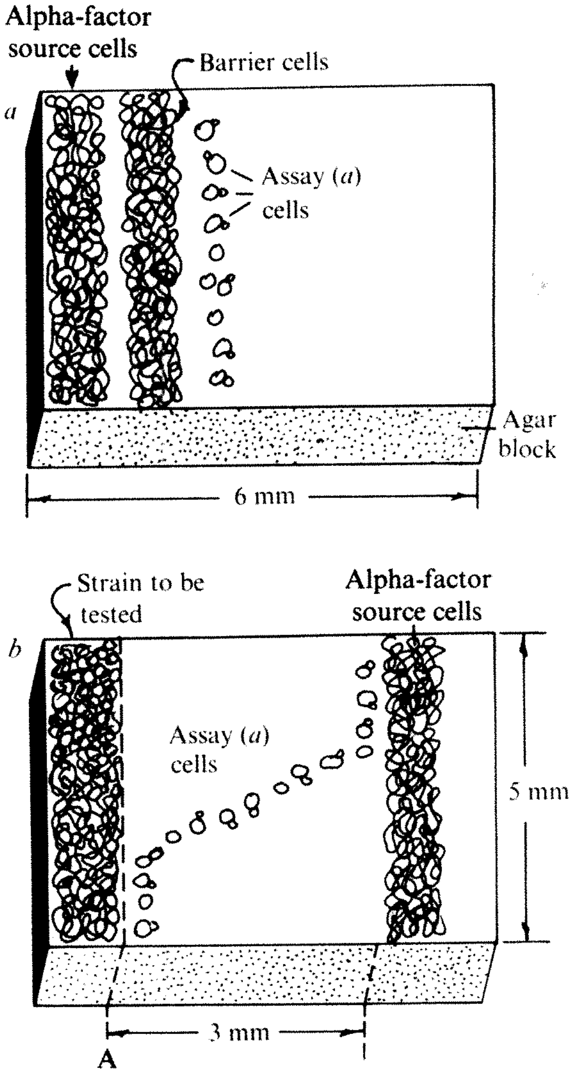


Fig. 2 Experimental arrangement for studying the barrier effect (*a*) and the diffusible inhibitor (*b*) of response to the α factor. Cells were pregrown overnight at 30 °C on YEPD agar (2% peptone, 1% yeast extract, 2% glucose, 2% agar). In the barrier test, α cells ('α-factor source') and barrier cells were applied to blocks of dissection agar (2% peptone, 1% yeast extract, 4% glucose, 4% agar) in streaks containing approximately 10^7 cells. The blocks were placed on a glass coverslip and inverted over a dissection chamber. From 10 to 20 individual mating type *a* cells ('assay cells') were then placed by micromanipulation on the agar in the position shown, 2±0.2 mm from the source cells, and the chamber was sealed to prevent any loss of moisture. The growth rate and morphological characteristics of the cells were used as an assay of α-factor activity in the agar. The presence of α-factor activity in the agar distal to the barrier cells was indicated by distorted cell morphology (shmooing) and the absence of cell division by the assay cells after 12 h incubation at 30 °C (Bar phenotype; Fig. 1: *c*, *d*, *e*). The absence of α-factor activity was indicated by the ability of the assay cells to divide normally and form microcolonies (Bar$^+$ phenotype; Fig. 1: *a* and *b*). To determine whether strains produce a diffusible inhibitor of α-factor response, the streak of cells to be tested was applied to each agar block first as in arrangement *b*. After growth for 6 h at 30 °C, the section of agar containing this streak was cut away (along dotted line A in the diagram), and α-factor source cells and *a*-assay cells applied to the block as shown. The response of the assay cells was observed microscopically at 6, 12, and 24 h.

What would be the role of the barrier effect and diffusible α-factor inhibitor in the normal mating process? We offer three suggestions. First, the inhibition of α-factor response may be part of the mechanism by which *a* cells recover from an α-factor block[4] and by which newly-formed a/α zygotes escape from inhibition by *a* and α factors in their environment. Second, successful mating between individual cells requires cell contact. The α factor can, however, act at a distance to inhibit the growth of *a* cells. The 'anti-α factor' activity may reduce the effective concentration of the α factor in the immediate environment of an *a* cell so that only the *a* cells very close to α cells will respond.

Third, the successful mating between populations of haploid cells requires equal numbers of cells of each mating type. In situations in which the number of *a* cells is greater than the number of α cells, mating would result in a small number of diploid cells and a large number of unmated *a* cells. If, however, the response to the α factor is blocked by a high concentration of the inhibitor, mating could be delayed until the further growth of α cells has occurred. The number of *a* and α cells would thus become comparable, and a greater fraction of the population could mate successfully.

We thank Jeff Strathern and Rick Dahlquist for discussions and suggestions, and Tom Manney, Russell Chan, and Lee Hartwell for strains, unpublished information and discussion. Regulation of the fibroblast cell cycle by serum

WHEN "normal" fibroblasts are deprived of serum they cease growing and accumulate in the G_1 or G_0 stage of the cell cycle[1]. On restoration of serum, the cells begin to enter S phase quasi-synchronously after a well defined lag period which seems to be characteristic of the cell type. Following the studies of Todaro *et al.*[2], Bürk[3], and Temin[4], it is widely believed that exposure to serum for only a portion of this lag period is sufficient to commit the cells irreversibly to initiate a round of DNA replication. Thus, removal of the serum after only a few hours, and before the end of the lag period, does not affect subsequent DNA synthesis in a significant proportion of the population. It has been apparent, nevertheless, that the proportion of such "committed" cells depends on the duration of the serum pulse[2–5]. Indeed, the relationship between the length of exposure to serum and the proportion of committed cells is approximately linear with time and (with 3T3 cells) extends beyond the end of the lag phase itself (Fig. 1). Clearly, some cells which are stimulated to initiate DNA synthesis during continuous exposure to serum are not committed by the end of the lag period, since removal of the serum at this point reduced the proportion of labelled cells, at 24 h, from 76 to 53% (Fig. 1*b*).

Experiments such as these have been interpreted as evidence that some cells require longer periods of mitogenic stimulation than others to become irreversibly committed to division[6]—a view which is apparently reinforced by the well known asynchrony with which cells begin DNA synthesis, even when the mitogen is present continuously. Recently, however, it has been shown[7] that this asynchrony is not necessarily evidence of cellular heterogeneity but may be a consequence of the very nature of the commitment event itself[7]. In the presence of micromolar concentrations of metabolisable purines or purine nucleosides (which potentiate the serum response[8,9]) the rate of entry into S phase increased very abruptly after the lag period, rapidly becoming first order[7]. Thereafter, a constant fraction of the G_1 population began DNA synthesis per unit time. This suggested that commitment was a random event occurring with a characteristic probability, as proposed earlier by Smith and Martin on other grounds[10]. The rate constant (or transition probability) for entry into S phase was found to be a function of the serum concentration, which means that this determines the rate of commitment rather than the number of committed cells. In the absence of exogenous purines, the rate constant increased slowly with time, but in their presence, the new value was attained abruptly with

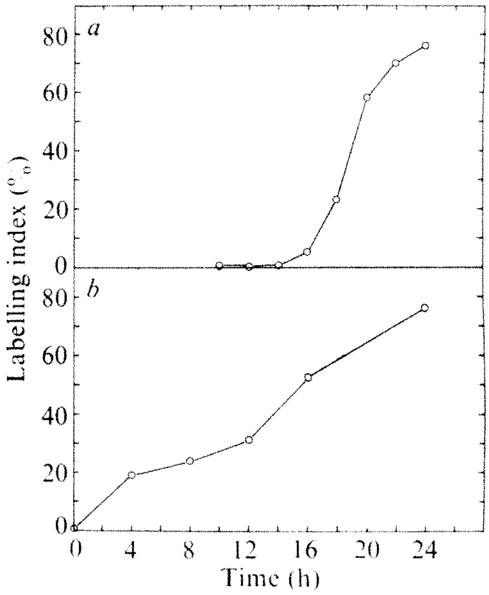

Fig. 1 *a*, Time course of entry into S phase after stimulation of quiescent 3T3 cells with 4% serum. Subconfluent, quiescent cultures of (Swiss) 3T3 cells[13] were prepared by plating 3×10^4 cells on to 15-mm glass coverslips in each well of a Linbro multidish tray (Linbro 24-16-TC), in 1 ml of 0.5% calf serum in Vogt and Dulbecco's modified Eagle's medium[14], followed by incubation at 37 °C for 3 d. Coverslips were then transferred to 3-cm plastic Petri dishes containing 2 ml of fresh medium and 4% calf serum (previously dialysed against 2×50 volumes of isotonic phosphate-buffered saline), together with inosine (25 µM) and ^{3}H-thymidine (1 µCi ml^{-1}; 3 µM thymidine). With this ratio of medium volume to cell number, depletion or inactivation of serum activity[15,16] is not significant during the subsequent course of the experiment.) At the times indicated, pairs of coverslips were removed and processed for autoradiography as described previously[7] using Kodak NTB3 nuclear track emulsion. After exposure for 2 weeks at 4 °C, autoradiographs were developed, stained with Geimsa solution and the proportion of cells with labelled nuclei determined. *b*, The effect of serum pulse length on the proportion of cells in S phase at 24 h. Quiescent 3T3 cells were stimulated with 4% dialysed calf serum in medium containing inosine (25 µM) and ^{3}H-thymidine (1 µCi ml^{-1}; 3 µM thymidine). At the times indicated, pairs of coverslips were transferred to fresh medium containing 0.25% dialysed serum, but with the same concentrations of inosine and ^{3}H-thymidine. After 24 h all coverslips were removed and prepared for autoradiography. The abscissa represents the duration of exposure to 4% serum.

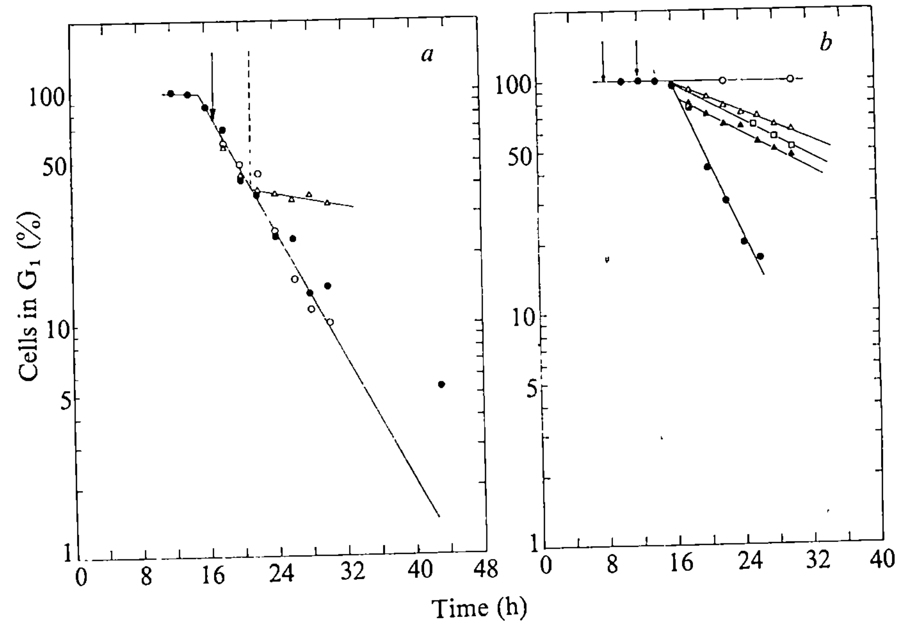

Fig. 2 *a*, The effect of serum step-down on the rate of entry into S phase. Quiescent 3T3 cells were stimulated with 10% dialysed calf serum in the presence of inosine (25 μM) and ^{3}H-thymidine (1 μCi ml^{-1}; 3 μM thymidine). After 16 h, some coverslips were washed with warm (37 °C) serum-free Dulbecco's modified Eagle's medium and transferred to fresh medium containing the same concentration of inosine and ^{3}H-thymidine and either 10% dialysed serum (○) or 0.25% dialysed serum (△). Other coverslips remained untouched (●). Pairs of coverslips from each set were removed at the times indicated and processed by autoradiography. The labelling index was determined and the proportion of cells remaining in G_1 obtained by subtraction, except for the point at 44 h which was calculated by counting the number of unlabelled cells per field and estimating the original cell density (that is, before cell divisions) from the preceding coverslips. *b*, As for (*a*) except that the highest serum concentration used was 4%, and the step-down to 0.25% made at either 8 h (△) or 12 h (▲). ○, 0.25%; □, 1%; ●, 4%. For clarity, the early points for the 1% serum control (□) have been omitted.

little evidence of passing through intermediate values. Once attained, the new value remained constant for at least a further 30 h (unpublished data). This suggested that the probability of initiating the cell cycle might reflect an equilibrium steady state in the rate of some cellular activity which in turn was controlled by the serum concentration. According to this interpretation, maintenance of the transition probability is regarded as a dynamic process dependent on the continuous presence of the growth stimulus, while much (and perhaps all) of the lag period is considered to be the time required to alter this equilibrium state. This hypothesis predicts that a reduction of the serum concentration at any point will be accompanied, some time later, by a decline in the rate of initiation.

Evidence in favour of this interpretation has been obtained by measurement of the proportion of cells remaining in G_1 at various times following stimulation. When the serum concentration was reduced from 10 to 0.25% at 16 h, the rate of initiation declined abruptly 5 h later (Fig 2*a*). This decline was not the nonspecific result of manipulations involved in changing the medium but depended on the alteration of serum concentration. In other experiments, serum step-downs have been made after 12 h (Fig. 2*b*) or 20 h exposure (not shown): in each case the rate of initiation declined to a new steady state between 3 and 5 h later, regardless of how many cells had reached S phase at the time of the perturbation.

Following the step-down, the rate of entry into S phase does not decline to the very low value of the control (0.25% serum continuously), but remains elevated at a rate approximately equivalent to 1% serum. Whether this is the result of serum growth factors remaining absorbed to the cell surface in a manner that survives washing, or to some other reason, is not known This residual rate of initiation shows some dependence, however, on the duration of the preceding serum pulse. When the step-down is made more than 5 h before the end of the lag phase, it is precisely this residual rate of initiation which seems to be responsible for the apparent "commitment" described by others following short serum pulses[2-5] (Fig 2*b*). As when serum is present continuously, the number of cells stimulated to begin DNA synthesis depends on the interval of time considered.

These experiments indicate that the apparent simplicity of the relationship between the length of exposure to serum and the proportion of committed cells (Fig. 1*b*) conceals a complex situation involving both the interval of observation and changes in the rate of initiation. There is no compelling evidence for subpopulations of hypersensitive cells poised, to varying degrees, close to the commitment step and requiring only short serum stimulation. The experiments also suggest that commitment to DNA synthesis in 3T3 cells does not occur earlier than 5 h before S phase, regardless of when initiation actually takes place in each cell relative to serum addition. This must be so because otherwise it would not be possible to prevent the initiation of DNA synthesis in a committed cell by withdrawal of serum unless there were some additional serum-dependent step between commitment and the start of S phase. This possibility can be dismissed because the initial lag period between serum addition and the beginning of DNA synthesis—which, by definition must include such a hypothetical step—is completely independent of serum concentration[4,7].

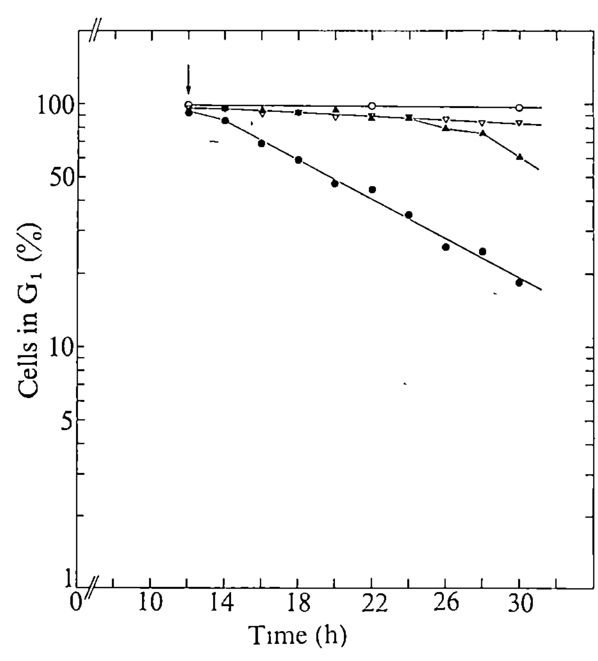

Fig. 3 The effect of serum step-up on the rate of entry into S phase. Quiescent 3T3 cells were stimulated with either 1 (▽) or 4% (●) dialysed serum. After 12 h some of those coverslips which had been placed in 1% serum were transferred without washing to fresh medium containing 4% dialysed serum (▲). (○, 0.25% serum). At the times indicated, pairs of coverslips from each set were removed and processed by autoradiography. The labelling index was determined and the proportion of cells remaining in G_1 obtained by subtraction Inosine (25 μM) and ^{3}H-thymidine (1 μCi ml^{-1}; 3 μM thymidine) were present throughout.

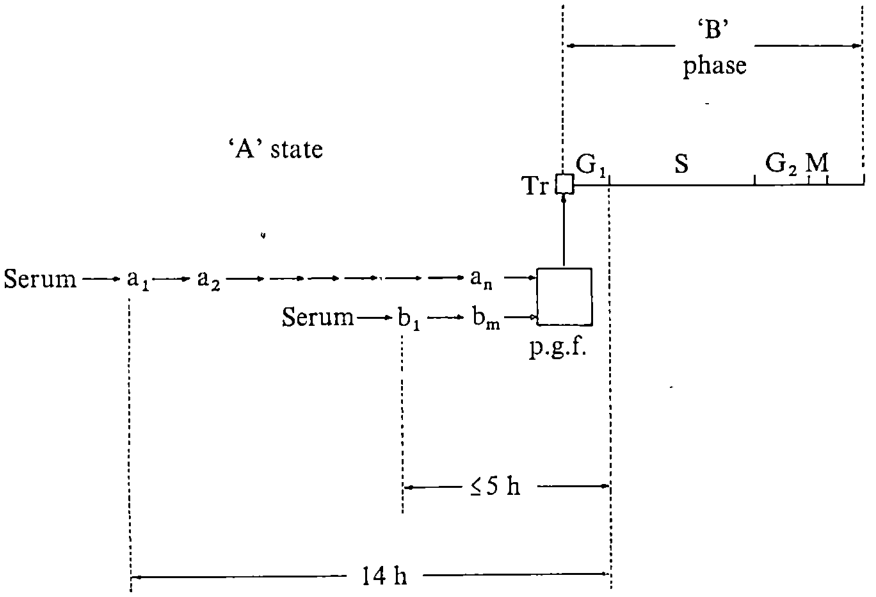

Fig. 4 A schematic view of the regulation of the cell cycle by serum. Serum concentration is considered to control the rate of at least two independent, convergent sequences of interconnecting, on-going processes (a or b). The point of convergence has been drawn, arbitrarily, at an hypothetical "probability generating function" (p.g.f.) postulated to activate a "trigger" (Tr) which, in turn, establishes the commitment to divide. Following commitment, the series of deterministic events leading up to mitosis have been labelled 'B' phase, after Smith and Martin[10]. All other processes are considered to take place in G_0 or 'A' state[10], though these activities do not necessarily cease after commitment has occurred.

Although the commitment event cannot occur more than 5 h before S phase, however, the present data are not incompatible with an even closer coincidence with the beginning of S phase, as suggested recently by Rubin and Steiner[11], and by Smith and Martin[12].

In contrast to the effect of a serum step-down, which is manifest within 5 h, when the serum concentration is raised from a subsaturating level (1%) to a higher serum concentration (4%), no further increase in the rate of initiation is observed until after another 12–14-h lag (Fig. 3). This is the case whether the step-up is made after 12 h (Fig. 3) or 8 h, or from a higher initial serum concentration (not shown), and is thus independent of previous stimulation. Step-ups have not been made later than 12 h because continuation of such experiments beyond 30 h is complicated by the appearance of mitoses which render the cumulative labelling index less meaningful. For this reason, it is therefore not possible, at present, to prove rigorously that the final rate of initiation after step-up is identical to that produced by the higher serum concentration when present from the beginning. From the available data, however, this seems to be a reasonable supposition.

It is thus evident that the 14-h lag represents the time required to effect any increase in the probability of commitment, regardless of the initial value. Nevertheless, the transition probability decreases within 5 h on withdrawal of serum. This disparity suggests that serum controls at least two distinct cellular activities necessary for the maintenance of the transition probability. This is depicted schematically in Fig. 4 as two independent sequences of interconnecting processes, arbitrarily drawn to converge at the "probability generating function" (p.g.f.). Serum is considered to regulate the rate of the initial process in each sequence (a_1 or b_1) while the lag after either step-up or step-down is determined by the relaxation time for the respective sequences (a or b) as a whole to reach the new steady state. In the sense that each constituent process is viewed as ongoing (with serum concentration determining the rate), they should not be considered as events through which the cell must progress. Indeed, they should be regarded as outside of the cell cycle in G_0 (the 'A' state of Smith and Martin[10]), in so far as they occur before the commitment step. The value of the transition probability would seem to be set by the longest sequence, while the shorter is presumably concerned with some permissive function. It will be interesting to determine whether the processes a_1 and b_1 are regulated by different serum factors. The possible basis of the p.g.f. has been discussed previously[12]; further speculation is inappropriate here.

I thank Dr R. W. Holley for facilities and discussion. This work was supported in part by grants from the National Science Foundation, National Institutes of Health and the American Cancer Society. I am a Fellow of the Leukemia Society of America, Inc.

T-lymphocyte response to Friend virus-induced tumour cell lines in mice of strains congenic at *H–2*

Mice immunised with infectious lymphocytic choriomeningitis virus (LCMV) produce T lymphocytes which can kill LCMV-infected target cells *in vitro* only if the killer and target cells are syngeneic at the *H-2K* and/or *H-2D* loci[1,2]. We now report analogous results obtained in studies of the immune response of syngeneic or semi-syngeneic mice to cultured cell lines derived from tumours induced *in vivo* by Friend murine erythroleukaemia virus (FV) Our studies further indicate that the *H-2* type of the cells used for immunisation is also a decisive factor in the specificity of the killer cells generated.

The mice used were of strains congenic at the *H-2* region on the BALB/c (*H-2*^{d}) background: BALB.B

Table 1 T-killer cells in PEC from mice immunised with syngeneic or semi-syngeneic FV-induced tumour cells

Mice immunised*	Tumour cells used for immunisation and target cells	% ^{51}Cr release following various pretreatments of the PEC† *A*	*B*	*C*	*D*
BALB.B	HFL/b	30	1	36	30
BALB.K	HFL/k	10	2		
(BALB.B × BALB.K)F$_1$	HFL/b	20	4		
(BALB.B × BALB.K)F$_1$	HFL/k	45	8		

In the LMC, 2.5×10^6 PEC in 1 ml and 5×10^4 ^{51}Cr-labelled tumour cells in 0.1 ml (PEC–target cell ratio, 50 : 1) were mixed and incubated at 37 °C in 5% CO$_2$ atmosphere for 6 h. The cells were suspended in Medium 199 plus 20% foetal calf serum. Specific release of radioactivity into supernatant was compared with that from tumour cells alone frozen and thawed four times.

*PEC were collected at previously determined peaks of activity, 5 d after the second or third immunisation except for PEC obtained from the BALB.K anti-HFL/k immunisation which were collected after 7 d. Immunisation was done intraperitoneally with 5×10^6 tumour cells suspended in normal saline except in the case of BALB.K anti-HFL/k for which all immunisations after the first were with 10^7 cells.

†Pretreatments: *A*, normal mouse serum plus complement; *B*, mouse anti-Thy-1 2 plus complement; *C*, goat anti-mouse IgG plus complement; *D*, absorption on washed nylon column 10^7 PEC were first incubated at 4 °C for 30 min in 0.4 ml of antiserum (1 : 2 dilution), then resuspended and incubated at 37 °C for 40 min in 0.6 ml of guinea pig serum (1 : 3 dilution) as a complement source.

(*H-2^b* from C57BL/10), BALB.K (*H-2^k* from C3Hf/An) and the F$_1$ cross from these two strains (BALB.B × BALB.K) F$_1$ The cultured tumour cell lines induced in mice of these strains were of the HFL series: HFL/b (BALB B), HFL/k (BALB.K) and HFL/bk [(BALB.B × BALB K)F$_1$] (ref. 3). All three cell lines express both the FV-induced FMR cell-surface antigen and the virus envelope antigens associated with the gp70 viral protein[4]. Each of the cell lines readily induces transplantation immunity in syngeneic hosts, with concomitant immunity to spleen focus induction by FV.

BALB B, BALB.K and F$_1$ mice were immunised by intraperitoneal inoculation with *H-2*-compatible cultured tumour cells. Peritoneal exudate cells (PEC) from these mice, taken on day 5 or 7 after the second or third immunisation, were assayed for lymphocyte-mediated cytotoxicity (LMC) by the method of Berke *et al.*[5]. Targets for this assay were ^{51}Cr-labelled cultured tumour cells or phytohaemagglutinin (PHA)-induced blasts originating from mice of the same congenic strains. The blasts were obtained from spleen cells incubated at 37 °C with PHA (1 : 100) for 3 d in an atmosphere of 5% CO$_2$.

Tables 1 and 2 show the results of our studies. LMC was completely abolished by pretreating the immune PEC with anti-Thy-1 2 and complement, whereas pretreating the immune PEC with normal mouse serum or goat anti-mouse IgG and complement or incubating the PEC at 37 °C for 45 min on a washed nylon column had no effect on ^{51}Cr release (Table 1). Thus, target-cell killing in this system was mediated by T lymphocytes.

In agreement with other studies[1,2,6], we observed a requirement for shared *H-2*-region genes between the killer and target cells PEC from BALB B mice immunised with HFL/b tumour cells killed HFL/b and HFL/bk but not HFL/k target cells, and PEC from BALB.K mice immunised with HFL/k tumour cells killed HFL/k and HFL/bk but not HFL/b target cells. PHA blasts of either *H-2^b* or *H-2^k* type were not killed.

In previous studies of cellular immunity to virus-infected cells, the animals have been immunised directly with infectious virus, which is, in effect, an immunisation with autochthonous infected cells[1,2,6]. Since our immunisations were performed with cultured virus-induced tumour cells, we could study the response of F$_1$ mice immunised with parental strain tumour cells. From these experiments (Table 2) we have observed that T-cell killing also requires at least partial *H-2* region identity on the part of the immunising cells and the tumour cells used as targets. Thus, PEC from (BALB.B × BALB.K)F$_1$ mice immunised with HFL/k killed only HFL/k and HFL/bk but not HFL/b target cells, although the immune PEC possessed an *H-2* haplotype in common with all three target cells. Similarly, PEC from F$_1$ mice immunised with HFL/b killed HFL/b but not HFL/k target cells. These findings are analogous to those of Shearer *et al.* in which the T-killer cell response of F$_1$ mice to TNP-modified parental strain spleen cells was studied[7].

A comparison of the responses of BALB.K and of F$_1$ mice to HFL/k cells suggests the involvement of an *H-2*-associated immune response gene. In BALB.K mice the peak response was reached on day 7 rather than day 5, required a larger immunising dose of tumour cells and produced a lower level of ^{51}Cr release in tests on HFL/k target cells (Tables 1 and 2). It is conceivable that the presence of the *H-2^b* haplotype in the recipient confers a greater capacity for this immune response than the *H-2^k* haplotype.

To explain the requirement for common *H-2* genes between T killer and target cells in virus-specific systems, two mechanisms have been proposed: (1) compatibility at *H-2* is a physiological requirement for T-killer cell–tumour cell interactions specific for viral antigens; or (2) an alteration of the *H-2* molecules on cell surfaces occurs as a result of virus infection, and these altered molecules, rather than viral antigens *per se*, are recognised as "non-self" by responding T-cell populations.

The first of these possible mechanisms implies that killer cells from (BALB.B × BALB.K)F$_1$ mice immunised with either HFL/k or HFL/b cells should kill both HFL/k and HFL/b cells since these killer cells share *H-2* determinants with both parental strain tumour cell lines. Since F$_1$ T lymphocytes killed only the parental tumour cell with which they were immunised, this hypothesis does not seem correct.

If, according to the second proposed mechanism, *H-2* molecules are altered as a result of the cell's infection by FV, two possible types of alteration may be envisaged: either the primary structure of the *H-2* molecule itself is altered (pre-translational modification) or an interaction takes place between a viral molecule and an *H-2* molecule (post-translational modification). In either case, the modification of *H-2^b* molecules must be of a similar nature on both HFL/b and HFL/bk cells, and the modification of *H-2^k* molecules must be similar on both HFL/k and HFL/bk cells although determinants on modified *H-2^b* and *H-2^k* molecules are not recognised as cross reacting

Table 2 Selective killing of ^{51}Cr-labelled target cells by PEC from mice immunised with syngeneic or semi-syngeneic FV-induced tumour cells

Mice immunised	Tumour cells used for immunisation	% ^{51}Cr release from different target cells HFL/b	HFL/k	HFL/bk
BALB.K	HFL/k	3	10	66
BALB.B	HFL/b	59	10	46
(BALB B × BALB.K)F$_1$	HFL/k	4	55	60
(BALB B × BALB K)F$_1$	HFL/b	20	−5	

Methods as for Table 1.

antigens by the F_1 hosts. In spite of the possible occurrence of altered *H-2* molecules on these cells, they continue to express high levels of unaltered *H-2* specificities, as shown by their capacity to absorb antibodies to private *H-2* specificities expressed on uninfected cells (unpublished data). Thus, if the alteration of the *H-2* molecule is so extensive as to involve most of its antigenic features, then only a small proportion of *H-2* molecules can be so altered; otherwise the alteration in *H-2* must affect only a minor portion of the molecule.

We thank Philippe Roe for technical assistance and Dr Barry R Bloom for discussions. This work was supported by a contract with the Virus-Cancer Program of the National Cancer Institute. K.J.B. is supported by a National Institutes of Health training grant in genetics.

Demonstration of sensory neurones in the ectopic cuticle of spineless-aristapedia, a homoeotic mutant of *Drosophila*

MANY mutations in *Drosophila melanogaster* cause the development of body parts in inappropriate places. Several of these homoeotic mutations (reviewed in ref. 1) result in the appearance of leg bristles and other leg cuticular structures in place of their antennal counterparts. In the mutant spineless-aristapedia (ss^a, 3-58.5) the antennal arista is replaced by tarsal segments[2]; the mutations Antennapedia (*Antp*, 3-48) and Nasobemia (*Ns*, 3-48) produce a more extreme transformation: most of the antennal cuticular structures are transformed into leg cuticle, and, in the latter, part of the head cuticle is replaced by sternopleural cuticle[3,4]. In insects the sensory neurones are derived from epidermal cells[5]. When sensory epidermis is surgically transplanted to ectopic sites, neurones develop from it and form connections with the central nervous system[6]. These neurones act according to the type of epidermis from which they are derived rather than according to the position in which they develop[6]. In homoeotic mutants cuticular structures develop at ectopic sites as a result of genetic modification In this report I examine whether in homoeotic mutants sensory neurones are formed, and, if so, whether they behave according to the homoeotic structures that develop, or according to their general position in the body.

Antennae of Canton-S (C-S) and ss^a flies were examined histologically by three methods. In the first, half-heads of C-S and ss^a flies were fixed in glutaraldehyde and embedded in Epon, and sections 1 μm thick were cut and stained with methylene blue. In the second, flies' heads were fixed in Bouin's fluid, stained by the Bielchowsky silver technique, embedded in Epon and sectioned at 2.5 μm. Finally, flies were frozen and sectioned at 8 μm with a cryotome, and the sections were fixed and stained for acetylcholinesterase by the Karnovsky–Roots technique. The antennal tarsi of ss^a flies bear bristles, at the base of which can be seen nerve cells. By taking serial sections it was possible to show that processes extend from these cells and join to form a small bundle of fibres, containing acteylcholinesterase, that passes proximally through the tarsal segments into the second antennal segment where it joins the antennal nerve, which runs into the brain. The first and second antennal segments of ss^a flies seem normal, and the Johnston's organ is indistinguishable from that in antennae of normal flies. No muscles were found in the ss^a tarsus.

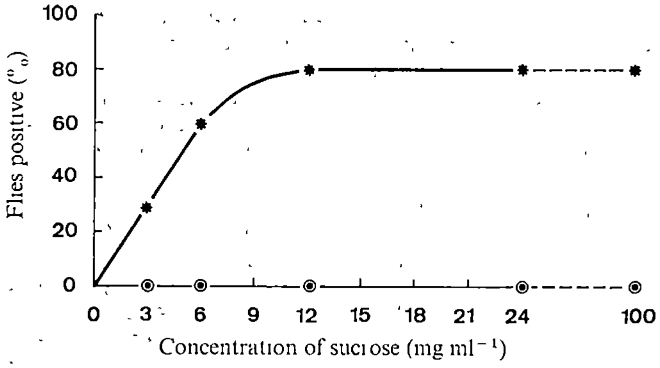

Fig. 1. Proportion of flies showing a proboscis-extension response when cuticular structures were stimulated with sucrose solutions of various concentrations. *, C–S legs; ⊙, C–S antennae. Each point is based on a minimum of 40 flies. The order in which the different appendages were treated with different solutions was varied randomly for each fly. For example, after being starved, attached to a slide, and water satiated (see text for details) a fly was tested as follows: five trials on tarsus of first left leg with sucrose (12.5 mg ml^{-1}), 10-min wait, during which the tarsus was washed, and the fly water satiated, five trials on left antennal tarsus with sucrose (6 mg ml^{-1}), 10-min wait, as above, five trials on tarsus of first right leg with sucrose (12.5 mg ml^{-1}) containing NaCl (150 mg ml^{-1}) and so on, for about 10 tests.

Histological examination, therefore, shows that neurones develop from homoeotic cuticle. A simple behavioural test was used to see whether such neurones are sensory, and whether they behave like receptors in leg structures. When the tarsal chemoreceptors of a normal hungry fly are stimulated with sucrose solution, the fly extends its proboscis[7]. Stimulation of antennae with the same solution elicits no response. This behavioural test (the proboscis-extension response) can be used to establish the presence in the cuticle of gustatory chemoreceptors the stimulation of which results in proboscis extension.

Male and female flies (5–10 d old) of the different genotypes were kept for 18 h in vials without food but containing moist filter paper They were then anaesthetised with carbon dioxide and attached, ventral side up, to a microscope slide, by a small drop of myristic acid (Baker) applied with a warm soldering iron. They were then left for 2 h to recover from the anaesthesia.

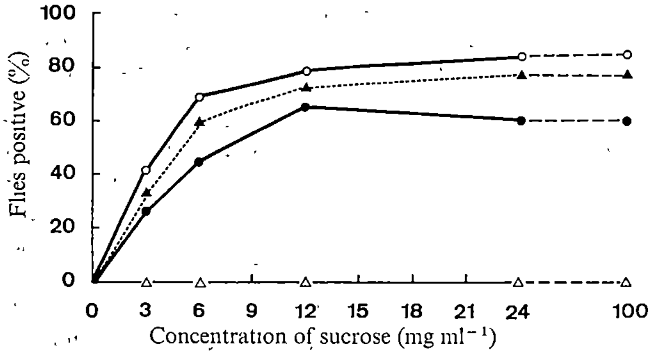

Fig. 2 Proportion of flies showing a proboscis-extension response when cuticular structures were stimulated with sucrose solutions of various concentrations. ○, ss^a legs; ●, ss^a aristal tarsi; ▲, *Antp*^{B} legs; △, *Antp*^{B} antennal legs. Each point is based on a minimum of 40 flies.

All flies were satiated with water before they were tested with sugar solutions. A droplet of water on the tip of an eyebrow hair was applied to one of the fly's tarsi. If the proboscis was extended in response, droplets were placed on the labellum and the fly was allowed to drink until further stimulation of the tarsus resulted in no extension of the proboscis—the fly then was water satiated. If this was not done the flies extended their probosces in response to water alone, which interfered with measurement of the dose–response curve for stimulation with sugar.

Presentation of a solution to a fly can modify its response to a second solution by changing the central excitatory state of the fly[8]. In C-S flies the response returns to normal within a few minutes (personal communication from Ghysen). To ensure that the central excitatory state was not influencing the flies' response, each was tested at 10-min intervals with solutions of different composition and concentrations, presented in random order. During each 10 min the test area of cuticle was washed with water to remove traces of the solution previously applied, and the fly was permitted to drink by placing a droplet of water on its labellum to ensure that it remained water satiated. Each test consisted of five consecutive applications at approximately 20-s intervals of the test solution to one of the test areas (that is, one of the leg tarsi, one of the antennae, or one of the antennal legs). A test was scored as positive when it resulted in extension of the proboscis twice or more in the five trials.

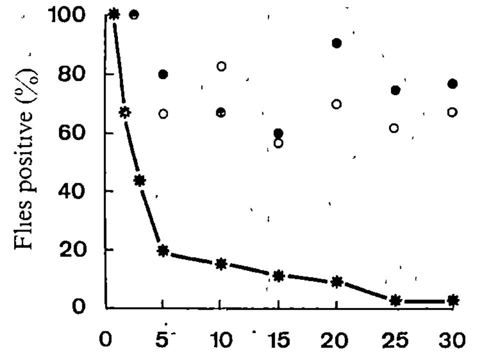

Fig. 3 Effect of NaCl on the response of tarsi to sucrose (12.5 mg ml^{-1}). *, C–S legs; ○, ss^a legs; ●, ss^a aristal tarsi. Only those flies showing a positive response to sucrose (12.5 mg ml^{-1}) were assayed; each point is based on a minimum of 20 flies.

The proboscis-extension response elicited when tarsi of the first legs of C-S flies were presented with sucrose solutions of various concentration is shown in Fig. 1. A maximum response (80%) was obtained with sucrose at a concentration of 12.5 mg ml^{-1}. Touching the antennae of these flies with the same solutions did not elicit a response (Fig. 1). About 20% of the flies did not respond to sugar at all; most of these were very inactive, and some died during the experiment.

Figure 2 shows that when the leg tarsi of ss^a flies were similarly stimulated the response was the same as that for C-S flies. When homoeotic antennal tarsi were stimulated a similar but weaker response was obtained (Fig. 2). A smaller proportion (60%) of flies showed the response when their antennal tarsi were stimulated than when their leg tarsi were stimulated (80%), and those flies that responded did so less rapidly to stimulation of their homoeotic tarsi than of their leg tarsi. Most of the 20% of flies that did respond to leg tarsal stimulation were also not stimulated by application of sugars to their antennal tarsi. It is not clear why of the 80% of flies that did respond normally to stimulation of their leg tarsi one quarter were unresponsive when their homoeotic tarsi were stimulated.

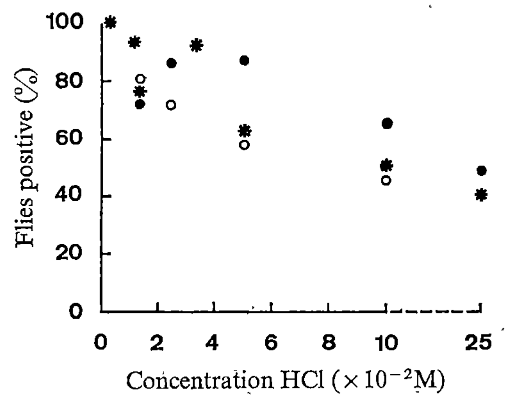

Fig. 4 Effect of HCl on the response of tarsi to sucrose (12.5 mg ml^{-1}). *, C–S legs; ○ ss^a legs; ● ss^a aristal tarsi. Only those flies showing a positive response to sucrose were assayed; each point is based on a minimum of 20 flies.

To establish whether the tarsal chemoreceptors in the antennae of ss^a flies respond with the same specificity as those in the legs, several sugars were tested by the same procedure. Only those flies were tested that showed a proboscis-extension response when their tarsi were tested with 12.5 mg ml^{-1} sucrose. Table 1 shows that the specificity of response of the antennal tarsi in ss^a flies was the same for these sugars as that of leg tarsi in C-S and ss^a flies, that is, the homoeotic tarsus was responding to these sugars as if it were a normal leg tarsus.

Sodium chloride and other salts added to the sugar solution inhibit the proboscis-extension response[9]. Figure 3 shows the effect of sodium chloride on the response of flies to sucrose. The tarsi of C-S flies were sensitive to sodium chloride, while those of ss^a flies were relatively insensitive. This was true both for the normal and for the antennal tarsi of ss^a flies, showing that, although this mutant is abnormal with respect to its response to sodium chloride, the ss^a antennal tarsi still behave exactly like ss^a leg tarsi.

In *Phormia regina* hydrochloric acid added to the sugar solution also inhibits extension of the proboscis[9]. The same is partially true for *Drosophila melanogaster;* in the case of this inhibitor ss^a leg and antennal tarsi responded to the same extent as C-S tarsi (Fig. 4).

In the mutants *Antp*^{B} and *Ns* the antennae are largely transformed into leg structures[3,4]. In both mutants the second and third antennal segments are partially or totally replaced by trochanteral, femoral and tibial structures[10], while in *Ns* the first antennal segment includes more proximal leg structures, and the head bears sternopleural cuticle.

Table 1 Specificity of response of tarsi

Genotype	Structure tested	Sugar (100 mg ml^{-1}) Melibose	Mannose	Fructose	Trehalose
C–S	Tarsus of first leg	19/53(36)	23/25(92)	25/25(100)	64/98(65)
	Antenna	0/50(0)	0/25(0)	0/25(0)	0/95(0)
ss^a	Tarsus of first leg	10/22(45)	19/19(100)	18/18(100)	21/42(50)
	Antennal tarsus	9/19(47)	14/15(93)	17/17(100)	19/40(47)

The figures given are the number of flies showing a positive response (that is, two or more proboscis extensions in five trials with the test sugar on the test area) out of the total number of flies tested with each sugar (percentages in parentheses).

Histological examination of femoral and tibial segments of the homoeotic legs showed that the bristles also have nerve cells at their bases. Axons from these cells run together through the leg and antennal segments to the antennal nerve, which passes into the brain. In $Antp^B$ flies the Johnston's organ is markedly reduced in size; in *Ns* flies this is even more extreme. No muscles were found in the antennal legs of $Antp^B$ flies; in *Ns* flies, muscles were only found in proximal homoeotic structures that correspond to the first antennal segment. In normal flies only the first antennal segment contains muscle; this perhaps explains why muscles are not found in the transformed second and third segments even though muscles would normally be present in the femur and tibia of the leg.

Stimulation of the antennal legs of $Antp^B$ flies did not elicit extension of the proboscis, whereas stimulation of the tarsi of the legs produced a response (Fig. 2). The same was true for *Ns* flies. This is expected since in neither stock of these mutants were tarsi present on the antennal legs. Unlike that of ss^a flies, the suger-elicited proboscis-extension response of the leg tarsi of $Antp^B$ and *Ns* flies was inhibited by salt at the concentrations that inhibit the response of normal flies. Hydrochloric acid also had the same effect on these mutants as on normal flies.

These results show that in the homoeotic mutation ss^a, which results in ectopic development of tarsal cuticle, a sensory apparatus is produced that can transmit information which can be interpreted correctly and used by the central nervous system of the fly. This ectopic sensory structure acts according to the type of epidermis from which it is derived rather than according to the position in the body in which it develops. This finding confirms, by genetic methods, the results of surgical transplantation experiments such as those done with the cricket, in which transplantation of sensory structures to ectopic sites resulted in the formation of functional sensory neurones[6].

EEG α asymmetry and visuospatial performance

THE discovery of complementary cognitive specialisation of the two cerebral hemispheres has led to speculation about its significance for understanding individual differences in cognitive style. It has been suggested[1,2] that some people rely primarily on the left hemisphere whereas others rely on the right, and that this may be an important determinant of a person's cognition of his world.

Electroencephalographic (EEG) results have demonstrated that differential activation of the right or left hemisphere can be observed by analysing EEG α-band activity (8–12 Hz) during performance of appropriate cognitive activities. Since α waves are usually taken to be an indicator of cortical deactivation[3], relatively smaller α amplitudes in one hemisphere would presumably occur when that hemisphere is more active. A number of studies[4–10] have found changes in the relative amounts of α activity in the two hemispheres which depend on the type of cognitive tasks a subject performs. The direction of this asymmetry is predictable from the known cognitive capabilities of each hemisphere. Linguistic tasks, such as composing a letter or mental arithmetic, show relatively more right deactivation. Similarly, visuospatial and musical tasks, which have been linked with right-hemisphere capabilities, show relatively more left deactivation.

If the suggestion that there are individual differences in hemispheric usage is correct, then it would be expected that persons who scored highest in objective tests of visuospatial abilities would have the lowest ratios of right-hemisphere α to left-hemisphere α. We tested this hypothesis by recording right and left posterior EEGs while subjects solved problems involving the imaginal manipulation of visually-presented forms. We have found that subjects with relatively less activity (and consequently more activation) in the right hemisphere perform more efficiently tasks which are known to rely on the right hemisphere.

Subjects were 16 right-handed students, recruited from an introductory course in psychology at Dartmouth College. The test of visuospatial imagery consisted of a series of 20 problems, selected from three different sources. Two types of problem were adapted from chronometric studies of visual imagery by Shepard and coworkers[11,12], and the third type was taken from a standardised test of spatial ability[13]. The three problem types were similar to each other in requiring the imaginary manipulation of objects in space, an ability shown to be preferentially impaired by right-posterior cortical lesions[14,15] and performed poorly by the left hemisphere of commissurotomised patients[16,17]. Figure 1 illustrates these problems.

The series of test items was presented to each subject in the same fixed order, in three blocks of trials separated by 2-min rest periods. Each problem was mounted on a card (5 × 8 inches) which the subject held in his hands during the test. Subjects were instructed to answer each problem verbally as soon as the answer was known, and to avoid double-checking their answers before responding. They were also instructed to keep their eyes open and to look at the card while solving the problem. Answers and time of response were recorded on the EEG polygraph protocols, and latencies were estimated to the nearest 0.5 s from the protocols.

Two EEG channels were recorded while the subject worked on the problems, and also during a 30-s eyes-open baseline before the problem series. The EEG channels were derived from homologous occipitoparietal sites: one at the midpoint between O_1 and P_3; the other halfway between O_2 and P_4. Each of these was referenced to its ipsilateral earlobe. The EEGs were recorded conventionally with Grass gold-cup electrodes, Grass 7P511 amplifiers, and an Ampex PR500 tape recorder.

The recorded EEG signals were subsequently played back through matched α-bandpass filters (half-amplitude points at 8.5 and 12 Hz), and the output of the filters was integrated by circuits which reset every second. Two polygraph pens were driven by the integrators, and α amplitudes for each channel were measured by the distance the pens traversed on being reset. The output of this system was linear with the amplitude of a 10-Hz sine wave in the range of amplitude values used in this study.

Ratios of integrated α activity from the right hemisphere to α activity in the left hemisphere (R/L ratios) were computed for each 1-s epoch. A rank order plot of overall average ratios against average time to problem solution for each subject is shown in Fig. 2, indicating that those subjects with the lower R/L ratios solved the problems most efficiently. This result is in the direction predicted by the hypothesis of Bogen *et al.*[1] and is consistent with previous studies of EEG asymmetry[4–10]. Subjects who have relatively less right-α activity and therefore relatively more right activation, perform better on a putative right hemisphere task.

The correlation found here is nearly as strong if R/L ratios recorded during the resting baseline period are correlated with the average problem–solution latencies ($\rho = 0.508$, $P<0.05$). Apparently, most of the correlation observed in these data is a product of a tonic asymmetry in the EEG rather than a momentary activation pattern.

Dumas and Morgan[6] failed to find a relationship of the type reported here. These investigators used occupational category as the criterion variable for cognitive ability, arguing that a group of engineers would be expected to exhibit higher R/L α ratios than a group of artists. One difficulty with this research strategy is that there may be too many variables other than cognitive predisposition which determine occupational choice. Correspondingly, there may be, within any one occupation, great variety in the ways in which one can approach a task. For example, it is frequently observed that some mathematicians are clearly geometers—that is, they think about mathematics in visuospatial terms, and their proofs tend to be based on geometrical conceptions. There are also other mathematicians who are said to be algebraists, who tend to think mathematically in terms of the propositional manipulation of symbols. Similar kinds of differences are likely to be found within any occupational category.

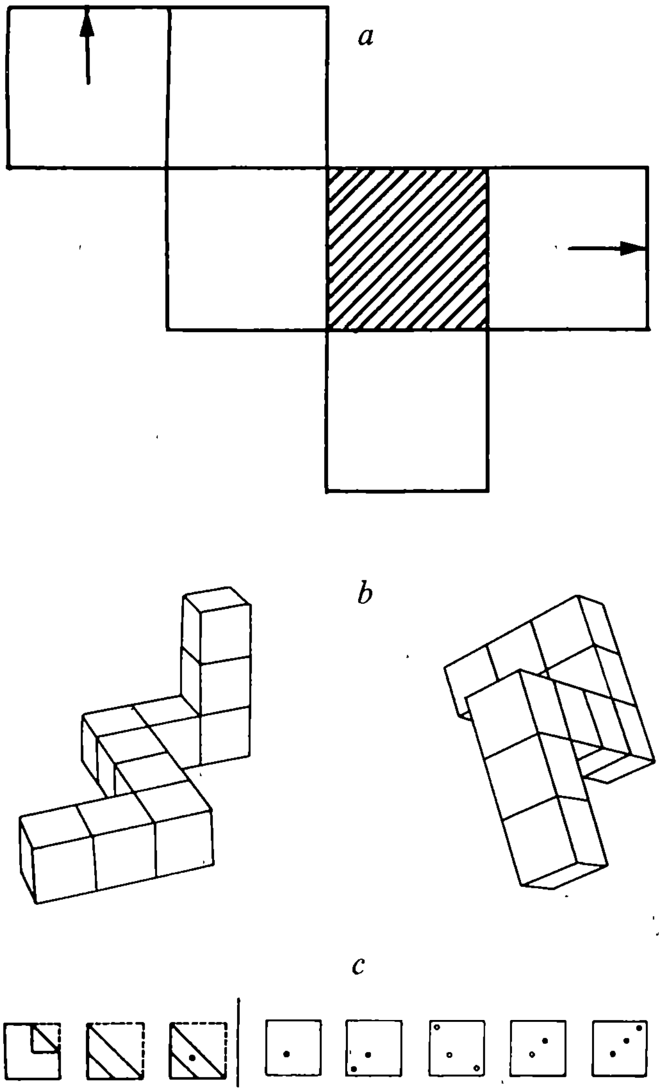

Fig. 1 Examples of the three types of visuospatial problems. *a*, Cube folding: mentally fold the figure into a cube, using the striped side as the base, and decide whether or not the two arrows meet (after ref. 12). *b*, Three-dimensional rotation: rotate in space one of the two figures and decide whether they are congruent or mirror opposites (after ref. 11). *c*, Paper folding: observe the sequence of folding operations in the left figures and decide the outcome of punching the indicated hole by choosing the correct figure on the right (from ref. 13).

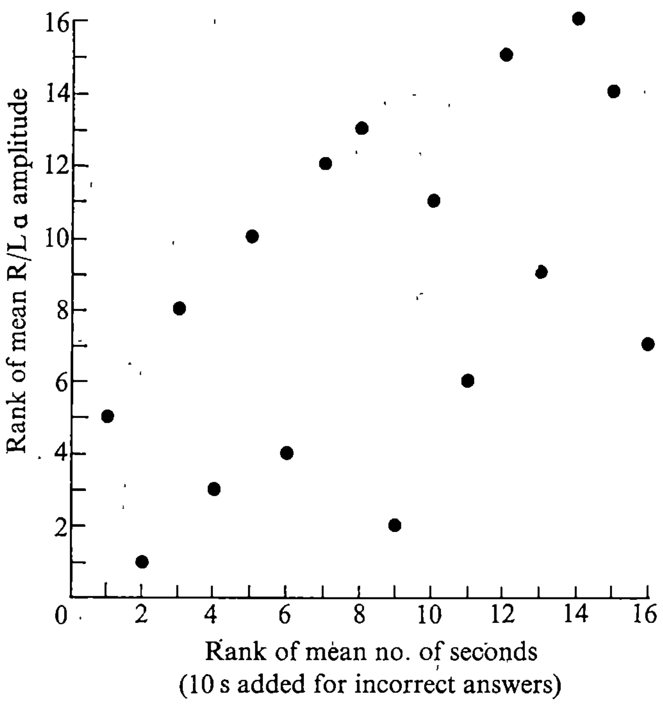

Fig. 2 Rank order scatter plot of average EEG asymmetry against average problem–solution latency. Ratios of right-to left-α activity were computed for each 1-s epoch and averaged over each trial for each subject. Values shown here are subject averages over all problems. Rank data are given because of the skewness of the distribution of average latencies. These data produce a rank order correlation of 0.546 ($t = 2.44$, d.f. $= 14$, $P < 0.05$). The latencies ranked here have been corrected for errors by adding 10 s to the time to solution on incorrect trials. If no correction is made for incorrect answers, the value of the correlation is attenuated only slightly ($\rho = 0.515$, $P < 0.05$).

The subjects tested in the present investigation, being sampled from a group of bright college students, were no doubt selected in part for visuospatial ability. It is a well known statistical fact that such a restriction in the range of one variable tends to reduce the value of the correlation coefficient[18], indicating that the present result might underestimate the correlation in the larger population.

Bicuculline reversal of deprivation amblyopia in the cat

CATS deprived of visual experience in one eye during a critical period of early life develop marked changes in the functional organisation of their visual system[1-3]. Useful vision seems to be lost in the deprived eye, and neurophysiological studies reveal a loss of binocular input to neurones in the visual cortex. Most neurones fail to respond to stimuli presented to the deprived eye; whereas almost all respond to stimulation of the normal eye. In normal neonatal kittens without visual experience, most cortical neurones respond to stimulation of either eye. Moreover, this binocular neuronal input persists when subsequent visual experience is prevented by binocular lid suture. Thus, asymmetrical visual experience seems necessary to produce a loss of binocular input. This loss of functional input from the deprived eye could result from a loss of the normal excitatory synaptic connections or from inhibitory suppression of afferent input. We postulate that asymmetrical visual experience causes synaptic inhibition of input from the deprived eye and that reduction of such inhibition might restore binocularity.

Several lines of evidence suggest that inhibition in the cat visual system may be mediated by γ-aminobutyric acid (GABA). Of particular importance are the reports that bicuculline, a GABA-receptor blocker[4], is able to alter receptive field (RF) properties of normal visual neurones[5-8]. We, therefore, attempted to restore binocularity in monocularly deprived cats by intravenous administration of bicuculline. This drug was able to restore binocular input to more than half the cortical neurones tested.

Five kittens were monocularly deprived of vision by lid suture in their fourth week of life. After 8 months of monocular deprivation, extracellular single unit recordings were made in the area centralis of visual cortex. We used paralysed (gallamine triethiodide) and locally anaesthetised (xylocaine) preparations to avoid possible confounding of our results by the known neurophysiological effects of general anaesthesia[9]. Single-cell activity, electroencephalogram (EEG), stimulus marker, and a voice channel were tape recorded. Each eye was independently stimulated with moving slits and bars of light projected on a tangent screen on which the eye was focused by a contact lens. An insulated tungsten microelectrode was advanced while stimulating the normal eye. RFs of responsive cells were characterised as "simple, complex, or hypercomplex"[10,11]. Next, the amblyopic eye was stimulated before and after the administration of intravenous bicuculline, usually given in 0.1–0.2-mg aliquots (0.03–0.06 mg kg^{-1}).

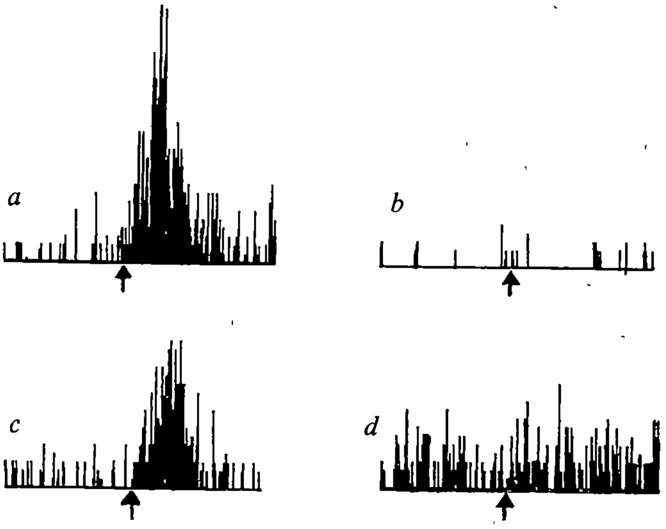

Fig. 1 Stimulus-related response histograms for monocular stimulation ($n = 10$) of a single cell in cat visual cortex with a complex RF. Time base is 512 ms Arrow indicates entry of light-bar stimulus into the receptive field of the cell. Same stimulus parameters (size, shape, orientation, direction and speed) used for each histogram. *a*, Normal eye open, pre-drug; *b*, amblyopic eye open, pre-drug: no response; *c*, amblyopic eye open, 2 min after 0.06 mg kg^{-1} of intravenous bicuculline: note response to stimulation and its similarity to *a*; *d*, amblyopic eye open, 15 min after bicuculline: note disappearance of response in spite of higher background firing rate. 20 of 33 cells developed similar responsiveness to stimulation of amblyopic eye after bicuculline which was independent of changes in background firing rate.

Table 1 Response of neurones to bicuculline by RF type (responsive cells/total cells tested)

Cat	All cells	Simple	Complex	Hyper-complex
1	1/1	1/1	0/0	0/0
2	4/8	3/4	2/4	0/0
3	6/10	1/1	3/7	2/2
4	5/10	2/3	2/5	1/1
5	4/4	0/0	3/3	1/1
All:	20/33	7/9	10/19	4/4
	(60.61%)	(77.78%)	(52.63%)	(100%)

All 33 cells evaluated responded to stimulation of the normal eye and had normal RF patterns. In contrast, only one could be driven by the amblyopic eye. Few unresponsive cells were encountered. These results agree with other neurophysiological studies of monocular deprivation amblyopia[1-3].

Administration of intravenous bicuculline produced a striking change in more than half the cells studied. Nineteen cells now responded to stimulation of the amblyopic eye (Figs 1 and 2). Although the brief duration (Fig. 2) of the response limited our study, the new amblyopic receptive field of a given neurone seemed similar, if not identical, with respect to location, size, shape, orientation specificity and directional specificity to the RF found with stimulation of the normal eye Cells of each RF type (simple, complex, hypercomplex) showed a response to bicuculline (Table 1). The amblyopic RF tended to show wider orientation tuning[12] than the pre-drug RFs to stimulation of the normal eye; however, most normal eye RFs showed a similar widening of their orientation tuning after bicuculline. The one cell responsive to stimulation of the deprived eye before bicuculline, which had shown an abnormal RF type, developed a more normal RF after bicuculline. Thus, relatively normal RFs to stimulation of the deprived eye were brought out in 20 of the 33 cells studied (60%). The remaining 13 cells (40%) failed to respond to stimulation of the amblyopic eye in spite of sufficient bicuculline to produce seizure discharges on EEG. The responses of 17 cells began within 30 s of bicuculline administration and lasted up to 10 min. The remaining 3 cells had a delayed response onset and a longer duration, lasting up to 30 min.

The administration of bicuculline was often complicated by its potent convulsive effects. Seizure discharges lasting 2–3 min often followed the bicuculline response within 15–30 s. We do not feel, however, that the restoration of binocularity was due to some nonspecific increase in excitability associated with seizure activity. All neurones which responded to stimulation of the deprived eye did so at subconvulsive doses of bicuculline Moreover, the appearance of seizure discharges at higher dose levels was always associated with loss of any response from the amblyopic eye. Finally, in two cells which had previously responded to bicuculline, we found that intravenous physostigmine failed

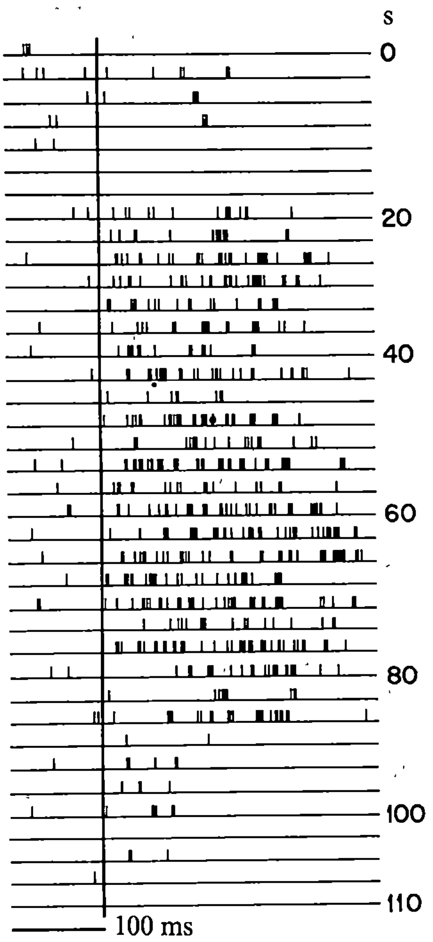

Fig. 2 Neuronal activity (Schmitt trigger output) of a complex visual cortical cell during monocular stimulation of the deprived eye. The continuous vertical line indicates entry of an optimally oriented light bar into the RF. Time base is 400 ms Responses of the cell to sequential stimuli are shown in temporal order from top to bottom. The first line is immediately after 0.03 mg kg^{-1} of intravenous bicuculline. Time (s) after bicuculline is shown to the right. Note the rapid onset of response at 20 s and its disappearance by 90–100 s. At higher dose levels, binocularity could be restored for longer periods of time.

to restore binocularity even at dose levels producing seizure activity.

Thus, our results indicate that intravenous bicuculline can make visual cortical neurones accessible to stimulation of the deprived eye in cats with monocular deprivation amblyopia. Access from the deprived eye could be restored after full development of the amblyopic condition with 8 months of visual deprivation. Moreover, the amblyopic eye RF showed the same properties as the normal eye RF. These observations suggest that the pathways between the amblyopic eye and the visual cortex may be capable of normal physiological function in spite of morphological changes which have been found in such preparations[13]. Since bicuculline was given intravenously, our data do not indicate where it acts to restore binocularity.

We postulate that the restoration of binocular input by bicuculline occurs by reduction of inhibitory mechanisms by way of GABA-receptor blockade. This mechanism is compatible with available information about the cat visual system. First, inhibitory input has been proposed as an important determinant of the normal response characteristics of visual neurones[14,15]. Second, GABA has been implicated as a visual inhibitory transmitter[16,17]. Finally, bicuculline alters the RFs of normal visual neurones in a manner consistent with reduction of inhibition[5–8]. If our interpretation is correct, then the total dominance by the normal eye results from active inhibition of the relatively intact input from the amblyopic eye and suggests that feline amblyopia may not involve a permanent, irreversible loss of visual function.

Dopamine release in substantia nigra?

IN addition to the axons which project to the nucleus caudatus[1,2], the dopamine (DA)-containing perikarya of the substantia nigra have extensive dendritic processes. These dendrites, observed after Golgi staining[3–5] and by electron microscopy[3,4], contain relatively large amounts of DA—revealed by histofluorescence[6]—and vesicle-like structures[4]. The DA seems to be stored in reserpine-sensitive structures[6]. The question has arisen whether DA can be released from the dendritic processes, as well as from nerve terminals of the nucleus caudatus[7,8]. Our investigation of the metabolism of released DA suggests that it can.

3,4-Dihydroxyphenylacetic acid (DOPAC) is the main metabolite of striatal and limbic DA and less than 50% of DOPAC is converted to homovanillic acid (HVA)[9]. We have investigated the metabolism of DA after electrically stimulated release in areas containing exclusively nerve terminals (nucleus caudatus[10], nucleus accumbens and the olfactory tubercle) and in a mesencephalic area devoid of nerve endings, but containing cell bodies (groups A_8, A_9 and A_{10})[1,11] and DA-rich dendrites[6] Rats (males, 200–230 g, Wistar-derived strain) were anaesthetised with chloral hydrate (400 mg kg^{-1}, intraperitoneally) and placed in a stereotaxic device A monopolar electrode was inserted through a burr hole in the exposed skull, with the coord-

Table 1 Alterations of striatal concentrations of DA, DOPAC and HVA after electrical stimulation of MFB

	Concentration in corpus striatum (μg g^{-1}±s.e.m)		
Compound	Ipsilateral	Contralateral	Difference

Nucleus accumbens (6)	3.31±0.21	2.27±0.19	1.04±0.20
Corpus striatum (9)	3.30±0.16	1.78±0.11	1.52±0.24

N, Number of observations (in parentheses). All differences between ipsi- and contralateral sides are significant at $P < 0.005$. Stimulus parameters: 300 µA; biphasic; frequency 30 Hz; duration 10 min

inates as described before[8]. The tip of the electrode was placed in the median forebrain bundle (MFB) which was stimulated electrically for 10 min (biphasic constant current of 300 μA; frequency 30 Hz; pulse length 2 ms). These stimulation parameters were found to give a maximal release of DA, and subsequent formation of DOPAC and HVA[8,12]. After stimulation we dissected various brain areas, including the nucleus caudatus, nucleus accumbens, olfactory tubercle and 12 mg of mesencephalic tissue containing both the substantia nigra (catecholamine groups A_8 and A_9) and group A_{10} of the ventral tegmental area, as described before[8,9,13,14].

In all cases the concentrations of the metabolites of DA in areas ipsilateral to the electrode were compared with those in the corresponding contralateral areas. DOPAC, HVA and DA were analysed as before[8,13,14].

Within 10 min of stimulation striatal DA was decreased by about 20%, while the concentration of DOPAC and HVA had increased (Table 1) The rise of the concentration of DOPAC was about double that of HVA, indicating that DA after release is predominantly deaminated. In these stimulatory conditions the potent inhibitor of DA uptake, nomifensine, had no effects on the metabolism of DA, demonstrating that there is no reuptake of released amine[8]. In all areas studied, DOPAC was increased by electrical stimulation of the MFB, thus including the non-terminal areas of the brainstem, which are antidromically activated (Table 2) These observations strongly suggest that when a nerve impulse is generated in dopaminergic neurones, DA is released not only from nerve terminals, but also from the cell bodies and dendrites. In addition we found (unpublished) that various drugs, including morphine, oxotremorine and neuroleptics, increase the concentrations of DOPAC and HVA not only in striatal and limbic structures, but also in the mesencephalic area containing dopaminergic cell bodies and dendrites.

What function can be attributed to DA released from non-terminal structures? We shall consider three possibilities First, DA may inhibit the neurone from which it is released (self- or auto-inhibition). Bunney and Aghajanian[15] found that DA-containing neurones of the substantia nigra were inhibited when the amine was applied microiontophoretically in the vicinity on the perikarya. With this proposed mechanism dopaminergic neurones may restrict the range of their firing frequencies. Second, DA released in the substantia nigra may inhibit other neurones, located near the dendrites releasing the amine (lateral inhibition). Such mechanisms have been described in other areas in the central nervous system, including the retina. Dendro-dendritic contacts in the substantia nigra have been revealed by electron microscopy[4] Groves *et al.*[16] found that local infusion of amphetamine, a drug which causes release of DA, also inhibits neuronal activity in the substantia nigra. This finding, however, does not discriminate between the two hypotheses.

The third possibility is that dopaminergic neurones have no preferential orientation Thus the observed dendrites can be considered to have the same function as the aminergic varicosities observed in the other parts of the brain. Neurones without obvious polarity include the retinal amacrine cells, of which a subpopulation seems to use DA as a neurotransmitter[17]. Which of these possibilities, or combination of possibilities, is valid for dopaminergic cells of the substantia nigra cannot be decided from available knowledge, including the data reported here. Our data do show that released DA is rapidly converted to DOPAC, not only in areas of the brain containing nerve terminals, but also where only perikarya and dendrites are found. These results challenge the concept that DOPAC is formed exclusively intraneuronally and that release of a neurotransmitter occurs only from nerve terminals.

Release of dopamine from dendrites in rat substantia nigra

THERE is increasing evidence that neurotransmitter synthesis, storage and release are not confined to axon terminals Much of this evidence has come from studies of the dopaminergic neurones of the substantia nigra (see Fig. 1). The terminal dendritic processes of dopamine (DA) neurones in substantia nigra are varicose and contain clusters of small vesicles[1,2]; histochemical studies have shown that the dendrites contain DA and are able to take it up[3,4]. There is also evidence that the components necessary for the synthesis and storage of DA are transported

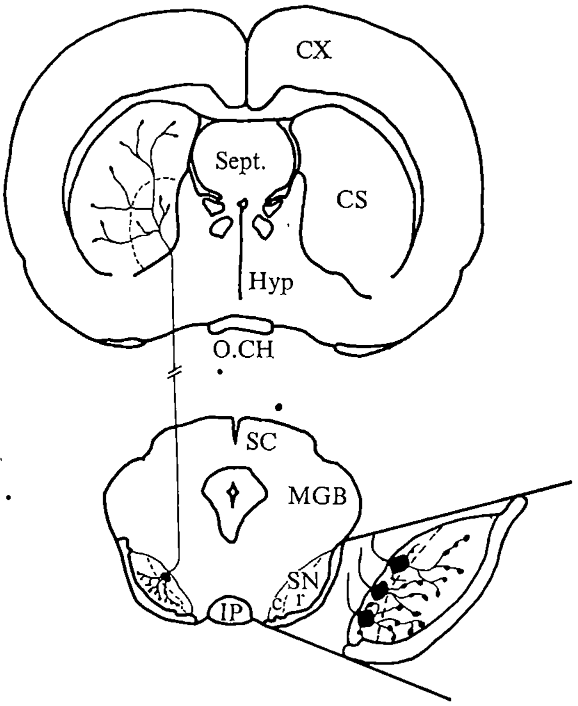

Fig. 1 Schematic representation of the dopaminergic nigrostriatal pathway. The cell bodies of dopaminergic neurones are largely confined to the pars compacta of substantia nigra with a well defined anatomical segregation of their axonal and dendritic processes[1]. Within substantia nigra, the dendrites of these neurones radiate ventrolaterally into the pars reticulata, whereas the axons project rostromedially ending mainly in the corpus striatum. Some dendrites are also present in the pars compacta. CX, Cerebral cortex; CS, corpus striatum; Sept., septum pellucidum; Hyp., hypothalamus; OCh, optic chiasma; SC, superior colliculi; MGB, medial geniculate body; IP, nucleus interpeduncularis; SN, substantia nigra; c, pars compacta of the substantia nigra; r, pars reticulata of the substantia nigra.

somatofugally in dendrites of substantia nigra[3,5]. Finally, the local application of DA agonists to the substantia nigra produces an inhibition of firing of neurones in the pars compacta that is blocked by DA antagonists[6,7]. On the basis of these observations, it has been proposed that a local dendritic release of DA may modify the excitability of dopaminergic neurones in substantia nigra[7]. There has, however, been no direct demonstration of transmitter release from these or other dendrites. In this study we present evidence for the release of DA from dendrites of dopaminergic neurones in rat substantia nigra.

We have used a combination of methods that provides a refinement of previous techniques for the study of the release of neurotransmitters in the central nervous system (CNS), enabling separate superfusion of fresh, microdissected areas of rat brain rich in cell bodies, dendrites or axon terminals of the same neurones.

The entire substantia nigra and samples of corpus striatum were dissected from serial slices (300 μm) of rat brain using the method of Zigmond and Ben Ari[8]. The pieces of tissue were incubated in ^{3}H-DA and uptake of labelled amine was measured after a 15-min incubation (Table 1). The endogenous DA content of similar samples was measured by a radiochemical enzymatic method[9]. ^{3}H-DA uptake per unit wet weight of tissue was 57% higher in corpus striatum than in substantia nigra, whereas the striatal DA concentration was more than sevenfold higher. Expressed in terms of endogenous DA concentration, therefore, ^{3}H-DA uptake and retention was greater in substantia nigra than in corpus striatum. One explanation of this finding is that vesicles in dendrites may have a lower endogenous transmitter content and a higher capacity for retention of exogenous DA than vesicles in axon terminals. In sympathetic neurones, axonal vesicles have been shown to increase their noradrenaline content fourfold on migration down the axon[10], with a concomitant decrease in capacity for uptake and retention of exogenous noradrenaline[11].

The evoked release of neurotransmitters from axon terminals in CNS by depolarising potassium concentrations has been extensively studied *in vitro*[12,13]. Slices of substantia nigra and corpus striatum were labelled with ^{3}H-DA and superfused with Krebs bicarbonate solution. The spontaneous release of ^{3}H-DA was initially rapid but became stable after 20 min superfusion. Brief exposure to high potassium (23.5 mEq l^{-1}) evoked large and reproducible increases in ^{3}H-DA efflux from both substantia nigra and corpus striatum (Fig. 2*a* and *b*). Slices of substantia nigra released a significantly higher proportion of their ^{3}H-DA content than corpus striatum, both spontaneously and in response to potassium stimulation (Table 2). This may be related to the observation that the specific activity of ^{3}H-DA in substantia nigra was considerably greater than in corpus striatum (Table 1).

The spontaneous efflux of ^{3}H-DA from both tissues was unaffected by removal of calcium from the perfusion medium, but potassium-evoked release was reduced by 88±2% in substantia nigra and 85±6% in corpus striatum in the absence of calcium (mean±s.e.m. $n=4$) (Fig. 2*c* and *d*). In each case, potassium-evoked release of ^{3}H-DA could be restored by a brief exposure to normal calcium. Raising the magnesium concentration in the presence of calcium also reduced the potassium-evoked release, by 59±1% in substantia nigra and by 72±10% in corpus striatum (mean±s.e.m., $n=4$) (Fig. 2*c* and *d*). There were no significant differences between substantia nigra and corpus striatum in the inhibitory effects of low calcium or high magnesium concentrations. Since the release of neurotransmitters by exocytosis is known to be calcium dependent and to be inhibited by high magnesium concentrations[14], it is likely that DA released from corpus striatum and substantia nigra was vesicular in origin.

Further evidence for vesicular release was obtained by estimating the proportion of radioactive metabolites of

Table 1 Dopamine uptake and content in rat substantia nigra and corpus striatum

	Tissue wet weight (mg)	Endogenous DA (ng mg^{-1})	^{3}H-DA uptake (ng mg^{-1})	^{3}H-DA/endogenous DA ratio
Substantia nigra (cell bodies and dendrites)	3.11±0.22 (12)	0.34±0.02 (4)	1.22±0.10 (7)	3.59
Corpus striatum (axon terminals)	6.16±0.33 (10)	2.55±0.31 (4)	1.92±0.16 (7)	0.75

Adult male Wistar rats were anaesthetised and perfused through the left ventricle of the heart with 100 ml Krebs phosphate solution at 4 °C. Coronal slices (300 μm thick) of the brain were cut in a 4 °C cold room with a McIlwain tissue chopper, and the entire substantia nigra and a portion of corpus striatum at the level of the optic chiasma were dissected using a stereomicroscope. Tissue samples were weighed and preincubated in Krebs–Henseleit solution at 37 °C for 5 min ^{3}H-DA (specific activity 8.95 Ci mmol^{-1}; NEN Chemicals) was added to a final concentration of 1 μM and incubation continued for a further 15 min. After rinsing, the tissue radioactivity in acid methanol extracts of nigral and striatal tissue was shown by ascending chromatography (*n*-butanol–acetic acid–water, 4:1:1 v/v) to migrate with authentic DA. Each value is mean ± s.e.m. Number of samples in parentheses.

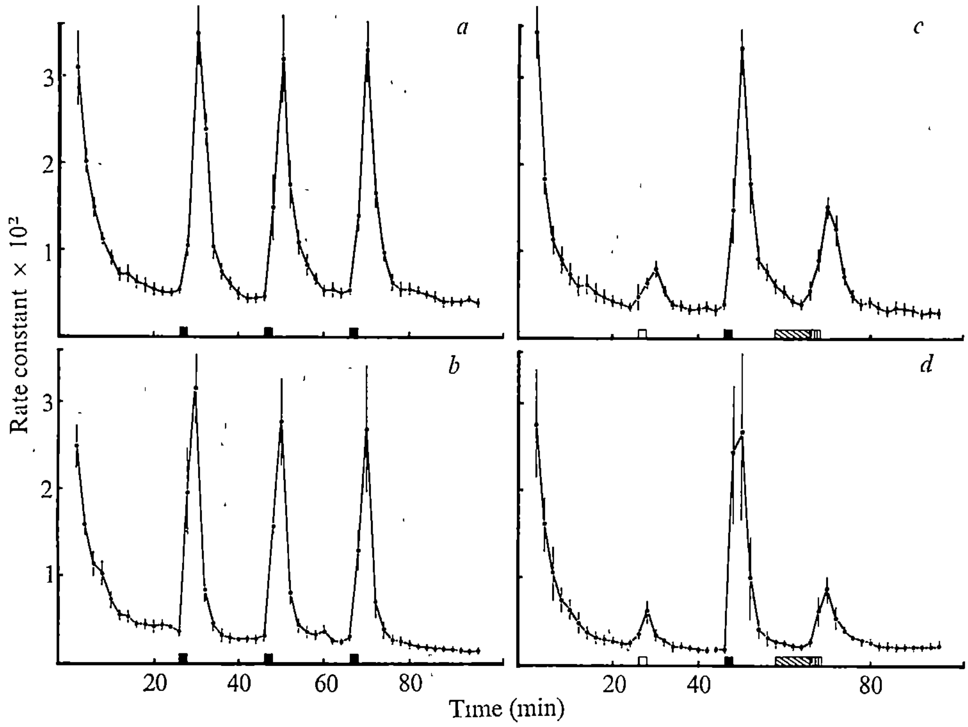

Fig. 2 Release of ^{3}H-DA from superfused slices of rat substantia nigra (*a*, *c*) and corpus striatum (*b* *d*). Tissues were superfused at a rate of 30 ml h^{-1} with normal Krebs bicarbonate solution. At 20-min intervals, pulses of high potassium (23.5 mEq l^{-1}) were given for 2 min. In *a* and *b*, potassium pulses were given during perfusion with normal Krebs (■); in *c* and *d*, superfusion throughout the experiment was with calcium-free Krebs. The first potassium pulse was applied in the continued absence of calcium (□). For the duration of the second (■) and third (vertical hatching) potassium pulses the calcium concentration was restored to normal. Four fractions before, and during the third potassium pulse, the magnesium concentration was raised to 24 mEq l^{-1} (diagonal hatching); after the third potassium pulse, the magnesium concentration was restored to normal. Efflux of radioactivity was expressed as the fractional rate constant (d.p.m. released per min in superfusate/d.p.m. in tissue stores at time of collection). Each value is mean ± s.e.m. of four experiments.

^{3}H-DA in the superfusates. During stimulation of sympathetic nerves it has been shown that the ratio of released noradrenaline to its metabolites increases greatly[15], presumably because transmitter released by exocytosis is not susceptible to intraneuronal metabolism. In some of the present experiments samples of superfusate were chromatographed on alumina columns[16]. The proportion of total radioactivity recovered in the catechol fraction was 60.1 ± 4.5% in basal samples and 90.5 ± 1.7% during the peak of the potassium-evoked release in both substantia nigra and corpus striatum (mean ± s.e.m., $n=4$).

To minimise the possible contribution to ^{3}H-DA release made by dopaminergic cell bodies in the substantia nigra, further experiments were carried out using only the pars reticulata of substantia nigra, removed by careful microdissection. Each potassium pulse released 7.8 ± 0.5% (mean ± s.e.m., $n=4$) of ^{3}H-DA stores in pars reticulata. Thus, although it is not yet possible to assess the magnitude of ^{3}H-DA release from neurone cell bodies in the pars compacta it is clear that a substantial proportion of the ^{3}H-DA release observed in experiments on the entire substantia nigra occurs from dendritic processes

Table 2 Fractional release rates of ^{3}H-DA from substantia nigra neurones

	Spontaneous	K$^+$ evoked
Substantia nigra (cell bodies and dendrites)	0.50±0.02	5.76±0.33
Corpus striatum (axon terminals)	0.32±0.03*	4.25±0.54†

Values for spontaneous efflux are expressed as the mean ± s.e.m., ($n=12$) percentage of tissue ^{3}H-DA stores released in the three fractions before each potassium pulse; for potassium-evoked release as the total increase in ^{3}H-DA release over basal level for each pulse. Significance of difference between substantia nigra and corpus striatum: $^*P < 0.001$; $^\dagger P < 0.05$.

The release of transmitter from dendrites may have a number of functions. Coordination of excitability of dopaminergic neurones within substantia nigra could be mediated by a DA receptor located either on the DA neurones or presynaptically on the axon terminals innervating them, or both. Release of transmitter close to cell bodies could also provide a mechanism for the local control of neuronal metabolism. A third regulatory function for the dendritic release of transmitter could be in the control of plastic and regenerative sprouting of neuronal processes and the establishment of new synapses.

Foetal thymidine kinase in tumours and colonic flat mucosa of man

WE have characterised two forms of deoxythymidine kinase (TK) using antisera prepared against the enzyme partially purified from human colonic mucosa. One of these forms is associated with rapidly proliferating lower colonic crypt cells and the other, with non-dividing surface cells. Antibody to the latter cross reacted with several tumours and placental extracts but not with phytohaemagglutinin (PHA)-stimulated or leukaemic lymphocytes. This cross reactivity of surface cells and colonic tumours supports the concept that surface cells rather than crypt cells are the site of origin of colonic cancer[1,2].

Studies in preneoplastic tissues showed a persistent incorporation of labelled deoxythymidine into DNA of the normally quiescent cells of colonic[1–3] and gastric[4] mucosae and cervical epithelium[5]. These observations directed our attention to the enzymes associated with DNA synthesis in these non-dividing cells as well as normal and malignant proliferating tissues. The concomitant increases in DNA synthesis and the pyrimidine salvage enzyme, TK, in proliferating cells and tissues and physiologically stimulated systems[6,7] focused on this enzyme as a parameter linked to proliferation and malignancy. For example, human colorectal tumours contain more TK than the homologous, normally rapidly proliferating tissue[8]. In the latter, TK activity is found primarily in the lower third of the colonic crypt, the region containing most of the rapidly proliferating cells[3,8,9]. Tumour TK differs from the normal enzyme in its response to mercaptans and is more thermolabile in the presence and absence of mercaptans[8].

These data, as well as the observations that TKs induced by infection with herpesvirus types 1 and 2 are biochemically and antigenically distinct not only from cellular TK but also from each other[10,11], suggested that the serological properties of TK could be used to detect and characterise colorectal malignancies. Antisera were prepared in the rabbit, using partially purified TK from total normal colonic mucosa as immunising antigen (Table 1), and screened by Ouchterlony double diffusion technique[12] against cytosol (127,000g supernatant fraction) TKs from normal total colon, colonic surface and crypt cells, placenta, PHA-stimulated lymphocytes, leukaemic cells and tumours from sites other than the colon.

Both preimmune and immune sera were tested against homologous and heterologous enzymes. Preincubation with preimmune sera did not have any effect on TK activity of any

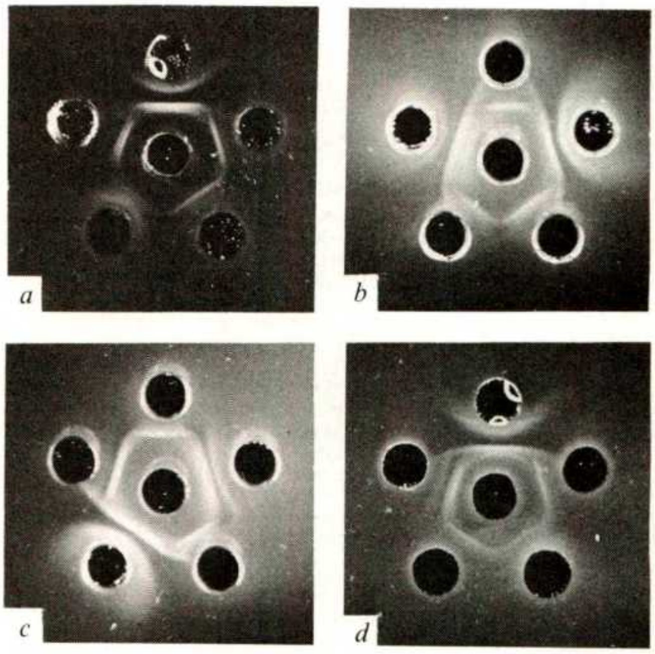

Fig. 1 Double diffusion precipitin reactions in agar gels. Immune serum (0.004 ml) is used in the centre wells and antigen extracts (35–40 µg cytosol protein), in the peripheral wells of micro-Ouchterlony plates (5-mm well spacings, Hyland Laboratories). The peripheral wells are designated as 1, at the top and sequentially numbered in a clockwise direction. In *a* the extracts are 1, total colonic mucosa; 2, adenocarcinoma of the colon (J.G.); 3, colonic surface (tip) cells; 4, colonic lower crypt cells and 5, placenta I. In *b* the extracts are 1, placenta I; 2, total colonic mucosa; 3, osteosarcoma, lung; 4, adenocarcinoma of the rectum (N.I.) and 5, ascites from metastatic adenocarcinoma of the colon (I.R.). In *c* the extracts are 1, adenocarcinoma of the colon (A.S.); 2, ovarian carcinoma; 3, adenocarcinoma of the rectum (C.W.); 4, total colonic mucosa and 5, colonic polyp. In *d* the extracts are 1, total colonic mucosa, 2, adenocarcinoma of the colon (I.R.); 3, colonic polyp; 4, adenocarcinoma of the colon (J.G.) and 5, placenta II.

Table 1 Purification of TK from human colonic mucosa

	Total protein (mg)	Total activity (µU)	Specific activity (µU per mg protein)	Yield (%)
Whole homogenate	9,940	52,682	5.3	
Supernatant (10^5g)	4,552	45,975	10.1	87.2
$(NH_4)_2SO_4$ precipitation (40%)	358	34,117	95.3	64.8
Heat at 50 °C (1 mM TdR)	143	28,629	200.2	54.3
$(NH_4)_2SO_4$ precipitation (40%), concentrated on Amicon after dialysis	64	25,446	397.6	48.3
Negative $Ca_3(PO_4)_2$ gel	22.7	19,034	838.5	36.1
Sephadex SG 200 (KCl) chromatography	6.9	10,554	1,529.6	20.0
BioGel P-150 chromatography	1.4	6,327	4,519.3	12.0
DEAE–cellulose chromatography	0.3	3,347	11,156.5	6.4

Pooled total mucosal scrapings (140 g frozen wet weight) from autopsy colons of patients with non-involvment of the gastrointestinal tract, obtained through the Tumour Procurement Service of Memorial Hospital, New York, were homogenised in a Waring Blendor at low speed with 0.25 M sucrose–0.2 M Tris-HCl (pH 8.2, 25 °C)–0.15 M KCl–0.17 M 2-mercaptoethanol (25:1.5:1:0.5), strained through gauze and centrifuged at 100,000g for 90 min. The pellet was washed and re-extracted twice and the combined supernatant fractions were adjusted to 40% saturation with respect to ammonium sulphate. The precipitate collected by centrifugation at 20,000g for 20 min was redissolved in 0.05 M Tris-HCl–0.25 M sucrose–6 mM 2-mercaptoethanol-1 mM TdR, heated at 50 °C for 5 min, rapidly cooled, centrifuged and reprecipitated with ammonium sulphate. The precipitate collected by centrifugation was dissolved and purified by absorption on calcium phosphate gel, followed by gel filtration in Sephadex SG-200 in the presence of salt and in BioGel 150 in the absence of salt and finally by elution with a linear salt gradient (0.05 M–1.0 M KCl) from DEAE–cellulose. This resulted in a 2,100-fold purification of the enzyme with respect to the activity in the whole homogenate. All steps were carried out at 4–8 °C. TK activity was assayed as before. A unit is defined as the enzyme phosphorylating 1 µmol TdR per min at 37 °C. For immunisation, 1 mg of purified colonic TK in 1.0 ml of 0.05 M Tris-1 mM TdR–6 mM 2-mercaptoethanol was emulsified by mixing with an equal volume of Freund's complete adjuvant and injected subcutaneously into New Zealand white albino male rabbits. This was followed a week later by a similar preparation with incomplete adjuvant. A booster injection with incomplete adjuvant was administered 6 weeks after the initial injection. Blood was collected from the marginal ear vein once a week for about 4 or 5 weeks after the booster.

Table 2 Residual activity of TK in various tissue extracts after preincubation with anti-human colonic TK from rabbits

Source of TK	Control TK activity* (pmol per incubation sample)	% Residual activity† Undiluted		
		Undiluted	1:10	1:1,000
Partially purified by a single precipitation with ammonium sulphate				
Normal colon	40±2	8	27	37
Adenocarcinoma colonic (J.G.)	66±3	54	67	86
Placenta I‡	68±2	60	77	87
Crude extract				
Ovarian carcinoma	80±4	35	48	65
PHA-stimulated lymphocytes	76±2	95	99	100
Myeloblastic leukaemic leukocytes	85±4	95	98	100

Cytosol TKs were prepared from surgical samples after homogenisation in the buffer described in Table 1, with a Potter–Elvejehm homogeniser and centrifugation at 127,000g for 60 min; the supernatant could be stored at –20 °C for more than 2 months with little loss in activity and at –80 °C for more than a year. Lymphocytes and leukaemic cells were washed with phosphate-buffered saline, pelleted, resuspended in a minimal volume of distilled water and lysed by repeated freezing and thawing. The lysed cell suspension was adjusted to the same concentration of homogenising medium and gently homogenised as were the surgical samples. TK activity was assayed as before[8].

*Figures are pmol per incubation sample. Control activity is the average of the enzyme activity in preparations preincubated with preimmune serum. The latter had no effect on the TK activity of any of the preparations tested. TK activity was assayed as before[8].

†Values signify percentage residual activity obtained with antisera relative to activity with preimmune serum. Various dilutions of both preimmune serum and serum (No. 317) of rabbit immunised with human colonic TK were preincubated overnight at 4 °C with equal volumes (0.20 ml containing 250–300 µg protein) of either dialysed preparations of TK partially purified by ammonium sulphate precipitation or crude 127,000g supernatant fractions. Three samples of the supernatant containing 50–60 µg antigen protein were removed and assayed for TK activity.

‡Placentae used in all these studies were flushed for at least 15 min with physiological saline through the umbilical artery. A portion of the foetal placenta free of maternal elements was removed and homogenised as described for surgical samples.

of the preparations examined. Antisera, which markedly inhibited homologous colonic TK were much less effective in neutralising the activity of enzymes from colonic adenocarcinoma, placenta (two samples, I and II) and ovarian carcinoma and did not inhibit the enzyme from either PHA-stimulated lymphocytes or myeloblastic leukaemic leukocytes (Table 2). The latter two preparations did not react with antisera to produce double diffusion precipitin lines in contrast to the extracts of total colonic mucoae, colonic crypt cells, colonic surface (tip) cells, placenta and tumours of diverse origin (Fig. 1). The precipitin lines were absent when supernatant from total colonic mucosa preincubated with undiluted antiserum was used as antigen, suggesting that these lines are essentially attributable to TK–antibody reactions. There were cross reactions between colonic TK and heterologous enzymes from placenta and colonic tumours (Fig. 1*a* and *d*), osteogenic sarcoma (lung) and placenta (Fig. 1*b*), rectal carcinoma and colonic polyp (Fig. 1*c*) and total mucosa from small intestines, suggesting partial antigenic identity of the enzymes in these preparations. There seemed to be cross reactions between TK from ascitic cells (metastatic colonic adenocarcinoma) and the enzymes from placenta and rectal adenocarcinoma (Fig. 1*b*). Precipitin patterns similar to those presented here for tumours were also observed in a breast carcinoma, a myxoliposarcoma, a gastric carcinoma and a cervical carcinoma.

In mammalian cells, there are multiple forms of TK[13-15], the relative proportions of which vary with the origin and the metabolic state of the tissue. The different precipitin patterns in the rapidly proliferating tissues examined could be a reflection of quantitative and/or qualitative differences in the isozymes present. The biphasic nature of the thermal inactivation observed in crude cytosol fractions[8] as well as in the partially purified colonic TK preparations suggests the presence of more than one form of the enzyme. Preliminary studies also indicate that there are at least three electrophoretic forms of TK in some of these tissues, and in the 2,100-fold purified TK used as antigen. In the latter, TK activity was associated with the three protein-staining bands which constituted about 90% of the total protein. There seems to be at least one form of TK in colonic tumours, polyps and placenta which is antigenically similar, but not identical, to that of normal colonic TK, most likely the form found in the surface cells.

Although TK activities from placenta and a colonic adenocarcinoma (J.G.) were inhibited to about the same extent (Table 2), the enzymes do not seem to be serologically identical (Fig. 1*d*). There is a similarity between these placental and tumour antigens but not the complete identity which has been reported for isozymes of human alkaline phosphatase[16]. TK with the electrophoretic migratory pattern characteristic of the enzyme found in the early stages of development of human foetal liver has been observed in malignant tumours from various sites[15,17,18]. Enzymes with similar migration, however, are not necessarily antigenically related, for example, from cervical carcinoma and the virus-specific enzyme induced by the epidemiologically associated herpesvirus type 2 (ref. 19). The similarity between TKs from placenta and tumours from various sources is reminiscent of the appearance of embryonal antigens in murine[20] and human[21] cancer cells.

The data presented here suggest that TK of colonic tumour is serologically more similar to the enzyme from surface cells than that from lower crypt cells. This would be consistent with the hypothesis that colonic tumours arise from surface epithelial cells rather than from the depths of the crypts[1,2].

We thank the members of the Department of Surgery for making surgical materials available. We also thank the Tumor Procurement Service for autopsy samples and other tumours. This investigation was supported by a Public Health Service grant from the National Cancer Institute through the Large Bowel Cancer Project and by a US Public Health Service grant.

Immunofluorescent localisation of human pregnancy-specific β-globulin in placenta and chorioepithelioma

VARIOUS immunological methods have been used to define the existence on plasma of several pregnancy-associated macromolecules[1–3], of which between three and five are now well recognised in humans[4,5]. The cells and tissues responsible for their synthesis, however, remain to be clearly defined, although, of the two pregnancy-associated β_1-globulins, one was recently detected in the sera of patients bearing trophoblastic tumours[6]. This particular β_1-globulin does not resemble any known hormone, including chorionic gonadotropin[7], but seems to be identical with the pregnancy-specific β_1-glycoprotein of Bohn[9] and the PAPP-C described by Lin *et al.*[5]. The placenta has been suggested as the site of its synthesis[8,9]. Using indirect immunofluorescence, we have now located this β_1-globulin in human placenta and chorioepithelioma of the uterus, where we believe it is synthesised.

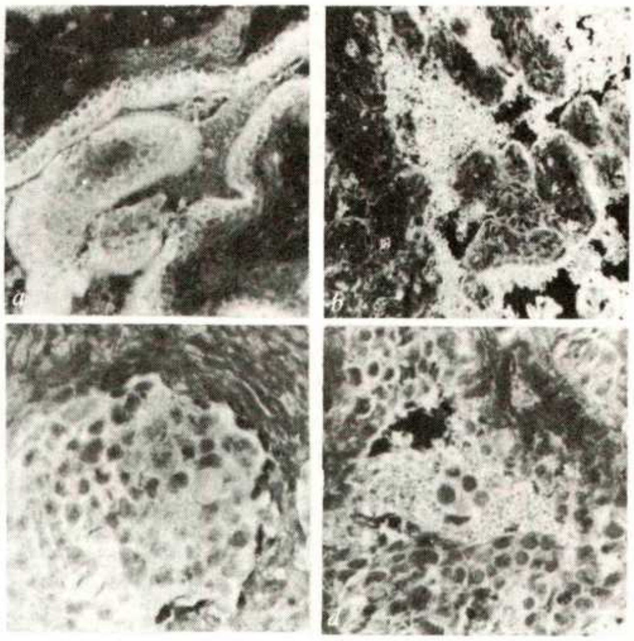

Fig. 1 *a*, Section of placental chorion (8-week gestation) treated with anti-β_1-globulin and anti-RGGFI, showing specific fluorescence in cytoplasm of cytotrophoblastic (Langhans) and syncytiotrophoblastic cells (×31). *b*, Section of the placenta (40-week gestation) treated with anti-β_1-globulin and anti-RGGFI, showing specific fluorescence in residual trophoblastic cells and in fibrin islands (×31). *c* and *d*, Sections of different chorioepitheliomas, showing specific fluorescence in cytoplasma and membranes of Langhans cells as well as in fibrin islands (also treated, ×52).

Samples of placenta were obtained from abortions, carried out at 6–12 weeks of gestation, or after normal birth. Chorioepitheliomas were obtained from affected patients at the time of hysterectomy. For controls, specimens of other organs were obtained at autopsy, 3–6 or 8–16 h after death, from patients with either chorioepitheliomas (without metastases) or non-malignant disease.

Tissue specimens (diameter 3–5 mm) were fixed in cold absolute ethanol with glacial acetic acid (99 : 1 v/v)[10] and subsequently embedded in paraffin and sectioned[11]. Anti-β_1-globulin was prepared as before[8]. Antibodies to anti-β_1-globulin and anti-albumin of human serum (anti-HSA) were raised in rabbits and then purified by the glutaraldehyde–immunosorbent technique[12]. Human albumin was chosen as the serum protein reference of nonspecific absorption because it is not produced by trophoblastic cells. The indirect immunofluorescence technique was used with donkey monospecific antibodies for rabbit γ-globulin labelled with fluorescent isothiocyanate (anti-RGGFI). Selected fields were photographed (ML-2B microscope) and subsequently stained with haematoxylin and eosin and mounted in glycerol buffer to facilitate comparison with definitively identifiable structures.

To ensure that the fluorescence exhibited by the anti-β_1-globulin sera was specific for the storage sites in the placenta and chorioepitheliomas, and to distinguish between specific and nonspecific uptake of the antibodies, the following controls were effected: (1) incubation of some sections only with anti-RGGFI; (2) use of anti-β_1-globulin neutralised with serum from pregnant women; (3) use of anti-HSA and anti-RGGFI on some sections, excluding the liver.

Specific immunofluorescence was found in placenta and chorioepitheliomas but not in lung, muscle, spleen, brain, pancreas, gastrointestinal tract or liver (when there was no metastasis or tumour). It was associated with the cytotrophoblast and syncytiotrophoblast of the chorion in immature placenta (Fig. 1*a*) and with residual trophoblast and fibrin islands, perhaps containing necrotic trophoblastic cells, in the term placenta (Fig. 1*b*). In chorioepithelioma, specific fluorescence was also associated with giant trophoblastic cells (Langhans cells) or fibrin islands (Fig. 1*c* and *d*).

The control experiments with 8-week gestation placental tissue and sections of liver after treatment with anti-HSA and anti-RGGFI showed little or no fluorescence.

We suggest that production of this particular β_1-globulin may start in the Langhans cells and continue in the syncytiotrophoblast of the normal chorion and in the trophoblast cells of chorioepitheliomas, where there may be less biosynthetic activity and secretory capacity.

Immunological and biochemical characterisation of type C viruses isolated from cultured human AML cells

TYPE C viruses are associated in several species with naturally occurring malignancy and have been isolated from a variety of species including several non-human primates. The ability to specify interviral relationships is crucial for evaluating the degree of relatedness of new isolates to known viruses, especially those which are potentially associated with human malignancy. Recent studies of Gallagher and Gallo[1] indicated the presence of a type C virus in cultured cells from a patient with acute myelogenous leukaemia (AML) (patient A.S.). Viruses from this culture have been propagated in homologous and heterologous fibroblastic cells[2] in sufficient quantity to be characterised in detail.

Recently, immunological and molecular hybridisation methodology has been applied to the type-specific differentiation of known primate viruses[3-9]. The viruses that can be distinguished include three members of the related woolly monkey (SSV-1)-gibbon ape group and three members of the endogenous baboon virus-RD114 group (Table 1). In investigating the relationship of the AML virus isolate to known type C viruses using the above methodology, certain of our initial observations were previously recorded as "personal communication"[2]. It is our purpose here to amplify these findings. The data reported here were derived from virus produced by secondary fibroblastic cells[2] after infection with virus from primary leukocyte cultures of the first peripheral blood sample[1].

The AML virus (HL23V), propagated in either canine thymus or human cells was initially found to contain proteins of both primate virus groups based on complement-fixation tests and radioimmunoassays which are specific for woolly monkey–gibbon virus p30 and RD114–baboon virus p30, respectively. Growth of the HL23 virus in normal rat kidney (NRK) cells, which are relatively non-permissive for viruses of the RD114–baboon group, yielded a virus which only showed immunological reactivity characteristic of the woolly monkey–gibbon virus group.

The suggestion that two viruses were present in infected human and dog cultures was confirmed by detection of viral RNA using complementary ^{3}H-DNA (cDNA) prepared in the endogenous reverse transcriptase reaction. Uninfected cultures were negative in these assays. On the basis of the extent of its reaction using S1 nuclease, one of the viruses was indistinguishable from the woolly monkey virus (Fig. 1*a*). The woolly cDNA preparation hybridised to a lesser extent with the two gibbon (GALV) viruses and gave no hybridisation with cultures infected with the baboon or RD114 viruses or a culture replicating endogenous rat virus. The gibbon (SFMC) cDNA used gave the expected reciprocal reaction, namely a partial reaction with woolly monkey and AS virus-infected cell RNA (Fig. 1*b*). In view of the >95% reaction it was not surprising to find that thermal dissociation profiles of wooly cDNA, and woolly or HL23V RNA had midpoints (T_m) within 1 °C, whereas in the same conditions (hydroxyapatite chromatography) woolly monkey and gibbon heterologous DNA–RNA hybrid molecules showed a ΔT_m of 6.5 °C compared with homologous reactants (data not shown).

The second virus present has sequences indistinguishable from the endogenous baboon virus isolated from *Papio cynocephalus* (Fig. 1*c*). The cDNA preparation used distinguished this virus from a highly related endogenous virus isolated from the baboon species *Papio hamadryas*, which reached saturation at 80% of the homologous reaction and RD114: maximal reaction ~20%. The cDNA did not hybridise with human cell RNA including that of the cell line (uninfected) used to propagate the virus. No cross hybridisation was obtained with RNA from cells producing the woolly monkey virus. RD114 cDNA (Fig. 1*d*) gave the expected reciprocal reaction with baboon and AS viruses, namely ~20% at saturation. Note also that AS virus grown in rat cells did not hybridise with baboon or RD114 cDNAs, consistent with the immunological data indicating the presence of only the woolly monkey viral p30 in this culture. The relationship between the two baboon viruses seems closer than that of the woolly monkey–gibbon group based

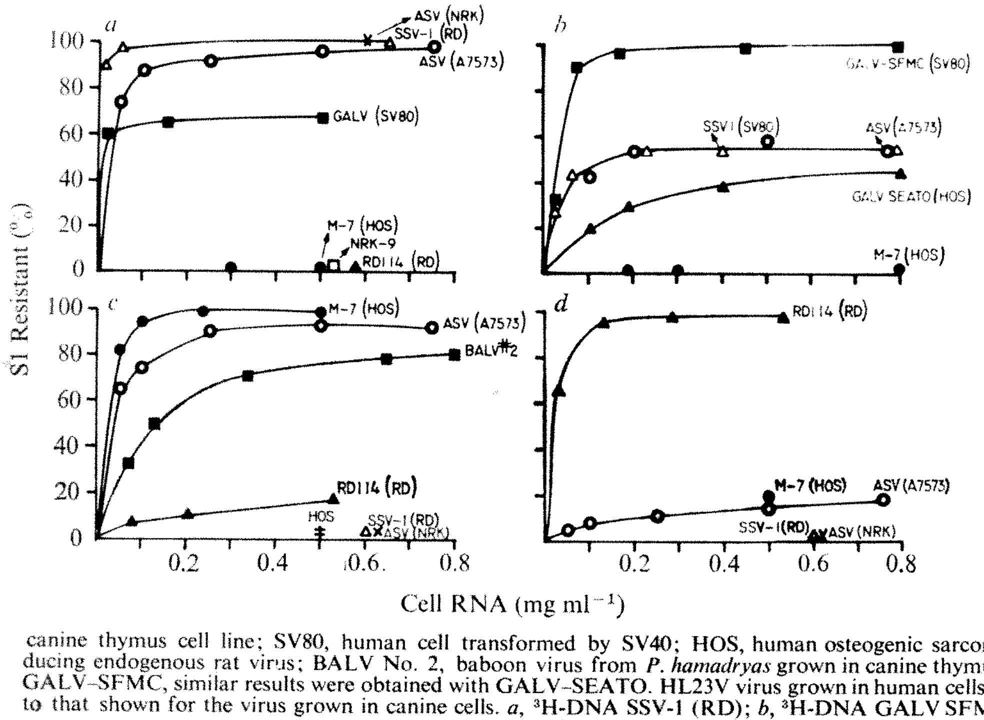

Fig. 1 ^{3}H-DNA transcripts (about 10^3 c.p.m. per assay) of woolly monkey virus (SSV-1) which represents the helper virus (SSAV) present in vast excess, the SFMC isolate of GALV, the baboon isolate of *Papio cynocephalus* (M-7), and the endogenous cat virus (RD114) were annealed with increasing amounts of cellular RNA. Incubation was at 67 °C for 18 h and mixtures were analysed by S1 nuclease digestion according to previously described methods[9]. The cDNAs used represent 60–70% of the various viral genomes based on resistance of labelled RNA to RNase digestion after annealing with excess cDNA. Values are normalised to 100% for the homologous reactants, actual values were 90% or greater for each of the four homologous sets of reactants. The cells in which the various viruses were grown are given in parentheses. NRK, Normal rate kidney; RD human rhabdomyosarcoma cell line; A7573, canine thymus cell line; SV80, human cell transformed by SV40; HOS, human osteogenic sarcoma cell line; NRK-9, rat cell producing endogenous rat virus; BALV No. 2, baboon virus from *P. hamadryas* grown in canine thymus cells. The data shown in *a* are for GALV–SFMC, similar results were obtained with GALV–SEATO. HL23V virus grown in human cells gave a similar hybridisation pattern to that shown for the virus grown in canine cells. *a*, ^{3}H-DNA SSV-1 (RD); *b*, ^{3}H-DNA GALV SFMC (SV80); *c*, ^{3}H-DNA M7 (HOS); *d*, ^{3}H–DNA RD114 (RD).

Table 1 Primate and related type C viruses distinguished by type-specific molecular hybridisation and immunoassays

	Virus	Origin
A (1)	Woolly monkey (SSAV-1)	Fibrosarcoma[10]
(2)	Gibbon ape (GALV-SFMC)	Lymphosarcoma[11]
(3)	Gibbon (GALV-SEATO)	Granulocytic leukaemia[12]
B (1)	RD114	Endogenous cat virus[13]
(2)	Baboon (BALV-M7-*Papio cynocephalus*)	Placenta[14]
(3)	Baboon (BALV No. 2-*Papio hamadryas*)	Lymph node of lymphomatous baboon[15]

Viruses of the *A* group are highly related as are those of the *B* group. The assays described in this report show no cross reactivity between groups. *B*-group viruses are endogenous in their species of isolation[16], while *A*-group viruses are not represented in cellular DNA of their species of isolation[17]. *A*-group viruses are believed to have originated in the remote past from ancestors of the genus *Mus*[18,19].

SFMC: San Francisco Medical Centre; SEATO: laboratory in Bangkok, Thailand.

on thermal dissociation data. Homologous heteroduplexes of the baboon viruses gave T_ms 2 °C higher than heterologous reactants. The HL23 virus, as expected from reaction extent, was indistinguishable by thermal stability criteria from the *Papio cynocephalus* virus (within 1 °C).

The distinct components of the HL23 virus preparation were further analysed in type-specific radioimmunoassays for low molecular weight viral structural polypeptides[3]. The HL23 virus and each of the woolly monkey–gibbon viruses showed complete cross reactivity in the woolly monkey virus p30 assay. In the woolly monkey p12 assay (Fig. 2*a*), HL23 virus and woolly monkey virus showed identical slopes and final reaction extents (complete displacement of the iodinated woolly monkey p12), while the two gibbon viruses were easily distinguished from the above viruses by these criteria. In the SFMC gibbon virus p12 assay, only the SFMC virus competed efficiently (Fig. 2*b*).

In analogous immunoassays for baboon–RD114 structural polypeptides (Fig. 3) both the AS virus and the endogenous virus of *P. cynocephalus* reacted efficiently in the *P. cynocephalus* virus p15 assay, but competed poorly in the RD114 p15 assay. In contrast, the *P. hamadryas* virus was poorly reactive in both p15 assays. RD114 competed completely in the homologous RD114 p15 assay but not in the *P. cynocephalus* p15 assay. In other studies the gp70s of the woolly monkey[4] and baboon components of the HL23 virus preparation were indistinguishable from the gp70s of the prototype woolly monkey virus and *P. cynocephalus* virus in competition assays for these polypeptides (data not shown).

To substantiate further the presence of two distinct viruses, HL23 virus preparations from canine thymus cells were mixed in separate tubes with neutralising antibody specific for baboon and woolly monkey virus and the mixtures added to human (RD) cells. At 3 weeks, cultures infected with HL23 virus plus anti-baboon serum contained only woolly monkey virus p30 and those infected with HL23 virus plus anti-woolly serum contained only baboon virus p30. It was also observed that passage of virus from diluted supernatant fluids readily selected for the woolly monkey virus component as might be expected from the severalfold excess of woolly virus proteins in the mixture.

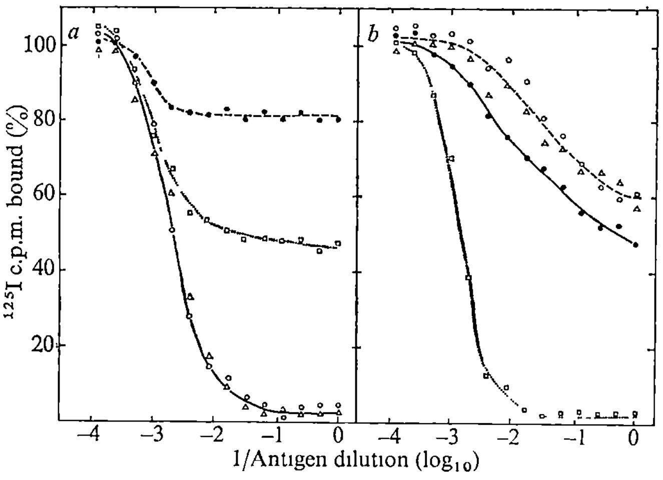

Fig. 2 Analysis of the HL23V virus in competition immunoassays for woolly monkey and gibbon ape virus p12 polypeptides[3]. Viruses were disrupted by incubation at 37 °C for 30 min in 1% Triton and were tested at serial twofold dilutions for ability to compete with ^{125}I-labelled p12 for binding limiting amounts of antiserum. Reaction mixtures contained 0.01 M Tris, 0.1 M NaCl, 0.15 M EDTA, 0.1% Triton X-100, and 1% bovine serum albumin (*p*H 7.8) in a volume of 0.7 ml Antiserum and unlabelled competing antigen were incubated at 37 °C for 1 h; ^{125}I-labelled antigen was added, and the incubation continued for 3 h at 37 °C and a further 18 h at 4° C. After addition of 0.025 ml undiluted swine anti-goat IgG to each tube, the mixture was incubated for 3 h at 4° C, centrifuged at 2,500 r.p.m. for 15 min and the resulting precipitate measured for radioactivity. Viruses tested included the woolly monkey virus[10] (○), SFMC gibbon ape virus[11] (□), SEATO gibbon ape virus[12] (●), and the HL23V virus[1,2] (△). *a*, Competition immunoassay using antiserum against woolly monkey virus to precipitate ^{125}I-labelled woolly monkey virus p12; *b*, competition immunoassay using antiserum against SFMC gibbon ape virus to precipitate gibbon ape virus p12.

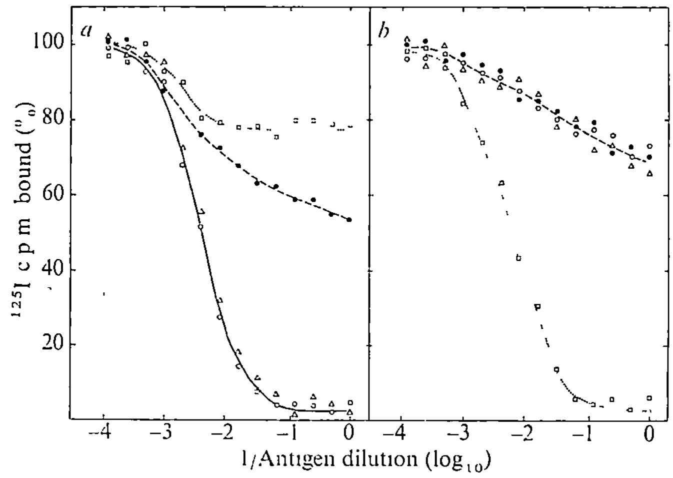

Fig. 3 Analysis of HL23V virus in competition immunoassays for the baboon virus and RD114 p15 (ref 5). Viruses were assayed as described in the legend to Fig. 2 and included the *P cynocephalus*[14] (○) and *P. hamadryas*[15] (●) baboon viruses; RD114[13] (□); and the AS virus[1,2] (△) *a*, Competition immunoassay using an antiserum against *P. cynocephalus* baboon virus to precipitate ^{125}I-labelled *P. cynocephalus* baboon virus p15; *b*, competition immunoassay using an antiserum against RD114 to precipitate ^{125}I-labelled RD114 p15.

The present studies thus show that HL23 virus preparations contain two distinct viruses; one indistinguishable from the woolly monkey virus, the second indistinguishable from an endogenous virus of the baboon species, *Papio cynocephalus*.

These data pose critical questions concerning the origin of the HL23 viruses. The high degree of relatedness to two known viruses constitutes argument for accidental contamination, yet other data (refs 1, 2 and refs quoted therein) have suggested the possibility of direct origin of the viruses from fresh cells of the patient. The important question is that of the relationship of these viruses to human disease, an issue which is under active investigation in several laboratories.

Characterisation of a virus (HL23V) isolated from cultured acute myelogenous leukaemic cells

THE isolation of a type C RNA tumour virus (HL23V) from cultured human acute myelogenous leukaemia peripheral blood leukocytes has recently been reported[1,2]. The reverse transcriptase of this putative human oncornavirus was found[1] to be immunologically related to the reverse transcriptase of the simian sarcoma virus, type 1 (SSV-1), the gibbon ape lymphoma virus (GALV), and to a small extent in secondary culture, RD114 (ref. 2). The spontaneously released virus was shown to be infectious for several cell cultures, including a human rhabdomyosarcoma cell line, A204 (ref. 2). This culture produced virus in sufficient quantities to permit biochemical studies. Here we describe the characterisation of the virus(es) grown in this culture. We find that the particles produced by the A204 culture infected with HL23V are a mixture of two viruses that are indistinguishable immunologically and in nucleotide sequence from two known non-human primate viruses, the baboon endogenous virus (BV-M7)[3,4] and the woolly monkey virus (SSV-1)[5].

Our findings complement those reported by Okabe *et al.*[6] elsewhere in this issue. These investigators looked for similarities with known oncornaviruses by molecular hybridisation with the cytoplasmic RNA from various cell lines infected with HL23V and by antigenic analysis using the type-specific p12 and p15 antigens. Our investigation emphasised molecular hybridisations with the RNA found in the particles released into the supernatant by A204(HL23V) and our antigenic analysis focused on the major structural antigens (p30 and gp45 of SSV and the p28 of BV-M7).

The A204(HL23V) culture produced high titres of particles that were found by ^{3}H-uridine labelling to possess a characteristic oncornavirus buoyant density of 1.16 g ml^{-1}. Simultaneous detection[7] assay of the culture supernatants demonstrated that the particles encapsulated 70S RNA and reverse transcriptase. The ^{3}H-DNA synthesised in simultaneous detection reactions and sedimenting as 70S complementary DNA (cDNA)–RNA complexes served as the source of the cDNA probe used in all the hybridisation experiments described here.

The reverse transcriptase from A204(HL23V) culture supernatants was examined for relatedness to the SSV enzyme. In contrast to the report of Gallagher and Gallo[1] (which indicated greater relatedness) but in agreement with Teich *et al.*[2], the results demonstrated (data not shown) that antisera prepared against the SSV reverse transcriptase was capable of inactivating the reverse transcriptase activity of HL23V particles only to about 60%. This partial inhibition of enzyme activity suggested the presence of a second virus containing an antigenically unrelated enzyme. To identify the unknown component in the HL23V particles, a search was instituted among known animal oncornaviruses using both immunological and molecular hybridisation techniques. The possibilities were quickly narrowed to the RD114/CCC baboon endogenous virus group.

Figure 1*a* and *b* shows hydroxyapatite temperature gradient elution profiles of viral cDNAs prepared from SSV and BV-M7 annealed to total RNA from HL23V particles. The extent of hybridisation and the thermal stability indicate that the HL23V particles contain the complete information of both the simian sarcoma virus (SSV) and the baboon endogenous virus isolated from *Papio cynocephalus* (BV-M7).

To determine whether all of the genetic information of HL23V can be accounted for by these two viruses, the reciprocal hybridisations were performed. In these experi-

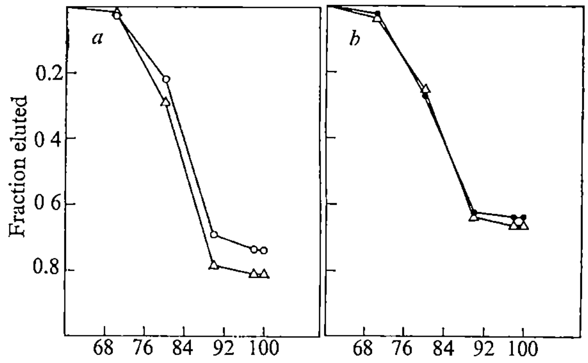

Fig 1 Hybridisation of ^{3}H-DNA transcripts of SSV-1 (*a*) and BV (M7 isolate) (*b*) to HL23V viral RNA. SSV-1 and BV were obtained from Pfizer, Inc. and were derived from sucrose density gradient-banded tissue-culture supernatants of a chronically infected human lymphoblastoid cell line (NC-37) and baboon kidney–canine thymus coculture (BKCT), respectively. HL23V virus was prepared from high speed pellets of 2-d-old media from HL23V-infected human rhabdomyosarcoma cell cultures ^{3}H-DNA probes for each of the viruses were isolated from the 60–70S RNA–DNA hybrids of standard large scale simultaneous detection assays. Hybridisation reactions were set up between the various probes (500–1,000 c.p.m. per assay) and viral RNAs (0.2–1.0 μg) in 20-μl volumes in sealed siliconised glass tubes in 0.8 M phosphate buffer (pH 6 8) 0.1% SDS and 10 mM EDTA. After heating at 100 °C for 1 min, the reactions were incubated at 68 °C for 20 h ($C_{r0}t > 2$). The reactions were analysed by thermal elution hydroxyapatite chromatography. Fractions of the total radioactivity eluted above 60 °C were plotted as a function of temperature. ○, SSV-1 RNA; ●, BV RNA; △, HL23V RNA.

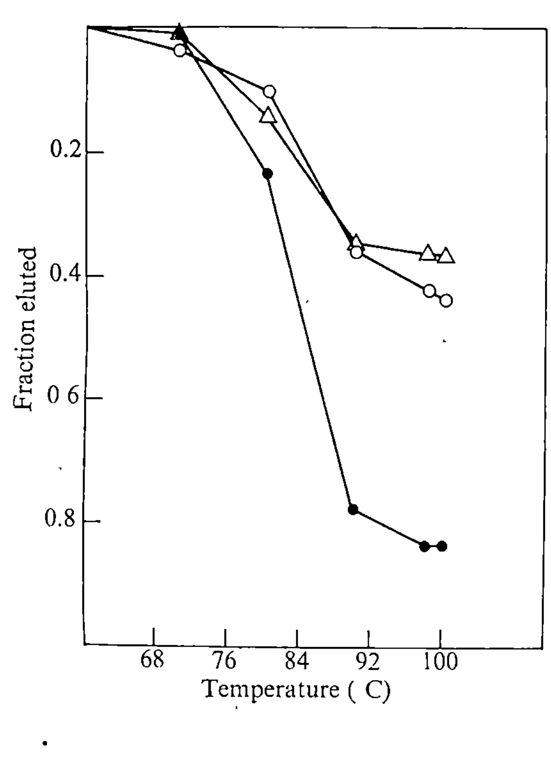
Table 1 Analysis of HL-23 for SSV genomic content by competition hybridisation

Competing RNA	Competing RNA ^{125}I-SSV RNA	Resistance of ^{125}I-SSV RNA %
None	—	72
SSV-1	1,500	3
GALV	1,200	15
MuLV-R	1,800	75
Mouse 18S+20S	450	74
HL-23	2,300	6

Hybridisation reactions (5.5 μl) were performed as described in Fig. 2 and contained 0 11 ng ^{125}I-SSV RNA (1.2×10^8 c.p.m. μg^{-1}), 0.68 ng ^{3}H-SSV cDNA (2×10^3 c p.m. μg^{-1}) and 0.5–0.25 μg of the indicated competing RNA. Following incubation at 68 °C for 48 h, the reactions were diluted with 0.01 M Tris-HCl (*p*H 8.0) 0.4 M NaCl, 0.01 M EDTA and divided into four equal aliquots. RNase A (25 U ml^{-1}) and RNase T$_1$ (5 U ml^{-1}) were added to two aliquots and the samples incubated at 37 °C for 1 h. Nuclease resistance was the ratio of acid-precipitable ^{125}I in the samples with and without ribonuclease. Recovery of input acid-precipitable ^{125}I was greater than 90%. SSV RNA was iodinated by the procedure of Commerford[8] as modified by Tereba and McCarthy[9]. SSV RNA was isolated from virions by disruption with SDS, Pronase treatment, rate sedimentation in a sucrose–SDS gradient and equilibrium density gradient centrifugation in potassium iodide. Viral RNAs from GaLV and MuLV-R were isolated by similar procedures excepting the KI gradient. HL23 VRNA was total RNA from purified virus and the mouse 18S and 20S RNAs were extracted from purified ribosomal subunits from NIH/3T3 tissue culture cells. ^{3}H-SSV cDNA was synthesised from SSV RNA and oligo(dT) with AMV DNA polymerase in the presence of 0.1 mg μl^{-1} actinomycin D and 0.5 mg ml^{-1} distamycin A. The reaction contained TTP, dATP and dGTP at 1 mM each and ^{3}H-dCTP (25 Ci mmol^{-1}) at 0.05 mM This SSV cDNA protected ^{125}I-SSV RNA 33%, 75% and 87% from ribonuclease digestion at molar input ratios of 0.4, 3 and 15, respectively (cDNA–RNA).

ments, cDNA probe was synthesised with HL23V particles and was annealed to RNAs from SSV-1 or BV-M7 or both. Figure 2 shows that the HL23V cDNA hybridised 37% and 44% to the BV-M7 and SSV-1, respectively. These individual hybridisations were additive as demonstrated by the complete complexing of HL23V cDNA to a mixture of BV-M7 and SSV-1 viral RNAs. These data indicate that the genetic information of HL23V virions is accounted for, within the limits of the sensitivity of the molecular hybridisation techniques used. It would seem that the HL23V genetic information contains the genomes of both SSV-1 and the BV-M7.

Fig. 2 Reconstruction hybridisations HL-23 ^{3}H-DNA probe was hybridised to SSV and BV RNAs individually and in combination. ○, SSV RNA; △, BV RNA; ●, SSV and BV RNAs.



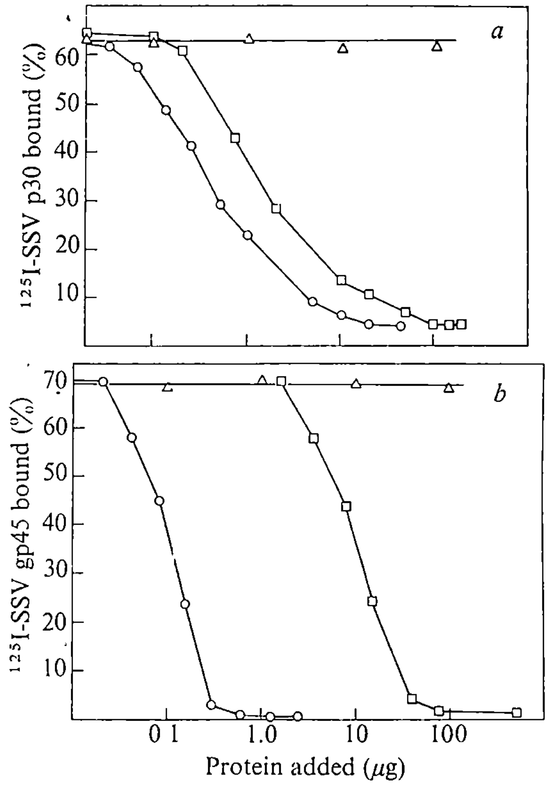


Fig. 3 Competition radioimmunoassays. HL23V virus was assayed for the presence of proteins antigenically related to the p30 (*a*) and gp45 (*b*) of NC-37 grown SSV-1. Antisera used for the studies with SSV-p30 were prepared by immunising rabbits with the purified p30. An NC-37 absorbed rabbit antiserum prepared by inoculation of disrupted virus and used for the studies with SSV-gp45 was kindly supplied by Dr D. Larson (Pfizer, Maywood, New Jersey). The p30 protein of SSV-1 was purified from sonicated virus, followed by phosphocellulose and Sephadex G75 column chromatography and isoelectric focusing It was iodinated and repurified as described by Hunter[18]. The iodinated p30 antigen preparations obtained had specific activities of 6×10^6 c.p.m. μg^{-1}. The gp45 protein of NC-37 grown SSV was purified from sonic-disrupted virus by column chromatography on Agarose 5M guanidium hydrochloride Analysis of the preparations by 5% sodium dodecyl sulphate polyacrylamide gel electrophoresis and isoelectric focusing indicated homogeneity of the 45,000-dalton antigen. The viral protein was labelled by the procedure of Bolton and Hunter[19]. Succinimidyl-(3-4-hydroxphenyl) proportionate (ICN Pharmaceuticals, Inc.) was first labelled with ^{125}I and purified. The purified gp45 was then labelled by conjugation with the ^{125}I-labelled ester and chromatographed on a Sephadex G-25 column. Titrations of the antisera were performed in 200-μl reactions that included 0.2% bovine serum albumin (BSA) in saline, 5,000 c.p.m. of ^{125}I-antigen and dilutions of antibody. After 1 h incubation at 37 °C, 100 μg of normal rabbit carrier IgG and a titred amount of goat anti-rabbit IgG were added. The reaction was incubated for 15 h at 4 °C. The samples were centrifuged and both precipitates and supernatants were counted in a Searle Autogamma counter model 1185. The results are expressed as percentage c.p.m. precipitated. More than 80% of the labelled antigen could be bound by specific antisera. Competition assays were performed in a similar manner, except that unlabelled competing antigen was added to the original incubation mixture. The unlabelled competing antigens were SSV (○); HL-23 (□); SSV-gp45 (●) and MPMV (△)

To supplement and confirm these findings by an independent method, competition molecular hybridisations were performed using cDNA synthesised from SSV. Viral 70S

RNA from SSV was radiolabelled with ^{125}I. SSV cDNA can protect this ^{125}I-SSV RNA more than 79% from ribonuclease digestion at molar input ratios of 5 : 1 (cDNA–RNA). Table 1 shows that when cold viral and other RNAs were added in vast excess to complete this homologous reaction, both SSV and HL23V RNA rendered the ^{125}I-SSV completely digestible. The GALV-1 competed less successfully, illustrating the sensitivity of this technique for detecting the small sequence differences known to exist between GALV and SSV.

HL23V was further tested for its immunological similarity to SSV and BV-M7. Virus was concentrated by ultracentrifugation from culture supernatants of A204(HL23V) and used as competing antigens in radioimmunoassays for the p30 and gp45 of NC-37 grown SSV. As shown in Fig. 3, the slope and extent of competition of HL23V in both of these radioimmunoassays were indistinguishable from SSV. Immunodiffusion analysis of HL23V with antisera prepared against the major internal structural proteins of the woolly monkey (p30) and baboon viruses (p28) demonstrated lines of identity with BV-M7 and SSV-1 indicating that, by these immunological criteria, HL23V is indistinguishable from a mixture of these two agents.

The association of SSV or BV with human material is not confined to the one patient from which HL23V was presumably derived. Four groups have now reported the isolation of agents related to SSV[1,10–12] from a variety of normal and neoplastic human tissues Further, in 7 out of 40 cases of acute myelogenous leukaemia, where a decision could be made, an enzyme was found[13,14] that was neutralised by anti-SSV reverse transcriptase. Fresh[15] or short term cultures[16] of human leukaemic cells have been shown to contain particles capable of generating cDNA having significant homology to SSV. Sherr and Todaro[17] have reported that two human tumours of 33 examined by radioimmunoassay demonstrated BV-M7 p28. The repeated encounters with SSV or BV-related material in human samples suggest that these viruses may be more widespread in the human population than had been suspected.

The fact that the HL23V particles have been identified as known animal viruses does not of itself eliminate them as candidate aetiological agents of the human disease. At the same time, it must be accepted that the identification of unknown tissue culture viruses with known laboratory agents raises the obvious possibility that they arose by contamination.

The key question is of course the relationship of the HL23V particles to human leukaemia. A resolution of this issue with respect to any candidate human tumour virus growing in culture requires answers to the following two questions: (1) Can one provide evidence at the level of protein and/or nucleotide sequence for the presence of the putative agent in the original tumour material from which the tissue culture was established? (2) Can one provide evidence at the level of protein and/or nucleotide sequence for the presence of the putative agent in the tumour cells of other patients with the same disease? Finding evidence for the particles in the original tumour cells would serve to eliminate the trivial explanation that they arose in the culture through laboratory contamination. The answer to the second question will decide the general relevance of the observation to human leukaemia. Unless a positive response is obtained in a large proportion of the patients examined, no basis exists for identifying the HL23V particles as clinically significant aetiological agents of human leukaemia.

We thank Drs J. Gruber and D. Howell for viral and immunological reagents, Dr R. Wilsnak for anti-SSV reverse transcriptase and anti-BV p28, and T. Mederios, B. Hills, B. Ma, P. Moy, I. Doneva and K. Tirk for technical assistance.

Construction of a P plasmid carrying nitrogen fixation genes from *Klebsiella pneumoniae*

THE wide host range of plasmids of the P-incompatibility class[1,2] has attracted interest in this group of R factors. A 3×10^6-dalton sequence which includes the TEM β-lactamase gene found on some plasmids of this group can integrate into the *Escherichia coli* chromosome[3] and into plasmids of other compatibility groups[1,4,5]. This translocatable sequence has been termed transposon A (TnA)[4,6] and resembles the insertion sequences (IS) of *E. coli*, in that TnA insertions can result in gene inactivation, giving rise to strong polar mutations[7].

We have described[8] the construction of an F-prime factor, FN68, carrying the nitrogen fixation (*nif*) and *his* region of the *Klebsiella pneumoniae* chromosome; other chromosomal markers detected on this plasmid include *met*G, *gnd* and *shi*A, though it is uncertain whether these determinants originated from *Klebsiella* or from *E. coli*. FN68 carries a TnA sequence which was translocated from R68, a plasmid of the P-incompatibility group. We have observed that FN68 can interact with the P plasmid RP4, which also possesses the TnA sequence, resulting in the formation of a recombinant molecule which retains P-incompatibility properties and carries the *nif his* region of the *K. pneumoniae* chromosome.

The P-group R factor RP4, which determines resistance to kanamycin (Km^R), tetracycline (Tc^R) and carbenicillin (Carb^R) was introduced into an *E. coli* K12 strain SB1801, carrying FN68. The resultant strain SB1801 (RP4) (FN68) was mated in broth with a His$^-$ recipient *E. coli* UNF502 (Table 1, Experiment 1). F-prime transfer (selection for *his*) occurred at a higher frequency than R-factor transfer (selection for Km^R) but cotransfer of both markers was not infrequent. Ten of the

Table 1 Transfer properties of *nif* plasmids in *E. coli* K12 strains

4	JC5466 (RP41)	SB1801	Km^R	B	2×10^{-3}	10/10 Carb^{R}Tc^{R}His$^+$Nif$^+$
			His$^+$	B	2×10^{-3}	10/10 Carb^{R}Tc^{R}Km^{R}Nif$^+$

Donors in broth matings (B) were late log-phase cultures grown in nutrient broth with slow shaking at 37 °C and contained about 2×10^8 bacteria per ml. Recipients were grown overnight in nutrient broth without shaking. For agar surface matings (S), 0.1 ml of a late-log donor culture was mixed with 0.1 ml of a late-log recipient culture and the mixture plated on nutrient agar for 6 h at 37 °C. Bacteria were scraped off the surface of the plates, resuspended in saline phosphate buffer and plated on selective media. Transfer frequencies were calculated relative to the number of donors in the mating mixture at the time of plating on selective media. Transfer frequencies determined for surface matings can only be approximate since differential growth of donor and recipient occurred during the prolonged incubation of mating mixtures on agar medium. *E. coli* K12 strains were:

SB1801, *his*-750 (deletion covering *his gnd* RHA-2A) *str*^{R} λ^R *ara*$^-$ *gal*$^-$ *mal*A$^-$ *xyl*$^-$ m*tl*$^-$ (λ$^-$);
AB2463, *thi*$^-$ *arg*$^-$ *his*-4 *pro*$^-$ *thr*$^-$ *leu*$^-$ *str*^{R} *rec*A13 *lac*$^-$ *gal*$^-$ *ara*$^-$ *xyl*$^-$ *mtl*$^-$;
UNF502, *thi*$^-$ *arg*$^-$ *his*-4 *pro*$^-$ *thr*$^-$ *leu*$^-$ *str*^{R} *lac*$^-$ *gal*$^-$ *ara*$^-$ *xyl*$^-$ *mtl*$^-$ *nal*^{R};
JC5466, *trp*$^-$ *rec*A56 *his*$^-$ *spc*^{R}.

Plasmids were:
FN68, F-incompatibility group F′ *met*G$^+$ *gnd*$^+$ *his*$^+$ *nif*$^+$ *shi*A$^+$;
RP4, P-incompatibility group Km^R Carb^R Tc^R;
RP41, recombinant plasmid described in the text.

Km^R, Resistance to kanamycin sulphate, 30 μg ml^{-1}, Tc^R, resistance to tetracycline-HCl, 15 μg ml^{-1}; Carb^R, resistance to carbenicillin (Beechams), 200 μg ml^{-1}.

twenty His$^+$ Km^R exconjugants obtained were Carb^R Tc^R Nif$^+$ and sensitive to P-specific phage PRR1, but had lost sensitivity to F-specific phage MS2. Several of these clones cotransferred *his nif* and Km^R to the *E. coli rec*A strain JC5466. One derivative of JC5466 was studied in detail; it contained a plasmid designated RP41 which cotransferred Km^{R}Carb^{R}Tc^R *his* and *nif* at high frequency in matings carried out on an agar surface (Table 1, Experiments 2 and 3) but at low frequency in broth matings (Table 1, Experiment 4). Such differences between surface and liquid matings are characteristic of P plasmids[8].

RP41 did not coexist with the P-group plasmid, R751; when selection was made for trimethoprim resistance (a marker on R751), 35 exconjugants tested were His$^-$ Nif$^-$ and sensitive to tetracycline, kanamycin and carbenicillin (Table 2, Experiment 3). RP41 and the F-prime factor F′Cm, however, coexisted stably (Table 2, Experiments 4 and 5). These results suggest that RP41 has P-group incompatibility and does not retain the incompatibility properties of F. RP41 was stable in the *E. coli rec*A host JC5466 and no loss of *his nif* or drug resistance was detected after 15 generations in nutrient broth.

The nitrogenase activity of JC5466 (RP41) as measured by acetylene reduction *in vivo*[8] was 60 mol ethylene per mg protein per min, compared with 63 mol ethylene per mg protein per min for *K. pneumoniae* strain HF3 which has chromosomally located *nif* genes; both strains having been assayed in identical conditions. The host strain JC5466 did not reduce acetylene. In addition to *his* and *nif* genes, RP41 also probably carries a determinant for gluconate-6-phosphate dehydrogenase (*gnd*) since a *gnd* deletion strain *E. coli* SB1801 gave a positive reaction in the colorimetric assay for this enzyme[9] when RP41 was present. When RP41 was transferred to AB 2880, a His$^-$ShiA$^-$AroD$^-$ recipient, His$^+$ exconjugants inherited *shi*A, a marker located close to *his*, but not *aro*D. In contrast to the F′*nif*, FN68, RP41 does not carry *met*G, since cotransfer of this determinant with *his* was not detected in a cross with a His$^-$ MetG$^-$ derivative of *E. coli* C, and 30 His$^+$ exconjugants derived from this cross did not grow in the absence of methionine. RP41 thus carries the determinants *gnd his nif shi*A derived from FN68, but lacks *met*G.

Covalently closed-circular (CCC) DNA isolated from *E. coli* strain J62-1 carrying RP41 sedimented at 72S in neutral sucrose and 171S in alkaline sucrose gradients (Fig. 1) corresponding to a molecular weight of 59×10^6.

RP41 was transferable from *E. coli* to *K. pneumoniae* at high frequency. When the recipient was *K. pneumoniae* Kp52, a *nif his* deletion strain, no segregation of plasmid markers was detectable (Table 3, Experiment 1). Drug resistance, *his* and *nif* were cotransferred from *K. pneumoniae* Kp52 (RP41) to *E. coli* at high frequency (Table 3, Experiment 2).

It was also possible to transfer RP41 to a His$^-$ derivative of the unrelated bacterium *Agrobacterium tumefaciens*; cotransfer of *his* and drug resistance was observed but 10 clones tested were Nif$^-$ and did not give acetylene reduction in either anaerobic or aerobic conditions (Table 3, Experiment 3). Crude extracts of one of the His$^+$ exconjugants grown with low aeration in nitrogen-free medium containing aspartate (100 μg ml^{-1}), however, produced material which cross reacted antigenically (CRM) with antiserum prepared against purified *K. pneumoniae* nitrogenase molybdoprotein. No CRM was detected in extracts prepared from cultures grown on NH_4^+

Table 2 Compatibility properties of RP41

Exp. no.	Donor	Recipient	Selection	Transfer frequency	Exconjugant phenotype
1	J62-2 (R751)*	SB1801	Trim	>1

5	F′Cm†	SB1801 (RP41)	Cm	2×10^{-1}	36/36 Cm^R Carb^R His$^+$ Nif$^+$ Tc^R Km^R

Matings were carried out on an agar surface* or in broth† as described in the legend to Table 1. *E. coli* K12 strain: J62-2 *pro*$^-$ *his*$^-$ *trp*$^-$ *lac*$^-$ *spc*^{R}. Plasmids: F Cm, F prime factor, determines chloramphenicol resistance, (Cm^R) 30 μg ml^{-1}, R751, P-group plasmid, determines resistance to trimethoprim lactate (Trim), 50 μg ml^{-1}. All other bacterial strains, plasmids and symbols are as in Table 1.

as 1 mg $(NH_4)_2SO_4$ per ml, a nitrogen source which represses nitrogenase synthesis, in *Klebsiella*. When RP41 was transferred back to *E. coli*, several exconjugants were Nif$^+$, confirming that *K. pneumoniae nif* genes had been transferred to *Agrobacterium* (Table 3, Experiment 4).

Transfer of RP41 to *Rhizobium meliloti* occurred at low frequency and some segregation of plasmid markers was observed; only 2 out of 10 His$^+$ exconjugants were tetracycline resistant and only 12 of 20 Tc^R exconjugants were His$^+$ (Table 3, Experiment 5). RP41 was unstable in *R. meliloti;* a 48% segregation of *his* was observed after 3 subcultures in L broth. Ten His$^+$ and twenty Tc^R exconjugants did not reduce acetylene when tested in either aerobic or anaerobic conditions. A faint band of cross-reacting material for *Klebsiella* nitrogenase molybdoprotein was observed in extracts prepared from cultures grown on nitrogen-free medium containing aspartate but not from NH_4^+-repressed cultures. *Nif* genes were expressed when the plasmid was transferred back to *E. coli*, indicating that *K. pneumoniae nif* genes were present in *R. meliloti* (Table 3, Experiment 6).

Transfer of RP41 to *Pseudomonas aeruginosa* was not observed. Two *his*$^-$ strains known to accept RP4 (strains PA067 and PAT904) were tested by surface and liquid matings and no His$^+$ or Carb^R derivatives appeared.

Although the precise mechanism of the recombinational events described here remains obscure, it is probable that cointegration was promoted by insertion sequences associated with the β-lactamase genes present in both parent plasmids. We suggest that cointegration of FN68 and RP4 resulted in excision of a segment of FN68 DNA which included F sex factor genes and *met*G, by a process analogous to that shown for other plasmids formed *in vivo* by site-specific recombination[10]. RP41 may resemble a similar plasmid, RP1-*his* described by Olsen and Gonzalez[11]. Both plasmids show stable linkage of drug-resistance genes and *his* in *E. coli* but both plasmids dissociate in intergeneric matings.

A P plasmid carrying nitrogen fixation genes has many advantages over an F'*nif* factor for genetic studies of nitrogen fixation. It transfers at high frequency from *E. coli* to *K. pneumoniae* and retains transferrability in this host in contrast to the F'*nif* FN68 which is Tra$^-$ in *Klebsiella*[8]. Mutants of RP41 could therefore be useful for complementation analysis of the *K. pneumoniae nif* region. RP41 also has a wide host range and should be transmissible to many Gram-negative bacteria, although the failure to obtain transfer to *Pseudomonas aeruginosa* suggests that the host range has been modified.

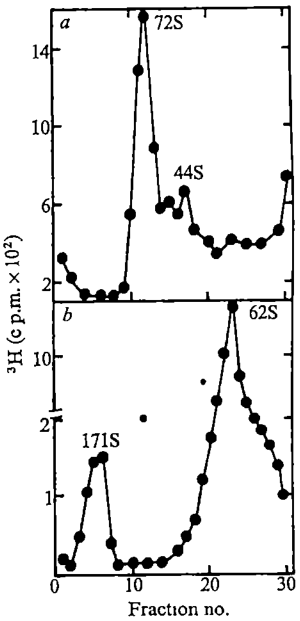

Fig. 1 Profiles of ^{3}H-labelled DNA from *E. coli* J62-1 (RP41) analysed by velocity centrifugation in neutral (*a*) and alkaline (*b*) 5 ml, 5–20% sucrose gradients. Supercoiled DNA, obtained from ethidium bromide–CsCl gradients[8], was dialysed against TES buffer (10 mM Tris-HCl, 1 mM Na_2EDTA, 100 mM NaCl *p*H 8.0). RP41 DNA (180 μl) was mixed with 20 μl of ^{14}C-labelled ColE1 DNA, layered on gradients and centrifuged for 60 min (*a*) and 33 min (*b*) at 120,000*g* at 20 °C in a 52 rotor using a Christ ωII ultracentrifuge. Gradients were fractionated by drop collection (7 drops per fraction) directly on to filter disks and TCA-precipitable label assayed for radioactivity.

The failure to express *K. pneumoniae nif* genes in *R. meliloti* is perhaps not surprising, since *R. meliloti* itself has *nif* genes which were not expressed in the conditions tested, but which are expressed in legume root nodules. It will be interesting to observe whether the *K. pneumoniae nif* system can be expressed in *R. meliloti* in symbiotic conditions or in the conditions developed for expression of nitrogenase in certain free-living rhizobia[12–16]. We did find CRM to antiserum to *Klebsiella* nitrogenase molybdoprotein in extracts of derepressed cultures

Expression of *Klebsiella* nitrogen fixation genes (*nif*) in *Azotobacter*

NITROGEN fixation mutants have been isolated and biochemically characterised in *Azotobacter vinelandii*[1], but the absence of chromosomal gene transfer systems such as conjugation in this genus has prevented a genetic analysis of such mutants. We now report the intergeneric transfer of *Klebsiella nif* genes carried on the P-type plasmid, RP41 (refs 2 and 3), to *Azotobacter*, and their expression in this host.

The *A. vinelandii nif* mutants lacked nitrogenase molybdoprotein (AvI) activity, iron protein (AvII) activity or were pleiotropically negative for both activities. Spontanenous derivatives resistant to 25 $\mu g\ ml^{-1}$ nalidixic acid were isolated before mating with an *Escherichia coli* K12 strain carrying the *nif* plasmid RP41. Matings were done on agar plates: cultures of donor *E. coli* grown at 37 °C in Oxoid nutrient broth and *A. vinelandii* recipients grown at 28 °C in Burk's sucrose medium[4] supplemented with 2 mg ml^{-1} ammonium acetate were grown to mid logarithmic phase and mixed in a 1 : 1 ratio; 0.1-ml portions of mixtures were spread on Oxoid nutrient agar plates and incubated overnight at 34 °C. Mating mixtures and parental azotobacter cultures were resuspended and diluted in sucrose-free Burk's medium[5] and spread on selective agar media: Burk's sucrose medium containing 25 $\mu g\ ml^{-1}$ nalidixic acid to select Nif^+ exconjugants and a similar medium with 2 mg ammonium acetate and 10 $\mu g\ ml^{-1}$ tetracycline when tetracycline-resistant exconjugants were sought. Selective plates were incubated at 28 °C; all incubations were in air.

Presumptive nitrogen-fixing exconjugants were tested for acetylene-reducing ability by transfer to 5 ml liquid Burk's sucrose medium in 25-ml conical flasks. After growth at 30 °C, the cotton wool plugs were replaced by Suba-seal rubber closures. 2 ml C_2H_2 was injected and gas samples were removed at intervals for gas chromatography on a Porapak N column with a flame ionisation detector. Activities were compared with that of wild-type *A. vinelandii* grown in similar conditions.

Among the markers carried by RP41 are *nif*, *his*, resistance to tetracycline (Tc), kanamycin (Km) and carbenicillin (Carb). The transfer frequencies of *nif* and Tc to *Azotobacter* mutants are shown in Table 1. In contrast to the situation in *Klebsiella* and *E. coli*, Nif^+ exconjugants could be selected directly on plates in air. Although the transfer frequencies were low, they were significantly higher than reversion frequencies. The low observed frequencies arose at least partially from the poor growth of *A. vinelandii* on the mating plates: $\sim 10^7$ *A. vinelandii* compared with $\sim 10^8$ *E. coli* ml^{-1} when resuspended at the end of the mating period.

Fifteen of the 83 Nif^+ exconjugants listed in Table 1, including representatives of all positive recipients, were tested for nitrogenase by the acetylene test and all showed activity between 40% and 50% of that of the wild type.

Table 1 shows that nitrogenase activity was restored to three mutants which lacked AvI and one which lacked AvII activity but not to the one strain examined (UW1) which

Table 1 Intergeneric transfer of plasmid RP41 from *E. coli* K12 to *A. vinelandii*

was pleiotropically negative for both component activities. The presence of RP41 *nif* genes in one of each class of Nif$^+$ exconjugants, UW91(RP41) and UW100(RP41), was confirmed by using these strains as donors and observing transfer of *his, nif* and drug resistance markers back to *E. coli* (Table 2). Some segregation of markers occurred in these matings: exconjugants selected directly for drug resistance were mainly His$^-$ and Nif$^-$ while all but one of the His$^+$ exconjugants were Nif$^+$ and drug resistant. Such segregation has been observed in other transfers involving *nif* plasmids[3,6].

Loss of RP41 *nif* genes ought to restore the Nif$^-$ phenotype in these exconjugants. One *Azotobacter* strain UW91 (RP41) was cultured in non-selective conditions and spontaneous loss of *nif* genes occurred: After 10 subcultures in Burk's medium supplemented with 2 mg ml^{-1} ammonium acetate, all clones among 52 tested were Nif$^-$ and 28, screened for drug resistance, were resistant to Tc, Km and Carb. These drug-resistance markers, which originated on RP4, the parent plasmid of RP41 (ref 2), were stable in *A. vinelandii.*

One *Azotobacter* strain, UW100(RP41) was examined for immunological evidence for the expression of *Klebsiella nif* structural genes. Crude extracts of this strain, grown in Burk's medium, contained material which cross reacted antigenetically with antiserum prepared against purified *K. pneumoniae* nitrogenase molybdoprotein (KpI). This antigen was absent from extracts of the parental strain, UW100, grown in ammonium-limited conditions (100 µg N (as ammonium acetate) ml^{-1} Burk's medium) Material cross reacting with antiserum to purified *Azotobacter* nitrogenase molybdoprotein (AvI) was, however, present in both extracts. When these strains were grown with excess NH_4^+ ion, no such cross-reacting materials were detected in extracts prepared similarly.

We conclude from these experiments that the Nif$^+$ *Azotobacter* exconjugants carried RP41 and expressed its *nif* genes, which originated in *Klebsiella pneumoniae* strain M5a1 (ref. 2). The ability of *Azotobacter* to transcribe and translate *Klebsiella nif* genes and, in contrast to *Agrobacterium*[3], actually to make use of their products has several important consequences:

(1) The regulatory apparatus, whereby ammonia repressed nitrogenase synthesis in parents and exconjugants, is common to *Klebsiella* and *Azotobacter,* even at a molecular level For example, if glutamine synthetase (GS) is accepted as a positive activator of *nif* genes[7-9], then *Azotobacter* GS can activate *Klebsiella nif* genes.

(2) *Klebsiella nif* genes normally function only in an anaerobic environment, yet transfer to the obligate aerobe *Azotobacter* permitted their expression in air. Clearly they must have shared the oxygen exclusion processes[10] of *Azotobacter.*

(3) The possibility arises that hybrid nitrogenases, such as the active mixtures of AcI+KpII or KpI+AcII which can be studied *in vitro*[11], are functioning *in vivo,* but comparable experiments with characterised mutants of RP41 would be necessary to establish this point conclusively.

RP41 is thus potentially useful for a genetic complementation analysis of *nif* mutants in *Azotobacter.* It could also be used for the isolation of selected mutants in *Azotobacter* by introducing RP41 with characterised *nif* mutations into *Azotobacter* and preparing homogenates.

We thank J. Bardzo and J. Simkins for assistance, Dr R. A. Dixon for criticism of the manuscript and Professor W. J. Brill for the *A. vinelandii nif* mutants.

Errata

In the article "Cell differentiation by 3′,5′-cyclic AMP in a lower plant" by A. K. Handa and M. M. Johri (*Nature,* **259**, 480; 1976) there is an error in Table 3. The entries under the heading 'Medium' should read . . . MM, MM+1% glucose, MM+1 µM IAA, MM+1% glucose . . . and not as printed.

In the paper "Dopamine-like renal and mesenteric vasodilation caused by apomorphine, 6-propylnorapomorphine and 2-amino-6,7-dihydroxy-1,2,3,4-tetrahydronaphthalene", by H. J. Crumley, R M. Pinder, W. B. Hinshaw and L. I. Goldberg (*Nature,* **259**, 584; 1976) Dr Pinder's address should be : . . . Birkenhead, Auckland, New Zealand.

Nature Index and Binders

The **Index** for 1975 is now available, price £2.25. Copies of the 1974 index are still on sale, price £3.00. **Binders** for the journal are also available at £2.30 each, £6.25 for three (a year of *Nature* fits into three binders).

Postage is included in the above prices. **Orders** should be sent, accompanied by remittance to Macmillan Journals Ltd, Brunel Road, Basingstoke, Hampshire, England.

Abracadabra: watch it come down

It is no surprise that 'big science', that is astronomy, space research, particle and nuclear physics, is in for a lean time in the next five years in the United Kingdom. News of shrinking budgets for big science has been coming out for a year or more, generally on occasions that a particular project has "with regret" had to be abandoned. The publication last week of the report for 1974–75 of the Advisory Board for the Research Councils (ABRC) (HMSO, Cmnd 6430, 50p) only serves to give the decision a degree of finality (see following article). Nevertheless, since it is the advisory board which is charged with advising the Secretary of State for Education and Science on his responsibilities for civil science and on the allocation of the Science Budget, and since the Secretary of State generally takes that advice, it is appropriate that we should ask, at the time the report appears, how the 'big science' decision was reached, and whether it is in accord with feelings among scientists in general.

Present annual spending in the Science Budget (that is, not by government departments) is £13 million on agricultural research, £29 million on medical research, £19 million on natural environmental research, £9 million on social science research and £96 million to the Science Research Council (SRC). Of this £96 million, £7 million goes on engineering, £24 million on astronomy, space and radio, £35 million on nuclear and high energy physics, £16 million on 'science' (mathematics, physics, chemistry, biology and so on) and the rest on student support and administration. In 1980 the total expenditure is expected to be at exactly the same level in real terms, but the SRC's operations will have shrunk nearly 10% while all the other council's operations will have grown by between 6 and 10%. Within the SRC, the nuclear physics board will have had to cut back its expenditure by roughly 25%, astronomy, space and radio by roughly 16%—others will be slightly up.

The figures are actually bleaker still for big science. There has been some criticism of the growth permitted to all other activities as Buggins' turn, but the ABRC is possibly right in its assessment that increased experimental sophistication and a preponderance of young researchers probably require such financial growth just to maintain existing capabilities. Thus 25% off nuclear physics is probably more than 30% off capabilities. Finally, two major subscriptions, to CERN and the European Space Agency, account for 40% of the present expenditure on big science. These may not be renegotiable; the sum total of all this could be nearly a halving of the SRC's discretionary activities in big science by 1980.

Why is big science to be cut so severely to maintain the *status quo* elsewhere? The ABRC concedes that in these scientific fields the UK has a high reputation, and it admits that prospects of advance are "particularly good". "On the other hand, the big sciences engage relatively small numbers of research workers . . . " This is an argument with strange echoes from the most recent Commons Select Committee report—too much is in the hands of too few. It is a depressingly bad one for the ABRC to be putting forward, suggesting that, for all the agonising, it is size that has been the criterion, not quality nor even (and this would have been easier to swallow) lack of obvious pay-offs to the taxpaying public.

The ABRC was nearly unanimous in its decision. What is surprising is that the composition of the ABRC should allow it to be such. Big science expenditure is a third of all the science budget yet amongst all the research council heads, chief scientists of government departments and civil servants and academics who served on the board when the decisions were being made, only one out of nineteen had had any first hand experience of big science. Even more surprising, although the board offers seats to departmental chief scientists whose contributions to the support of non-departmental research projects can be as small as a couple of million pounds, it cannot include the Chief Scientist, Ministry of Defence, whose ministry is spending £550 million this year on research and development, but which does not sponsor non-departmental research projects by the Rothschild method. Quite apart from the experiences of the present incumbent, Sir Hermann Bondi, which would have been particularly relevant to recent discussions, it does seem wrong that a ministry which recruits large numbers of graduates and PhDs, which runs the Meteorological Office, and which co-operates in all manner of ways with outside organisations should have no formal say in the shaping of the future of Britain's civil science.

It would obviously be foolish to expect a slavishly democratic ABRC in which every interest was represented proportionally; it is clearly much better that reliance should be placed on a body of people informed by non-partisan commonsense. But there are aspects of the decision on big science and the poorly articulated reasons behind it which should at least make us wonder whether we have yet got the ABRC exactly right. ●

Research on the rack?

Chris Sherwell looks at two government documents which do not bode well for Britain's research effort

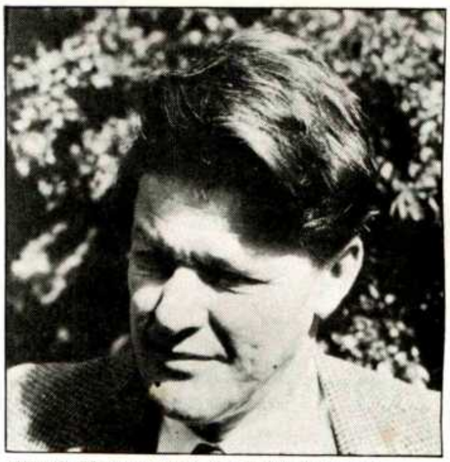
LAST WEEK, half-way between the publication three weeks previously of the Labour government's White Paper on Public Expenditure and its forthcoming revelations in the Budget, most of the country was being suitably distracted from the immediacy of its economic troubles by the resignation of Mr Harold Wilson, the Liberal Party's leadership problems and the state of Princess Margaret's marriage. Not so the scientific community. Two documents came out which directly affected its well-being. Neither can be said to contain any unexpected shocks, but the implications are that the fate of British scientific research may be hanging in the balance now more than ever: certainly the so-called "party is over" mentality has arrived.

The first document was the report of the Advisory Board for the Research Councils (ABRC)*. The report, the ABRC's second, covers the two years of its operation from the beginning of 1974 to the end of 1975; the first, published in June 1974, covered the year of its work following its formation in November 1972.

The ABRC's focus, understandably, is finance, for one of its main tasks is to advise (and its advice is usually accepted) the Minister of Education and Science, within whose departmental ambit it falls, on the allocation of the department's Science Budget. The allocation is principally amongst the Research Councils—that is, the Science Research Council (SRC), the Natural Environment Research Council (NERC), the Medical Research Council (MRC), the Agriculture Research Council (ARC) and the Social Science Research Council (SSRC)—the rest of the budget, amounting only to about 3%, is accounted for by the British Museum (Natural History) (NHM) and the Royal Society (RS).

It is through the Research Councils, which together with the University Grants Committee (UGC) constitute the "dual support system", that the government fulfils its strategic aim of maintaining a fundamental capacity for research in Britain. The Science Budget itself has grown in financial and in real terms over the last three financial years, and will do so again in the coming year (see Table 1). But for the SRC, whose share of that budget has increased up to a high point this year of more than 56%, a fall in that share is now indicated for the coming year, to 54.2%, and the expectation is for a fall to about 52% by 1980-81. More significantly, over the last two and the coming financial years, the SRC has experienced and will experience an absolute decline in real terms in the resources it receives. Annual percentage growth of 3.2% in 1973-74 gives way to negative real growth in succeeding years of 2.2%, 2.2% and, in 1976-77, 1.6%. It is a measure of the change that, in the seven years before 1973-74, growth was less than 3.2% only in 1969-70.

That change, moreover, is not regarded as a temporary phenomenon. The ABRC's guidelines regarding average annual percentage growth (also shown in Table 1) includes for the SRC a rate of −1.9% until 1980-81; and, for this year at least, the gap between the guidelines for the SRC and the other Councils will widen. As for the Science Budget as a whole, this is expected to remain at its present level up to 1980 apart from the 1.7% increase for the coming year, thus confirming both the gloomy prognosis of the White Paper on Public Expenditure and the previously indicated intentions of aiming for nil-growth.



ABRC Chairman Sir Frederick Stewart

The "keynote" of the ABRC's policy over the coming years, as its second report points out, was "redeployment away from big science (high energy nuclear physics and astronomy, space and radio sciences) to protect prospects for other natural sciences and social science" (see Figure 1). The consequence for the distribution of the SRC's resources within its own constituent parts is that nuclear physics and ASR (astronomy, space and radio) are the ones to suffer (see Figure 2). Thus, following the SRC's 1974 decision that it was unable to finance a major new £20-millions radio telescope at Jodrell Bank, and its 1975 decision (in light of the German decision approving Germany's PETRA accelerator project) that international finance would not be forthcoming for its proposed EPIC accelerator, it now looks as though existing big projects are in jeopardy. The most important is NIMROD, the 13-year-old 7000 MeV proton synchrotron at the SRC's Rutherford Laboratory, and a final decision is expected soon. A decision has already been taken regarding the closure of the NINA Synchrotron Radiation Facility.

**Second Report of the Advisory Board for the Research Councils* (HMSO, Cmnd. 6430).

Transferred funds are not included.

[1] SRC and NERC figures include an element of the costs of dispersal, not included in the Science Budget.

[2] Includes cost of buildings borne on Department of Environment Vote (1973–74, £0.9 million; 1974–75, £0.6 million).

Britain's position undermined?

All of which tends to reinforce the view that Britain's position in the "big science league" is likely to be undermined, which some may argue is a bad thing. The ABRC, however, has found itself obliged to take a somewhat different view. Aside from the government's own exhortation that cuts be made, and the fact that these are most readily achieved by axing the biggest and thus most expensive projects, two strands of thought appear to inform the ABRC's overall disposition regarding big science. The first is the general policy one described in its 1974 and 1975 reports: that, apart from the exigencies of overall redeployment, substantial priority also had to be accorded to the SRC's Engineering and Science Boards over the needs of big science, a priority reflected in Figure 2. In 1974-75, fully 60% of the SRC's budget went to big science, while only 11% and 15% respectively went to the Engineering and Science Boards. (Big science's 60% is equivalent to about 33% of the total Science Budget).

It was an imbalance the ABRC thought should be redressed, and one argument its Chairman, Sir Fred Stewart, voiced in justification, apart from the official one of maintaining a "general national scientific capability" overall, was that to support engineering, an activity central to Britain's economic performance, was to improve the chances of more resources for big science later when, with improved economic performance, those resources would be available. No assumptions about such a recovery are being made at the moment, however: the proportion of the total science budget going to big science is projected to fall rapidly from 33% to 27% in 1980-81.

The other important element in ABRC and SRC thinking is inescapable. The SRC faces certain crucial constraints on its capacity to redeploy its funds to the degree it might perhaps wish. These include important international commitments, to the European Space Agency, the European Science Foundation, CERN and so on. These commitments, as they stood last year, amounted to 26% of the SRC's expenditure—and were equivalent to 44% of the Nuclear Physics Board's funds and 24% of the ASR Board's. It is these sorts of commitments, of course, which must be considered in accounting for the sizeable shares going to big science, just as it is the often colossal cost of SRC projects as a whole which must be weighed in any judgments that are made about the majority share of funds which historically goes to the SRC rather than other Research Councils. Both of these factors, by their nature, must aggravate the impact on British science of the cuts now in store.

Other Research Councils are less harshly treated. The ABRC says it has decided to use extra funds made available by the increase for 1976-77 "in such a way as to reinforce the redeployment policy" it has adopted, bearing in mind that the increase was only a "temporary departure" from the nil-growth trend. It stresses that there is no modification in its policy of distributing resources secured from savings in big science roughly proportionately to the other Research Councils and to the Engineering and Science Boards of the SRC. As for maintaining the basic research "floor", which it endeavours to do through an improving co-ordination with the UGC, the ABRC says there is "likely to be a need for greater selectivity and concentration of resources on the part of the Research Councils".

White Paper on Defence

The trouble is, British scientific research is not starting to go through a particularly lean period just because of the reductions in funds available to big science, to the SRC, or even to the less badly hit ARC, MRC and NERC. A second document released last week, also in the wake of the Public Expenditure White Paper, is rather more difficult to interpret, but it tends to reinforce the pessimistic view. That document was the government's annual White Paper on Defence† It is worth remembering, if only for the sake of perspective, that the Department of Education and Science's Science Budget in 1975-76, for instance, accounted for only about 12½% of the total government expenditure on research and development—a level that has in fact tended to fall in recent years (it was closer to 17½% in 1971-72, for example). In 1975-76, when the Science Budget was around the £150 millions mark, government research and development spending in what is classified as "higher and further education" was approximately £116 millions, in "trade, industry and employment" it was about £246 millions—and in defence it was over £550 millions.

Not all of the figure ascribed to defence, of course, goes to pure research. A research and development figure of £702 millions in the latest White Paper compares with last year's forecast (at the same price level) of £669 millions and represents 12% of the overall defence budget of some £5,600 millions Of this £702 millions, £107 millions is forecast expenditure on research, while the rest goes to "development of approved systems"; of the £107 millions, about two-thirds, the White Paper says, relates to work, including exploratory development, in direct support of projects in the equipment programme. The remaining one third relates to longer term research. Another £22 millions is to be spent on research work "directed to civil objectives".

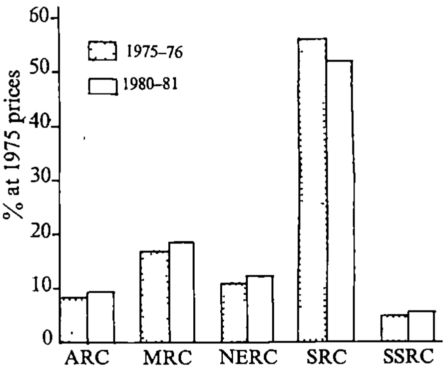

Fig. 1 Research Councils' percentage shares of the Science Budget 1975–76 and 1980–81, as reflected in in 1975 guidelines

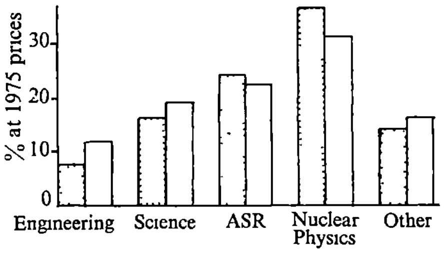

Fig. 2 SRC Boards' percentage shares of the SRC Budget 1975–76 and 1980–81, as reflected in SRC 1975 Forward Look.

The breakdown of the £702 millions is not very revealing: £258 millions is attached to military aircraft, £74 millions to guided weapons, £97 millions to "other electronics", £73 millions to ship construction and underwater warfare, £58 millions to "ordnance and other army", £139 millions to "other research and development"—and £3 millions to meteorological research and development. What is revealing, though, is the degree to which the overall cutbacks in defence are forcing the closure of research establishments attached to the ministry Economies in the Ministry of Defence's research programme, which is organised into 18 major fields (aerodynamics, electronics, armaments and so on) and is done in defence-related industries and university research laboratories as well as the ministry's own establishments, have forced the ministry not only to decide on the second stage of its rationalisation of its research and development programme but also to proceed with "and where practicable to accelerate" it.

---

†*Statement on the Defence Estimates 1976* (HMSO, Cmnd. 6432).

As a result, a number of sites will be closed "in due course", some "as soon as possible" but most within five to seven years. They include the Chemical Defence Establishment outstation at Nancekuke in Cornwall, reportedly associated with the development of nerve gas and CS riot gas; future levels of research and development on "defence against chemical and biological warfare", carried out at the parent Chemical Defence Establishment and the Microbiological Research Establishment (both at Porton), are to be reviewed "with the object of making significant economies". They also include the Admiralty's engineering, oil and materials laboratories, and one site of another of the Admiralty's laboratories, as well as a site of the Explosives Research and Development Establishment. In addition, there will be "a further cut on extramural research with industry and the universities where for the time being we shall have to sacrifice some of the longer-term work". Concentration of activities in the field of explosives will enable the work of closed sites to be carried out at the Atomic Weapons Research Establishment and the Royal Armament Research and Development Establishment. Other work will be concentrated as a result of the naval laboratory closures Redundancies are inevitable, and could amount to many hundreds.

The underlying aim of the rationalisation is to complete "the framework of a research and development organisation based on four main systems establishments—sea, land, air, and underwater—complemented and supported by a number of technology establishments". The aim, in other words, is similar to the comparable one in the civilian area which the Rothschild White Paper foreshadowed, namely, better and more efficient co-ordination of government-backed scientific research and development. While the cuts in defence appear to be encouraging the pace of such a rationalisation, though, the redeployment policy of the ABRC as implemented through the SRC is looking increasingly like an issue separable from the other main focus of the ABRC report, the more universal application of the "customer-contractor principle".

"Customer-contractor principle"

Government departments which act as regular "customers" for Councils to which they "contract" research are represented on both the relevant Councils themselves and the ABRC through the comparatively recent institutions of their own Chief Scientific Advisers (CSA). The "customer-contractor principle", outlined by Rothschild in respect of research and development conducted in accordance with objectives formulated by the departments themselves, has already been in operation for some time within the Ministry of Defence through its CSA; its contractor is the Procurement Executive. The principle should have been implemented within three years (that is, by next week) by certain other departments: thus, some of the funds previously lying with the ARC, MRC and the NERC (contractors) should by now have been transferred to their respective customer departments for the departments' own use, which could perhaps be outside the Councils through private research establishments.

The ABRC report is not discouraging about progress in this respect, at least regarding the ARC and MRC But it acknowledges the complexity of the case of the NERC and its customers, which stems from the sheer diversity of its activity: "There will continue to be some difficulties", the report says, "to which the Council and probably the Board itself will need to give careful thought" But while the ABRC recognises these matters, it studiously avoids the related question of co-ordination amongst the CSAs themselves. That co-ordination, such as it is, is currently pursued largely through the ABRC itself, for at the moment there is no CSA for the government as a whole: the last one, Sir Allan Cottrell, has not been replaced, and the presence on the ABRC of Sir Keith Berrill, head of the Central Policy Review Staff which advises the Cabinet on strategy, was affirmed as being in his personal capacity only.

These issues are not likely to disappear. But for the moment the main questions surround the government's financing of British scientific research. The country's research effort, while not a party issue, is a political issue insofar as it has to be resolved at the political level. At the moment, however, it manifests itself to the scientific community only as a matter to be rather mechanically resolved at Research Council and ABRC level; and is largely a question of slicing up a financial pie whose size is fixed by Treasury *diktat* Not only is the size of the pie itself not a major object of contention; the manner in which it is sliced was, as Sir Fred Stewart vigorously insisted last week, the product of consensus. The degree to which the claims of participants in the various branches of scientific research are recognised is unclear, but, in the case of the budget handled by the SRC, it is not obvious that its size, both absolutely and in relation to the other Councils, is an issue thoroughly discussed any lower than the SRC itself.

Thus, whether or not it is true, as the House of Commons Select Committee on Science and Technology recently argued, that SRC funds are directed largely at the behest of a small charmed circle of scientists, it seems clear that that alleged circle may now be losing (if indeed it is conducting) any fight to preserve the share of total funds it has quietly thought itself entitled to in the past. The difficulty, of course, is that in a new nil-growth era, when even the country's defence effort is under scrutiny, Britain's scientists as a whole, like the rest of the country, will over the next few years be losing as well. □

USSR

Broom at the top

Following the disasters of Soviet agriculture during the last Five-year Plan, the USSR Minister of Agriculture Dmitrii Polyanskii has been relieved of his post. Polyanskii was not re-elected to the Politburo at the end of the recent Twenty-Fifth Party Congress, when his Ministry faced sharp criticism, notably from Aleksandr Lyashko, the Prime Minister of the Ukrainian SSR; he did, however, retain his seat on the Central Committee of the Party. Now his dismissal as scape-goat for his Ministry appears to be a tacit acknowledgement that the criticisms were well-founded, and that more than "abnormal weather conditions" were responsible for the agricultural short-fall

The new Minister of Agriculture, Valentin K. Mesyats, is a graduate of the Moscow Agriculture Institute. From 1965–1971, he was Minister of Agriculture of the Russian SFSR. Since then he has held the post of Second Secretary of the Communist Party of Kazakhstan (one of the Republics most involved in the Virgin Lands scheme) He is a Member of the Central Committee, but not a member of the Politburo.

Two newcomers to the Politburo fill the places left by the departure of Polyanskii and the 80-year-old Anastas Mikoyan. They include Dmitrii Ustinov, who has for some 10 years been closely connected with the Soviet's armaments programme, including nuclear arms and missiles. This appointment gives two seats on the 16-man Politburo to military interests—the other being held by Minister of Defence Marshal Andrei Grechko.

Vera Rich

Siting the sun set

In the United States, the Energy Research and Development Administration (ERDA) has faced numerous complications over its solar energy plans. And, as Colin Norman reports from Washington, problems remain

IT HAS been several years since a major political scrap broke out in the United States over the location of a major new research facility, for the good reason that there haven't been many new facilities established recently. But in the next few months every state is expected to compete for a scientific prize—a Solar Energy Research Institute, to be established by the Energy Research and Development Administration (ERDA).

The location of the institute won't be the only source of dispute, however, for last week ERDA announced plans for the facility which suggest that it will be a much more modest enterprise than many of its proponents had envisaged.

Plans for the institute have been through a long, and difficult, gestation period. Approved by Congress as part of a bill passed in November 1974, the institute, known by its acronym SERI, was expected to be a major national laboratory for planning and carrying out government research on solar energy. Congress left ERDA to decide exactly what the role and scope of SERI should be, and it also asked the National Academy of Sciences to assist ERDA in the planning.

When the bill was approved, it was generally assumed by SERI's congressional sponsors that the institute would rapidly evolve into the focal point for the government's solar energy programme, and that it would develop into a major facility along the lines of ERDA's nuclear laboratories such as Oak Ridge or Los Alamos. And that assumption was reinforced by the Academy, which last October recommended that SERI should be provided with a budget of about $50 million and a staff of 630 by 1980.

Modest effort

ERDA officials also hoped to get moving quickly on a large facility but, following a series of disputes with the White House culminating in the resignation of a senior ERDA administrator, the agency last week announced plans for a much more modest effort. The plans, set out in a formal invitation for public and private institutions to bid for a contract to establish SERI, envisage a modest beginning over the next three years, with no absolute guarantee that the institute will ever develop into ERDA's leading solar energy laboratory.

ERDA, in short, has asked for proposals to establish a solar energy management and research team at an existing institution, with a budget of between $4 and $6 million for the first year, rising to $10–20 million in the third year. In addition, ERDA has asked the bidders to propose a nearby site for a larger, separate facility into which SERI could move at a later date if necessary. The idea is to provide for deliberate, phased growth possibly—though not definitely—to a major national laboratory in the early 1980s.

Under ERDA's direction, SERI will provide analysis and planning for research and development programmes on solar energy, ranging from direct use of sunlight for heating and cooling buildings to electricity generation, wind power, and bioconversion. In addition, SERI will perform some research and development itself. Dr Robert Hirsch, acting assistant ERDA administrator for solar, geothermal and advanced energy, said last week that he expects a contractor and location to be chosen in December, and that SERI will begin operations on January 1, 1977 A decision on whether or not SERI will move to a large, permanent site is expected in two or three years, he added.

Cautious approach

ERDA arrived at that pared down proposal after the White House Office of Management and Budget (OMB) had vetoed its earlier plans for a more ambitious facility. OMB, understandably, argued that ERDA should proceed with caution, moving to a large facility only if the need for a major enterprise is demonstrated. OMB's reluctance to move with dispatch on SERI, and on other parts of the solar energy programme, led to the resignation in January of John M. Teem, Hirsch's predecessor in charge of ERDA's solar energy efforts.

The cautious approach embodied in the proposals is likely to provide considerable ammunition for solar energy proponents, who have long argued that the solar programme has been held back in the past few years while funding for nuclear energy has been growing by leaps and bounds Though government expenditures on solar energy and development have grown from $200,000 in 1972 to an anticipated $116 million next year, the total proposed for the nuclear programme next year amounts to nearly $3,000 million. Solar energy proponents are particularly fond of pointing out that the breeder reactor alone—which, like some uses of solar energy isn't expected to make any contribution to energy supplies until the 1990s—amounts to $880 million next year.

Nevertheless, since SERI is likely to be a prestigious institute which will attract top-level talent and perhaps some associated industry, there is likely to be fierce competition between the states for the contract The competition in fact started several months ago when several states set up committees to plan their strategies for securing SERI. ERDA has also been inundated with inquiries from interested institutions.

The last tussle over the location of a major research facility in the United States was during the Johnson Administration, when the National Accelerator Laboratory was up for grabs. In the end, that facility was located in Illinois because, according to widespread speculation, Johnson needed the support of Illinois Senator Everett Dirksen, then Senate minority leader, on several key items of legislation. ERDA, however, is anxious to avoid any suspicion that such squalid political deals will decide the site for SERI, and it has insisted that the location will be chosen on strictly scientific and other "factual" criteria.

ERDA taken aback

ERDA officials were therefore somewhat taken aback when President Ford told a Colorado energy symposium last September that Arizona, New Mexico and Florida are the leading contenders to house SERI. Ford, moreover, told officials from Florida's Brevard County recently that their region would receive "excellent consideration" as the site for the institute.

Be that as it may, Hirsch said last week that SERI could be located anywhere in the United States, and that he expects to receive proposals from all 50 states. He noted that the institute will be performing a range of work on solar energy and that some technologies (generation of electricity from wind, for example) don't need large quantities of sunlight. It should not therefore be assumed that SERI must be located in the sunny southwest, he said.

Proposals must be submitted to ERDA by July 15, a site selection board composed of ERDA officials will evaluate them, and a final decision will be taken by ERDA administrator Robert C. Seamans, Jun. in December. ◻

CANADA

Eldorado radiates Hope

David Spurgeon reports from Ottawa on the Port Hope affair

As a result of continuing public concern about radioactive contamination in the Port Hope area of Ontario, a federal–provincial task force drawn from different departments of the national and Ontario governments was formed late last month to supervise a clean-up of the area. The force will also help the Atomic Energy Control Board (AECB) to discuss the significance of radioactivity in other locations in Canada.

The formation of the task force was announced by the Federal Minister of Energy, Mines and Resources, Alastair Gillespie, after documents were tabled in the House of Commons reporting on the Port Hope situation. These revealed a total of 109 locations in 25 areas of Canada where radioactivity is known or suspected.

Radioactivity from radon gas was discovered last year in a Port Hope school and at several other sites, including private homes. It came from waste disposal from Eldorado Nuclear Limited, which had recovered radium in the 1930s and 1940s from pitchblende-radium-silver ores mined in the Northwest Territories. The abundant pitchblende (uranium) content was largely discarded at that time because it was thought to be of little value. The radium extracted was used for cancer treatment and in luminous dial painting.

During that period, wastes were disposed of at Port Hope in piles on and close to the Eldorado plant. Toxicity and radiation hazards standards were not then well established. Some of the waste is believed later to have found its way to various parts of the town in the form of fill that was trucked about.

Wastes were also sold to a company in the United States for recovery of metals, which involved shipping the wastes about, and some of the contamination apparently came from spills *en route*, or from storage. A building programme by Eldorado Nuclear Limited may also have resulted in contamination of rubble, fill and reclaimed building materials.

During the Christmas festive period last year, a street-by-street survey of the whole town of Port Hope was made by the AECB and the Ontario health ministry. Samples of air were collected for analysis when abnormal radioactivity levels were found.

At one private home, air samples taken outside the house showed radon concentrations ranging from 200 to 400 times the acceptable level for continuous exposure. Contaminated fill had been used to fill a ravine behind the house. The health ministry has closed a school, and several families have vacated their homes.

A number of recommendations have already been carried out to remedy the situation in Port Hope. The task force's immediate priority is to complete the investigation and clean-up in Port Hope. The AECB has opened a public information centre there and has assigned two staff officers and two vehicles to the investigation, and plans have been made to carry out an aerial radiometric survey.

If nothing else it seems likely that any future plans to install nuclear capacity on the shores of lake Ontario will be subjected to close scrutiny in the wake of the Port Hope affair. All the same, it remains a source of worry that minor warnings about Port Hope had been given over many years before the latest developments occurred. ☐

SWEDEN

Generating nuclear heat

The use of nuclear energy, as Wendy Barnaby indicates in this report from Stockholm, is a sensitive issue in Sweden

Mr Ralph Nader, the American consumer expert, has said that the Swedes' nuclear energy programme is hindering their ability to work for world peace. At a meeting of environmentalists in Gothenburg, Mr Nader said he was disappointed with the Swedish Prime Minister, Mr Olof Palme, who had in his opinion been too quick to accept arguments for a rapid expansion of nuclear power. (Mr Palme's Social Democratic government plans to have 13 reactors in operation by 1985). If Sweden concentrated on nuclear energy it could not refuse to back other countries making the same choice. But, Mr Nader maintained, the only way to stop the proliferation of nuclear weapons is to stop the spread of nuclear energy for peaceful purposes as well.

Meanwhile, Mr Björn Gillberg—often called "Sweden's Nader"—is waiting for a court decision in one of his many battles against nuclear power. The case, fought on behalf of a local environment group by Gillberg and a lawyer, Gunnar Michelson, against the State Power Board, concerns permission to operate reactors three and four at the Ringhals plant on the west coast. Technicalities have put the case into the court of appeals of the Water Court, whose jurisdiction is limited to considering whether the reactors could damage their water environment. The only aspect of the plant able to be discussed has therefore been the release of cooling water into the sea.

If permission is given for the reactor to be operated, 175 cubic metres of cooling water per second—the largest release in the world—will flood into the sea through pipes so large that trucks can be driven through them. The environmentalists contend that the effect of a court decision in favour of operation would be to cause a certain number of deaths from the water's radioactivity, and that the court has no right to make decisions which kill people. The State Power Board agrees that every year of operation would cause some cancers and genetic defects, although its estimation of their number is smaller by a factor of eight than the environmentalists'.

As the reactors are already being built, it is highly unlikely that permission to operate them in some form or another will be refused. Mr Gillberg is of course aware of this, but maintains that nuclear power should be fought on all fronts, no matter how small the odds of winning may be.

Not that Mr Gillberg and his friends should be unhappy with the latest opinion poll on nuclear energy. Fully 54% of the sample wanted no more than the five reactors already built—and this position was taken by 41% of Social Democratic supporters. Only 34% of the sample wanted more than the present five: the rest did not know. More surprising, however, was that 75% of the sample preferred to curb their standard of living in order to avoid an increase in energy use, rather than to raise their standard of living and accept the consequences of using more energy. And the majority comprised 70% of the Social Democratic respondents. The vital question, though, is not the divisions in opinion polls, but the effects they have, in this election year, on public policy. ☐

IN BRIEF

Marine pollution

Delegates to the Inter-Governmental Maritime Consultative Organisation, meeting in Acapulco this week to discuss marine pollution from ships, will consider UK Government reports which survey national and international counter-pollution arrangements and outline UK contingency plans to tackle major oil spills in territorial waters. While claiming that existing UK measures have already proved partially successful in dispersing a 300-tonne spill in the English Channel last November, the reports stress the need for improved international cooperation. Discussions between France, Norway and Britain are already under way.

Anders move

In a surprise announcement, President Ford last week nominated William A. Anders, Chairman of the Nuclear Regulatory Commission (NRC), to be ambassador to Norway Anders, a former astronaut, established a reputation as a tough administrator during the first year of the commission's activities as watchdog over the nuclear industry Ford indicated that he would nominate Marcus A. Rowden, a former general counsel to the Atomic Energy Commission and a member of the NRC, to succeed Anders.

Cyclamate view

A committee of cancer experts in the USA has failed to reach a definitive conclusion about whether or not the banned artificial sweetener cyclamate is a carcinogen The committee, appointed by the National Cancer Institute to help the Food and Drug Administration decide whether to lift the ban on cyclamate, noted that most of the tests leading to a significant increase in tumours in cyclamate-treated animals have employed dubious procedures or used strains of animals which have a large incidence of spontaneous tumours, but said the results were a cause for concern

UK chemical industry

Following last week's National Economic Development Office report urging the UK chemical industry, now at "a decisive point", to reassess existing rates of investment and bring forward planned projects so as to improve international competitiveness beyond 1978, an independent publication from the Chemical Industries Association (CIA) has called on the Government to boost managerial confidence by easing the price and profit controls cutting into available revenue at a time when investment demands are three times higher than in 1974 The CIA report says that the industry's plans to spend £2,800 millions on new plant and equipment over the next three years indicate a willingness to meet projected market demands. The difficulties faced by the industry were simultaneously underlined by the publication of a third report, showing that several leading chemical companies have been trading at a real loss over the past three years

---

My lady nicotine

THOMAS H. JUKES

THE delights of tobacco were recorded in the panegyric "My Lady Nicotine" by James Barrie Perhaps he should instead have used the word "nitrosamine", as the *grande dame* who lurks in the fragrant weed *N′*-nitrosonornicotine (NNN) was identified by Hoffmann and coworkers in unburned tobacco at levels ranging from 2 to 89 parts per million Most samples contained about 4 p p m. This may be compared with about one four-hundredth of this level of nitrosopyrrolidine in bacon, a commodity that is now figuratively as well as literally in the frying-pan for its content of nitrosamines NNN induces multiple pulmonary adenomas in mice, but just how much of the carcinogenic effect of cigarettes is caused by nitrosamines is not known. The smoke from one cigarette contained 0 14 microgram of NNN, which is non-volatile, and other nitrosamines that are volatile. The well-televised habit of chewing tobacco is familiar to all baseball fans, but I have seen no epidemiological studies on pitchers

A few weeks ago my lady nicotine (or nitrosamine) came knocking at my door in the guise of a letter from Mr William D Hobbs, the chairman of the board of the R J. Reynolds Tobacco Company I was, he told me, a leader in my community, and, therefore, I would want to know about a technological achievement consisting of a new cigarette, which "draws free and easy" (*sic*). If I were not a smoker, he said, I might wish to refer this offer of two packages of cigarettes to someone who I thought might be interested I told him I had a better idea. I believed that all advertising of cigarettes should stop, and that direct mail advertising to start someone in the habit of smoking was particularly pernicious

My answer to this came from a company executive, Mr Crohn, presumably assigned by Mr Hobbs to respond to anti-cigarette cranks He sent a letter, and various pieces of literature favouring cigarettes One item was an article reprinted from *Executive Health*, a well-advertised publication that sends out appeals for funds to support an Institute for Orthomolecular Medicine. The article was entitled "The Case Against Tobacco Is Not Closed. Why smoking may not be 'dangerous to your health'" Good health, executives! Mr Crohn's letter told me that if advertising of cigarettes were to cease, then "the public would never know that low tar and nicotine cigarettes, which many persons desire, are available in the market place".

The phrase "which many persons desire" rang a faint mnemonic bell of the first casket scene in *The Merchant of Venice*—written before men were persons and coffins were caskets In this scene, the gold casket has the inscription "Who chooseth me shall gain what many men desire" Upon reading this, the Prince of Morocco says, "Why, that's the lady all the world desires her" Was Mr Crohn a crypto-Shakespearean? Did he mean many persons desire My Lady Nicotine? But then, in the play, the casket is opened to reveal

> "A carrion Death, within whose empty eye
> There is a written scroll!"

The scroll, I mused, perhaps said, "Warning The Surgeon General has determined that cigarette smoking is dangerous to your health".

We shall never know The warning was written in letters too small to read.

correspondence

Allergic reactions to laboratory animals

SIR—There is a growing concern about allergic reactions in laboratory workers who handle animals but little factual evidence is available. The British Society for Allergy and Clinical Immunology appointed a working party to investigate this subject and here we report preliminary findings, which give some idea of the size of the problem.

We used a questionnaire in two laboratories, one industrial and the other non-industrial, but the results were closely similar, so here we amalgamate them 474 individuals were questioned. Salient points were, that of this population,

- 23% had had one or more symptoms occurring repeatedly within 12 hours of animal contact
- 9% had had chest, 17% nasal, 10% eye and 11% skin symptoms
- 4% had had to stop working with animals
- after two years of exposure the incidence of allergy did not increase significantly with further exposure
- a family history of allergy was present in 22% of those who reported symptoms, 19% of those who did not. This surprisingly small difference calls into question the usefulness of a pre-employment family-history screen, and is at variance with results from a recent survey in the USA (Lutsky I. I., and Neuman, I., *Annals Allergy*, **31**, 201 (1975)).

We regard the figure of 23% as disturbingly high, higher than those reported recently from the USA (two surveys gave 15% and 11%), and we are starting a much larger survey to investigate factors which may alter the incidence of allergic reactions in exposed populations.

Yours faithfully,
GEOFFREY TAYLOR (CHMN.)

Volume publishing

SIR,—I write to draw attention to, to underline, and to generalise from, the exquisite review (March 4, page 82) of the *Handbook of Perception,* which I have not seen. Dr John Mollon lambasts non-editing, a feature not confined to the publishers of the *Handbook,* and unfortunately rife in the field of science publishing

Progressive specialisation and illiteracy make it clearly more and more difficult for any one author to cover a field in depth: hence the mushrooming of Editored volumes during the last decade or two. A publisher approaches a Name, offers a percentage out of all proportion to the services rendered (which frequently consist in no more than drawing up a list of contributors and acting as a relay station for the receipt of typescripts), and informs the Inland Revenue at the appropriate time.

The contributors are also offered a percentage out of all proportion to the services rendered: I know of a case where the typist was paid more than the author. They are often up-and-coming youngsters who will not heed the warnings of us older hacks. I always point out to younger colleagues that fixed payments are to be avoided like the plague especially if they are made after publication: inflation eats into the terms but the selling price of the book can protect the publisher and editor. I also stress the naïveté of the notion that they will derive any kudos: later references are almost invariably made to the Editor-so-called, with the author's name sunk in Lethe. The crowning insult occurs when a generous publisher sends along 25 reprints, and so ensures a reduction in sales.

It seems to me that there is a case for an agreed code of good conduct to protect the interests of (young) authors who probably cannot afford the luxury of membership of authors' protective associations—which can, in any case, do little more than offer advice. Moreover, if Editors started spelling their designation with a lower-case e, the interests of authors might begin to be guarded, and one of the last relics of child labour expunged from society.

Yours faithfully,
R. A. WEALE

Alternative refrigerants

SIR—The letter from Birks and Leck, (Correspondence, March 4, page 8) avers that while we can do without aerosol cans, our civilization cannot function without refrigerators. It is then suggested that, if we do not choose to give up refrigerators, we may have to continue tolerating atmospheric pollution by chlorofluorocarbons, even if we ban aerosol cans.

The implication that we are faced with such an awkward choice is not, I think, correct. It is true that we can prevent release of chlorofluorocarbons into the atmosphere by aerosol cans in only one way: ban aerosol cans. It is an essential part of their operation to release the gas they contain.

This is not true of refrigerators, which normally release their refrigerant gas only when junked. This release could be almost completely prevented by

- a law making it an offence carrying a heavy penalty to junk a refrigerator without first having a suitable public or private (licensed) agency remove the refrigerant, or
- much better, requiring a meaningfully large deposit to be left when a refrigerator is purchased and rebating that sum, plus inflation related interest, only upon presentation of proof that the refrigerant has been duly recovered by the designated agency.

We can, in short, keep refrigerators and save our atmosphere, even if it becomes necessary to discontinue using aerosol cans.

Yours faithfully,
F. A. COTTON

The pace of life

SIR—Hermits can communicate with everyone in their community by standing still (February 19, page 557 and March 18, page 188). But what about pedestrians in downtown Tokyo (population in excess of 10^7)? Can anyone confirm that they walk at almost 2 m s^{-1}?

Yours faithfully,

Suppression of foreign synapses

from Jeremy Brockes

WHEN a foreign nerve is implanted into a normally innervated skeletal muscle, it grows out over the surface of the muscle fibres but does not synapse with them. If, at this juncture, the normal innervation is removed by cutting or crushing the nerve, then the foreign nerve will now form functional synapses on the denervated fibres. The original nerve eventually regenerates and synapses again with the muscle. This results in muscle fibres which have been 'tricked' into accepting innervation from two sources. The subsequent fate of these dually innervated fibres is currently of great interest to neurobiologists, since one can ask the basic question of whether the foreign innervation is recognised, and somehow suppressed or removed in favour of the original. Such a mechanism could be of considerable importance in trying to account for the great specificity and plasticity of connections that is exhibited by the nervous system.

The principal proponents of such a mechanism have been Mark and his colleagues who have provided evidence that in both goldfish eye muscle (Marotte and Mark, *Brain Res.*, **19**, 41, 53; 1970) and adult salamander muscle (Cass *et al.*, *Nature*, **243**, 201; 1973), the foreign innervation can be functionally suppressed. Furthermore, they have claimed that the suppressed synapses are not retracted, but remain on the muscle fibre and appear normal when examined in the electron microscope (Marrotte and Mark, *Brain Res.*, **19**, 53; 1970). The assay for function in the goldfish eye muscle was indirect, involving behavioural testing of the eye movements, and their interpretation of the results is currently controversial since a repetition and extension of these experiments has led to the conclusion that the foreign innervation is not suppressed (Scott, *Science*, **189**, 644; 1975). Meanwhile, in several other situations, including one where the different synapses were formed on a neurone, the dual innervation has proved perfectly stable with no evidence of suppression, even after several months (Frank *et al*, *Nature*, **247**, 375; 1974 and Purves, *Nature*, **256**, 589; 1975). But in a timely contribution (this issue of *Nature*, page 350), Yip and Dennis have provided clear electrophysiological evidence that suppression does take place in dually innervated fibres of the adult newt By intracellular recording from individual muscle fibres, they have been able to show that transmitter release from the foreign nerve terminals is reduced as a consequence of re-innervation by the original nerve. Specifically, the amplitude of the synaptic potential decreases during the first two months following re-innervation. The synaptic potential is derived from a number of packets, or quanta, of transmitter that are recruited synchronously by stimulating the nerve. By analysing a number of fibres at different times during the period of suppression, Yip and Dennis have shown that the number of packets recruited (the 'quantal content') declines while the amount of transmitter in a single packet does not change significantly. This is a most important insight into the suppression process, since it characterises it as a presynaptic effect on transmitter release rather than a postsynaptic effect on, for example, the chemosensitivity of the muscle membrane.

An important question, which has yet to be answered, concerns the eventual fate of the suppressed synapses. Are foreign synapses withdrawn from the muscle when the original nerve returns, or do they remain structurally intact but functionally suppressed, as suggested by Mark and his colleagues? When, after six months, the original nerve was interrupted for a second time, Yip and Dennis found that the re-establishment of functional transmission through the foreign nerve appeared to occur more rapidly than after the initial operation. This suggests that the foreign nerve axons remain in relatively intimate contact with the muscle, but does not necessarily mean that foreign synapses are present In an analogous situation during normal development, it is known that mammalian skeletal muscle fibres are multiply innervated before birth (Redfern, *J Physiol., Lond.*, **209**, 701; 1970; Bennett and Pettigrew, *J. Physiol., Lond.*, **241**, 515; 9174); when this multiple innervation is eliminated during development, the extra synapses are completed retracted. Although this process is not identical to that observed by Yip and Dennis, it does illustrate that competitive interactions between synapses can lead to the removal of extra innervation.

Meanwhile, one wonders what rules govern the operation of suppression, and why it did not take place in several other situations Is it, as Yip and Dennis suggest, a question of retaining in the adult newt a faculty which is normally confined to development, or is it perhaps related to the way that foreign and original synapses are distributed along the length of the muscle fibres? It would be interesting to determine whether the foreign nerve in Yip and Dennis's study can become the correct one when the reciprocal experiment is performed in its own muscle. The most helpful insights, however, will probably come from an analysis of the mechanism. One would like to know if the interaction has to occur between synapses that are relatively close (of the order of microns) or whether it can occur over distances of the order of millimetres. If the latter is so, one might suspect that the muscle fibre plays a direct role in the process. An informative experiment could be to take a muscle that is only partially re-innervated by the orginal nerve, and determine if the suppressive influence can act on foreign synapses present on adjacent fibres that were not re-innervated. A second major question, which I have considered above, concerns the effect of the interaction on the anatomy of the suppressed synapses. If we knew the answers to these two questions, then the number of plausible mechanisms would be reduced.

I do not think that we can distinguish these possibilities with the available evidence, but some should be clearly excluded by an anatomical study. Other questions, such as the role of activity in the two nerves, and in the muscle fibre, also seem approachable. This whole problem illustrates the advantage of working on the neuromuscular junction—a preparation with which one can ask a basic question about synaptic function, and hope to answer it at several levels. Furthermore, there is every reason to believe that these answers will prove relevant to the experimentally less accessible situation of synapses in the central nervous system. ☐

Helping hand to nuclear technology

from Andrew Holmes-Siedle

As Townsend commented in a recent review (*Nature,* **258,** 293; 1975), in many universities, solid-state physics is taught in too ideal a fashion, as if real solids consisted of perfect arrays of atoms. While the existence of defects may be acknowledged, their importance or impact is not given its true weight. As a result, physicists often see the physics of defects as a fringe area of little importance. The commonly held belief is that colour centres and other invisible point defects are academic curiosities, confined to those near-useless materials, the alkali halides. So the report of a distinguished working party of the American Physical Society (Vook *et al., Rev. mod. Phys.,* **47,** Suppl 3; 1975) which states precisely the importance which small defects could have in nuclear technology and even makes a reasoned estimate of the possible cost of ignorance in this branch of physics is especially welcome.

The task at hand is to find out what will happen to the materials that constitute the structures and containment systems for the massive nuclear reactors (fission and fusion) which will supply most of our energy in two decades' time. Over the anticipated 20-year life of these reactors, some parts will receive fast neutron fluences in the range 10^{23} to 10^{42} fast neutrons cm^{-2}. The effect of this irradiation will be that every atom will have been moved from its lattice position about a hundred times and this constitutes a very serious case of radiation damage. The costs of ignorance in this field, it is claimed, could be as high as $10,000 million over the coming decade

One might ask whether all the basic radiation damage problems have not been worked out in the first development of power reactors. But the neutron flux levels envisaged in future fission reactors (fast breeder power reactors) are orders of magnitude higher than for present ones; the fluxes of particles expected to irradiate the walls of fusion reactors, moreover, are even higher and more varied in type Also, past research in radiation damage, though intensive, has only scratched the surface of a field of great depth and subtlety. In fact, present basic knowledge of defects is too superficial even for the needs of today's reactor designers.

The working party's estimate of future costs due to ignorance stem from a vision both of the immense overdesign which often results when knowledge is inadequate and of the inefficiency which results from "large-scale specific R and D testing imposed by limitations of basic knowledge". It sets out to delineate and dispel this limitation with detailed recommendations for research work which, although not costed in the report, could very probably be done for much less than $10,000 million.

In the report, entitled *Radiation Effects on Materials* and one of a series on "Physics Problems relating to Energy Technology", the radiation effects field is split into ten main aspects. The ideas and numbers were hammered out during a ten-day seminar at Brookhaven. The problems of the different classes of defects (small, extended and so on) are first discussed; then the complexities of theory and simulation of damage by neutrons and some special effects (hydrogen, helium, surface effects) are described mainly in relation to metals. Finally, the three other solid state forms of greatest interest are discussed —semiconductors, superconductors and insulators Reactor technology has its own section. In each case, a succinct description is followed by reasoned recommendations, while the main object —to point to specific areas in which the physicists can help the reactor designer—is kept in mind throughout.

The complexity of some of the physical problems can be illustrated by the void problem (see, for example, Bullough and Nelson, *Physics in technology,* **5,** 29, 1975) At temperatures in the 500–800 °C range, the conventional recombinations between atom vacancies and interstitial displaced atoms are disturbed, defects aggregate instead of recombining and the material swells A volume increase of 15% is not unusual The aggregated defects can be observed as interstitial loops, which are not new to us but the vacancies, at high damage levels, form a structure which is completely new to physics, namely an aggregate of vacancies large enough to form a visible void in the lattice. Such a structure introduces very great complications into the physical model of damage, since it represents an internal surface Among other practical consequences of its existence, the new surface can act as a sink for impurities and for gaseous transmutation products trapped in the material. Their presence will also affect strength, but it is hard to predict exactly what effects will result from a given change in the composition of a material. Without a predictive method, physicists cannot help the materials engineer to develop or select more radiation tolerant materials

The economic usefulness of the physicist here is in his ability to change what might otherwise be a near-random search for better materials into one in which principles for the needed improvement of materials can be stated and tested in the least expensive way Once the best possible material has been developed, the physicist's power to predict its properties after 20 years of bombardment may then tip the scales in the question of the reactor's economic viability Without these data the designer might, using a necessary conservatism, design a cart-horse of a reactor, immensely strong mechanically but poor at making power. There will also be a need, not mentioned in the report, for a common scientific/engineering language which will facilitate communication between specialists.

Because a magnetically-confined fusion reactor, unlike a uranium reactor operates at high voltage, thermonuclear power reactors (if they are ever developed) will require a variety of strong, long-lived insulators. The report dwells on our knowledge of radiation damage in the alkali halides, and our lack of it in the oxides. But it missed an excellent argument for extra effort in these fields. Whereas the damage problem is greatest in the structural metals, the techniques by which damage can be understood in conductors are more limited than those which can be employed for dielectrics, mainly because optical and magnetic resonance spectroscopy cannot be used There seems, however, to be a good chance that models for damage processes which are common to both types of material (for example the escape of defects from damage spikes, their diffusion in the lattice and their addition and loss from voids and loops) could be developed to a high level of sophistication using dielectric samples and the models could then be corrected as necessary for the case of metals and applied to the serious problem of degradation in strength.

Another little-known fact which is clearly documented in the report is the difficulty of simulating in a short time the 20-year torture which reactor structures will receive Neutron sources of the required flux and energy (14 MeV for fusion, and about 1 MeV for fission) do not exist for the damage range (up to say 500 displacements per atom) which we need to explore. For many purposes, beams of heavy ions can simulate neutron damage well enough. For example, about 10^{16} 7.5 MeV tantalum ions cm^{-2} in vanadium foils at 700 °C produce voids which are not dissimilar to those produced by 10^{22} fast neutrons cm^{-2} ($E > 1$ MeV). The latter irradiation would take months in the most powerful fission reactor while the former takes hours or minutes in an accelerator.

The working party makes two pleas —that the solid-state physicist should be brought more intimately into the nuclear programme and that, to save money, money will have to be spent on simulation machines and basic research. Good arguments are offered as to how overdesign through ignorance could undermine economic viability. Now, it is to be hoped that the agencies planning our future in the energy field will consider this message and implement it. Perhaps a similar call by European scientists, especially confirming the financial theme, would drive the point home to their own governments. ☐

Filamentous phage assembly

from P. J. G. Butler

The filamentous bacteriophages of *Escherichia coli* are a family of viruses consisting of a single-stranded circular DNA molecule, encapsidated into a very long, narrow and flexible particle (reviewed by Marvin and Hohn, *Bact. Rev.*, **33**, 172; 1969). Unlike other bacteriophages, they are neither lysogenic nor do they establish a lytic infection, but rather a productive infection resulting in the slow secretion of progeny virus during a comparatively long period. This poses particular problems during virus release, which occurs without either lysis of the cell membrane or the budding off of regions of this membrane as with lipoprotein coated virions. The solution lies in a series of specific interactions between the viral coat protein and the cytoplasmic membrane of the cell, which are now beginning to be described.

The virus particles contain predominantly a single type of coat protein of about 5,000 daltons. Marvin and Wachtel (*Nature*, **253**, 19; 1975) have analysed the X-ray scattering from oriented gels of one of these bacteriophages (Pf1) and were able to fit this with a model in which the protein molecules are fully α helical and are themselves arranged helically in the particle, with the axes of the α helices lying almost parallel to the particle axis. This results in a tight interlocking of the coat protein molecules, giving a high degree of protection to the DNA while allowing flexibility of the particle. The sequences of the coat proteins are compatible with such a structure and Nakashima *et al.* (*Nature*, **253**, 68; 1975) showed that the hydrophobic central region could readily form stable α helices which could interact in the appropriate way, while there is a slight excess of basic residues at the C terminus, which could be at the inside of the protein coat and help to neutralise the DNA phosphate residues.

Although the attachment of the phage to the host cell, on or near the few molecules of attachment protein per particle, appears to be relatively straightforward, the transport of the viral DNA both into and out of the cell through the cytoplasmic membrane involves more complex mechanisms. The DNA uptake during infection requires DNA synthesis in the cell, during which Marco, Jazwinski and Kornberg (*Virology*, **62**, 209; 1974) found the single-stranded viral DNA to be converted into the double-stranded replicative form (RF). As the DNA is drawn into the host cell, the viral coat protein becomes incorporated into the cytoplasmic membrane and Smilowitz (*J. Virol.*, **13**, 94; 1974) showed that it is reused during the subsequent maturation of progeny virions, being incorporated dispersively into their protein coats, and thus leading to an economy of protein synthesis.

After the establishment of the infection, with viral protein and DNA synthesis in the host cell, the assembly of progeny virus occurs. Initially the new virion DNA strands are assembled into a nucleoprotein complex with the protein product from gene 5, which is not the virus coat protein. These nucleoprotein complexes are again long, flexible particles and the protein molecules are probably helically arranged. However, Pratt, Laws and Griffiths (*J. molec. Biol.*, **82**, 425; 1974), while demonstrating their formation *in vivo*, found that these particles are much less stable than the mature virions, in which the gene 5 protein has been replaced by the coat protein. They suggested that the intracellular coat serves to protect the DNA until it acquires its final coat while being extruded through the cell membrane, to which the coat protein has already bound, and then recycles onto fresh DNA.

The site of the interaction between the phage coat protein (of M13) and the cytoplasmic membrane has been examined by Wickner (*Proc natn. Acad. Sci. U.S.A.*, **72**, 4749; 1975). He found that ^{125}I-labelled antibody raised against detergent-solubilised coat protein would bind specifically to both the intact phage and the coat protein in the membrane. Using this antibody to assay the coat protein, initially of the infecting virus, he confirmed that RF formation was necessary for the transfer of the protein from the incoming virus to the cytoplasmic membrane of spheroplasts, this process taking about 10 min and leaving the protein available for reuse in progeny virion assembly. After about 40 min, further coat protein begins to accumulate in the membrane as it is synthesised. Both the parental and the newly synthesised protein are similarly located in the cytoplasmic membrane, with the antigenic sites only detectable on the outside of the membrane and being masked if the spheroplasts are inverted by sonication. This observation implies that the protein must occupy a position in the membrane irrespective of whether it is inserted from the outside, during initial infection, or from the inside by *de novo* synthesis. Such rapid transport across the membrane is in marked contrast to the slow rate of flipping of phosphatidyl choline, which Kornberg and McConnell (*Biochemistry*, **10**, 1111; 1971) showed to have a half-time for equilibration of about 6.5 h, suggesting that some specific mechanism may be involved for its insertion through the membrane.

Further evidence for specificity in the insertion of M13 coat protein into the membrane, whether from the inside or the outside, comes from Wickner's observation that the antibody reaction is similar with either spheroplasts or intact cells. Since these cells do not release their periplasmic enzymes, the coat protein must have some special

A hundred years ago

Several letters have appeared in the *Daily News* calling attention to the fact that on Sunday week red snow was observed to have fallen in several parts of the country—at Forest Hill and Streatham in the south of London, at Reading and at Thurston in Norfolk. This phenomenon was observed in ancient times, and is referred to by Pliny; in modern times it has been frequently observed in all parts of the world, and is familiar to Arctic explorers. The phenomenon is generally ascribed to the presence of an algae, *Protococcus nivalis*.

from *Nature*, **13**, March 23, 415; 1876 localisation which allows access of the antibody.

In spite of the similar antigenic reaction of the coat protein, whether in the intact phage or incorporated into the cell membrane, Nozaki *et al.* (*Nature*, **259**, 335; 1976) suggest that the protein conformations show substantial differences. They examined the circular diochroism spectra of intact phage (f1) and of its coat protein in aqueous solution with various detergents or dissolved in micelle-forming lysolipids. The spectrum of the protein in the intact virus is quite unlike that of other proteins in simple aqueous solution, for while it shows the peak wavelengths characteristic of an α-helical chain, the intensities of these peaks are surprisingly different This unusual intensity distribution can be explained by the bunching of the chromophores which will occur in the packing of more than 2,000 protein molecules into a single virus particle. With this correction, the spectrum is consistent with the entirely α-helical conformation for the protein previously suggested by Marvin and his colleagues. The spectra of the amphiphile-solubilised protein are all similar to each other and different from that of the protein in the virus in a way which suggests less than 50% α-helix content This change is not, however, consistent with a significant part of the polypeptide having a random coil conformation and Nozaki *et al* suggest that the transition may be from α helix to β conformation. Such a conformation would be compatible with the observed dimeric state of the protein in detergents and with the amino acid sequence around residues 26 to 36.

This structural change does not essentially contradict the similar antigenicity, since Wickner cites preliminary evidence that the antigenic site is in the first eight amino acid residues from the N terminus. In the model proposed by Marvin and Wachtel, this region of the polypeptide chain is on the surface of the virus particle and it is not the region suggested to undergo the structural transition But this gross rearrangement of secondary structure is unique among the mechanisms so far proposed for virus assembly and the interest of this phage protein–cell membrane system should encourage further study. ☐

Kelp, abalone and sea otters

Robert M May

BEFORE being all but exterminated by fur traders in the 18th and 19th centuries, the sea otter (*Enhydra lutris*) occupied a range around the northeast rim of the Pacific Ocean from the northern Japanese archipelago, through the Aleutian Islands, and along the coast of North America as far south as Baja California. Natural populations have persisted mainly in remote parts of the original range, particularly in the Aleutians and parts of southeastern Alaska. Recently, however, with the enactment of protective legislation and the reintroduction of sea otter populations off the coasts of Oregon, Washington, British Columbia and parts of central California, the species is making a comeback along the Pacific coast of North America.

Although this fact is gratifying to conservationists, it is less pleasing to those involved with abalone fisheries. Adult sea otters in captivity have been found to eat 20–25% of their body weight daily, and benthic invertebrates (such as sea urchins or abalone) are the main component of this diet. Several studies have shown a decrease in sport and commercial abalone fisheries following the arrival of sea otters into previously unoccupied areas in California.

The dominant role played by sea otters in determining the structure and dynamics of nearshore communities is demonstrated by several recent ecological studies Estes and Palmisano (*Science*, **185**, 1058–1060; 1974) compared islands in the western Aleutians where sea otters have occurred naturally for at least 20–40 years (the Rat Island group) with islands lacking otters (the Near Islands). They found many floral and faunal differences between the lower intertidal marine communities on these islands· the Rat Islands have an almost complete mat of benthic brown algae (kelp), with both sessile filter-feeding invertebrates (barnacles and mussels) and motile herbivorous invertebrates (sea urchins and chitons) being inconspicuous, small and scarce; the Near Islands are heavily grazed by dense populations of sea urchins and chitons. The density of barnacles, mussels, sea urchins and chitons, respectively, averaged around 4.9, 3.8, 8, and 1 m^{-2} at the Rat Islands, and 1,200, 720, 78, and 38 m^{-2} at the Near Islands.

Dayton (*Fish Bull*, **73**, 230–237; 1975) has followed this with a very detailed study of the competitive interactions between three kelp canopy "guilds" in a community at Amchitka Island, Alaska, in which herbivorous invertebrates have been largely removed from shallow waters by sea otters. This work confirms that sea otters are extremely important in maintaining the structure of shallow water algal communities, and tempts Dayton to the evolutionary speculation that, by reducing herbivorous predation, the sea otters permit a competitive differentiation of niches whereby the several kelp species coexist.

All these people are in agreement that, as sea otters become more established along the California coast, there should be a pronounced increase in the abundance of nearshore kelp. Dayton cautions against accepting this as evidence of the "natural" order of things, and he emphasises that the once-abundant giant sea cow (*Hydrodamalis gigas*) must have had important consequences to the kelp populations, that undercut any present day speculation as to the evolutionary consequences of kelp competition. Indeed, Dayton conjectures, it is likely that by consuming invertebrate herbivores (particularly sea urchins) "the sea otter was indirectly responsible for the high productivity of large algae necessary to maintain the sea cow populations." This conjecture is supported by the overlap of otter and sea cow populations in the Pleistocene.

This story is typical of many, where layer after layer of complication unfolds as one seeks to elucidate the structure of the pristine ecosystem, as it was before first sea cows and then sea otters were removed. Dayton gives a general warning against drawing evolutionary morals from partially reconstructed systems, because one or more crucial species may have become extinct at a time which seems distant in human memories, but is recent on an evolutionary time scale. ☐

Glaciology's grand unsolved problem

from J Weertman

OVER the past two decades our understanding of the behaviour and the motion of glaciers, ice shelves, and ice sheets has progressed and increased very nicely. We know enough now to recognise a grand glaciological problem that remains to be solved. The West Antarctic Ice Sheet is this problem Actually it is a set of inter-related problems. The base of this ice sheet over a major part of its area is 0.5 to 1 km below sea level. A major fraction of its bed would remain below sea level if the ice sheet were removed and isostatic rebound took place. How then did this ice sheet form? Why does it remain in existence? Is it growing or disintegrating at the present time? The ice in one half of the West Antarctic Ice Sheet is draining primarily through very fast moving ice streams into the Ross Ice Shelf. These ice streams apparently are not centred over any deep, fiord-like channels cut into the bedrock, and therefore could not have existed in their present position for any great length of time. The velocity of ice in the ice streams, about 1 km yr^{-1}, is comparable to that of the ill-understood surging glaciers. (Surging glaciers temporarily move, over a 1 to 2-yr period, at velocities that are one to three orders of magnitude larger than a normal glacier velocity.) Why do very fast moving ice streams form at the periphery of the West Antarctic Ice Sheet? Why do they move so swiftly? Is their existence a premonitory phenomenon to a large scale surge of the whole ice sheet? Are the ice streams the start of a process that may cause the West Antarctic Ice Sheet in the near future to flow very rapidly and to discharge about one-third to one-half of its total volume of ice into the oceans over a short time period of the order, say, of 100 years?

Geological evidence that was studied by Denton, Armstrong, and Stuiver (in *Late Cenozoic Glacial Ages* (edit by Turekian) 267, Yale University Press, 1971) and by Denton and Borns (*Antarctic J*, **9**, 167; 1974) indicates that before 10,000 years ago the West Antarctic Ice Sheet was much larger and covered the area, now below sea level, presently occupied by the Ross Ice Shelf. The Ross Ice Shelf, although about 300 to 500 m thick, is afloat. Thus, the edge of the ice sheet has retreated about 1,000 km with an average rate of retreat of the order of 100 m yr^{-1}.

It is not likely that this large scale retreat was produced by any change in the climate. There is at present a net accumulation of snow on top of both the West Antarctic Ice Sheet and the Ross Ice Shelf; in fact, the accumulation rate is larger on the ice shelf than on the ice sheet. Studies of the ice cores from drill holes in both the ice sheet and the ice shelf have produced no evidence at all of any long lasting period of widespread ablation that would have caused the shrinkage of the West Antarctic Ice Sheet. A more likely explanation of the retreat is that it was caused by the large rise in sea level, 100 to 130 m, that occurred when the ice sheets in the northern hemisphere melted at the end of the last ice age According to theory (Weertman, *J Glaciol*, **13**, 3; 1974) the size of an ice sheet whose base is below sea level is a very sensitive function of changes in sea level Whether the ice sheet can even exist over a long period of time is dependent upon the sea level.

The geological evidence of fossil coral-reef terraces in the Barbados (Broecker *et al.*, *Science*, **159**, 297; 1968) indicates that 120,000 years ago the sea level was 6 m higher than it is today Old coral-reef terraces in New Guinea (Chappell, *Geol. Soc. Amer. Bull.*, **85**, 553; 1974) also support this conclusion. A 6 m rise in sea level requires the total removal (and melting) of ice from an ice mass of about the size of the West Antarctic Ice Sheet or the Greenland Ice Sheet and its emplacement into the world's oceans. This observation of a 6 m higher sea level 120,000 years ago suggests that the West Antarctic Ice Sheet can largely disappear under conditions that do not lead to the destruction of the East Antarctic Ice Sheet. The destruction of the latter ice mass would have raised the sea level by another 40 to 50 m.

Terence Hughes of the University of Maine has strongly advocated the view (and put forward supporting evidence) that the West Antarctic Ice Sheet is still disintegrating (*J geophys. Res*, **78**, 7884; 1973). He thinks that the rate of retreat of the edge of the ice sheet where it joins the Ross Ice Shelf is of the order of 70 m yr^{-1} This rate of destruction of the ice sheet would cause the sea level to rise with a velocity of the order of 0.5 mm yr^{-1}. The long term increase in mean sea level occurring now has been estimated from various measurements to be 1 mm yr^{-1} (Lisitzin, *Sea Level Changes*, 183, Elsevier, Amsterdam, 1974). Thus, a slowly occurring destruction of the West Antarctic Ice Sheet could account

---

Metallic glazes

from Robert W. Cahn

A NUMBER of alloys based on transition metals—notably nickel and iron —can be made in the form of glassy ribbons by ultra-rapid quenching of a molten jet on a rapidly spinning roller (see *Nature*, **252**, 100, 1974; **259**, 271, 1976). Iron-based glassy ribbons containing chromium have the further distinguishing feature of being extremely corrosion resistant. These materials, however, have to be in the form of thin (0 05 mm), narrow (1–2 mm) ribbons, and there is not a great deal that the most ingenious designer can do with them Much interest therefore attaches to a report of a novel method that allows the surface of bulk material to be converted into glass without affecting the interior.

A group of metallurgists at the United Technologies Research Center in Connecticut, led by Bernard H. Kear and Edward M. Breinan have described to the American Society for Metals how a continuous carbon dioxide laser can be used to "glaze" the surface of nickel or cobalt-based alloys. The Center is linked with a factory that makes aircraft engines, and the implications of the choice of alloys are clear enough.

A finely focused beam from the CO$_2$ laser is passed over the surface of the bulk material; the surface is rapidly melted and as rapidly refrozen as the hot spot moves on. A cooling rate exceeding a million degrees per second was claimed, during resolidification, and this suffices to generate a glassy (non-crystalline) phase at the surface The alloy compositions used are not specified it would be interesting to know whether they contain metalloid solutes such as P, C, B, Si; as do the alloys used to make glassy ribbons. It is particularly worth noting that the underlying crystalline grains do not act as nuclei for the resolidifying surface film.

The investigating team reports that the surface glaze is harder than the base alloy, and adds that it is "potentially more capable of resisting corrosion than the original alloys": the cautious choice of words leaves one uncertain whether the potential had been realised.

This is not the first time that a laser has been used to effect rapid quenching from the melt. Laridjani, Ramachandrarao and Cahn (*J. Mater. Sci.*, **7**, 627; 1972) used a stationary beam from a pulsed ruby-laser to produce metastable crystalline phases on the surface of Ag–Ge alloys, and Elliott, Gagliano and Krauss (*Metallurgical Trans.*, **4**, 2031; 1973) used a pulsed neodymium laser to create a continuous series of solid solutions in a range of Cu–Ag alloys which are only partially miscible in equilibrium. The United Technologies metallurgists have improved on this earlier work in two ways: they examined alloys based on transition metals which, unlike copper and silver-based alloys, are apt to form glasses on melt quenching, and they used a moving beam from a continuously acting laser to scan the surface. What is not clear from the report is whether it was feasible to make a series of overlapping passes in such a way to cover a surface entirely with a glazed layer If this can be done, the industrial potential is very considerable; it should in principle be possible to "coat" even the inside of a vessel with the aid of a guided moving mirror. There is also potential for the design of wholly or partially glazed bearing surfaces.

for the present rate of rise of the mean sea level.

It would be difficult to measure a yearly shift of the position of the edge of the West Antarctic Ice Sheet of the order of only 100 m. The thickness of ice at the junction of this ice sheet with the Ross Ice Shelf is at least 500 m. The position of the grounding line certaintly cannot be found with an error limit smaller than the ice thickness. It seems clear that a great deal of field data must be collected on such things as ice thickness on both the Ross Ice Shelf and the West Antarctic Ice Sheet before the question can be answered whether this ice sheet is disintegrating or growing and at what rate.

Many data have been collected now, at least for the Ross Ice Shelf (see Robin, *Nature*, **253**, 168; 1975). These and new data have been analysed by Thomas (*Nature*, **259**, 180; 1976). He thinks that at the grounding line the Ross Ice Shelf is thickening at the high rate of 1 m yr^{-1}. This rate of thickening then leads to his startling conclusion that the position of the edge of the ice sheet at least at one location is advancing at the very fast rate of 1 km yr^{-1} Thomas cautions that this result is not expected to be typical He believes that the apparent current thinning of the ice sheet nearer its centre is a delayed response to an earlier retreat of the grounding line.

So now a controversy exists about whether the West Antarctic Ice Sheet is growing or retreating and whether perhaps it is starting to surge. It will take a lot of new field data from the West Antarctic Ice Sheet as well as theoretical analyses to settle the question. □

Errors in lipoprotein metabolism

from a Correspondent

FAMILIAL hypercholesterolemia is an inborn error of metabolism in which affected individuals show a marked elevation in plasma cholesterol, progressive coronary, cerebral and peripheral vascular occlusive disease associated with accumulation of cholesterol in atheromatous plaques. Death from myocardial infarction often occurs before the age of 30. Cholesterol accumulation, which is the most striking biochemical change seen in these patients could arise because of increased synthesis or because of a failure of response by the liver to feedback controls on that synthesis by plasma levels of cholesterol. Some recent findings have gone a considerable way to defining at least one cellular abnormality carried by some patients with this disease. It does seem, however, that the clearly identified clinical phenotype may hide several different abnormalities at the cellular level and therefore what I report here refers only to a proportion of affected individuals. Nevertheless, the recent results of Brown, Goldstein, Steinberg and their colleagues provide exciting pointers to one probable cause of this disease.

A genetic abnormality characteristic of the disease trait in some instances is carried by skin fibroblasts established from biopsy material. It was shown by Brown and Goldstein (*Proc. natn. Acad. Sci. U.S.A.*, **70**, 2162–2166;1973), that normal skin fibroblasts exposed for about a day to foetal calf serum made deficient in lipoproteins accelerate cholesterol biosynthesis by activation of a key enzyme, 3-hydroxy-3-methylglutaryl coenzyme A reductase. The normal fibroblasts respond, through regulation of the level of activity of the enzyme, to inhibition of cholesterol biosynthesis by addition of lipoprotein. The response is rapid, occurring over a few hours. In contrast to the normal behaviour, skin fibroblasts from homozygous patients with hypercholesterolemia do not respond to lipoprotein and cholesterol synthesis continues unabated in lipoprotein-supplemented serum (*Proc. natn. Acad. Sci. U S.A.*, **70**, 2804–2808; 1973). Brown and Goldstein reasoned that the effect of lipoprotein on the fibroblasts must be mediated firstly by attachment of lipoprotein to surface receptors followed by internalisation of lipoprotein and a terminal effect on cytoplasmic events involved in cholesterol biosynthesis. On the basis of binding data of lipoprotein to normal or hypercholesterolemic fibroblasts, these workers proposed (*J. cell. Physiol.*, **85**, 425–436; 1975), that the specific block was in the lack of high affinity surface receptors in the latter cells. The binding data were, however, collected by treating cells with labelled lipoprotein at 37 °C, that is, under conditions in which other events, quite apart from the initial binding of lipoprotein molecules to their specific cell receptors, would be expected to take place. It seems probable that both binding and internalisation of lipoprotein molecules would occur, by analogy with the well studied capping and envelopment of lymphocyte surface immunoglobulin after combination with bivalent antibodies at elevated temperatures but not in the cold (see Raff, *News and Views*, **259**, 265–266; 1976). The binding data of Goldstein and Brown probably sums the levels of lipoprotein bound at the cell surface and intracellular lipoprotein, and it becomes difficult to distinguish a block in internalisation of bound lipoprotein molecules rather than in the binding process itself.

Stein *et al.* (*Proc. natn. Acad. Sci. U.S.A.*, **73**, 14–18; 1976) have reassessed this problem, and propose that it is indeed the internalisation step that is grossly defective, at least in the cells studied by them. They carried out experiments in which the binding of radioiodinated lipoprotein to fibroblasts was measured at 0 °C The differences compared with normal fibroblasts were small at best, not greater than about two-fold Essentially all the bound radioiodinated lipoprotein was released from both normal and hypercholesterolemic cells by mild trypsin treatment without disruption of the cells. Therefore, it was concluded that these measurements refer accurately to cell surface binding and the latter cells seem to be almost normal in this respect. Of course, it is certainly possible that this relatively small decrease in lipoprotein binding may be important in the physiological response of the cells to lipoprotein, for example by the specific loss of a class of cell surface receptors important for the subsequent events of lipoprotein action on cholesterol synthesis. But by far the most striking effect was seen in the amounts of labelled lipoprotein present inside the cells after incubation at 37 °C. This was measured after treatment with trypsin to remove surface located molecules. The normal cells contained from 14–115 times as much labelled material as the hypercholesterolemic cells, measured under the same conditions.

What is the nature of the "receptors" for lipoprotein in the fibroblast surface membrane? This is not known with any certainty, nor indeed whether there are specific "receptors". The lipid moiety of the lipoprotein could react in some way directly with other lipids of the cell membrane. It seems, however, that the sites at which lipoprotein molecules become associated with the membrane may be critical for exertion of the biological effect on cholesterol biosynthesis, implying recognition of these sites by lipoprotein. At high concentrations of endogenously added lipoprotein, the level of internalised material in hypercholesterolemic fibroblasts may rise to comparable levels to those found in normal fibroblasts exposed to more moderate concentrations. Yet there is no accompanying inhibition of sterol synthesis. Goldstein *et al.* (*Proc. natn. Acad. Sci. U.S.A.*, **72**, 1092–1096; 1975) therefore suggest that the interaction with specific receptors on the membrane is a necessary step in the overall control mechanism, and presumably this interaction is also critical in internalisation. If this turns out to be the case, the identification of the specific membrane components responsible is clearly of great importance in defining the ultimate defect in hypercholesterolemia. ☐

Who killed T7?

from Rich Condit

For people interested in control of translation, for those interested in phage protein–host membrane interactions, or for people who simply enjoy molecular whodunnits, the history of research into the abortive infection of male *E coli* by bacteriophage T7 makes a rather good story.

T7 is a virulent phage which grows only on female *E. coli* (Makela *et al.*, *Ann Med. exp. fenn.*, **42,** 188; 1964). When male *E. coli* are infected with T7, the cells are killed as is normal in a T7 infection, but no cell lysis occurs and no phage are produced. The initial probe into the molecular biology of the abortive infection indicated that the phage DNA entered the male cell and was completely transcribed, but that only early T7 proteins were produced In addition, the wild type F factor (PifA$^+$B$^+$) could be mutated so that the block in translation was either partially (PifA$^-$B$^+$) or completely (PifA$^-$B$^-$) relieved (Morrison and Malamy, *Nature new Biol*, **231,** 37; 1971). The hypothesis which emerged to explain these phenomena maintained that during a normal infection, T7 makes two translational control factors, each required for translation of a discrete class of late T7 mRNAs, and that the F factor encodes two proteins, each of which specifically sabotages one of the T7 coded factors. Because of this hypothesis, T7 has been regarded as a model system for studying translational control of protein synthesis.

In the past few months, several reports have appeared which render most of the translational control hypothesis untenable, and suggest alternative explanations for the abortive infection. One of the most important facts emerging from these studies is that, in contrast to initial findings, it now seems that T7 mRNA synthesis is abnormal in infected male cells. Analysis of phage RNA synthesis in male cells by pulse labelling, by hybridisation, and by translation reveals that although synthesis of early T7 mRNA is normal and synthesis of some late mRNA is close to normal, many late phage RNAs are synthesised in substantially reduced amounts, or not at all (see for example Britton and Haselkorn, *Virology*, **67,** 264; 1975; Condit and Steitz, *J. molec. Biol.*, **98,** 31; 1975; Young and Menard, *J. molec. Biol.*, **99,** 167; 1975). In fact, it seems that T7 infection of male cells results in a generalised paralysis in synthesis of macromolecules (RNA, protein, and DNA) rather than simply a block in protein synthesis. In short, the infection appears normal until late phage protein synthesis just begins (by which time some late RNAs have been made in substantial amounts) and then the infection simply dies.

Attempts to reconstruct the translational control hypothesis *in vitro* have met with only partial success. First, ribosomes from uninfected male and female cells are identical with respect to their ability to synthesise T7 proteins. Second, ribosomes from uninfected cells are fully capable of translating late T7 mRNAs, demonstrating that no phage-induced alteration of host ribosomes is necessary for translation of late T7 mRNA. Finally, though some groups have been unable to detect any significant defect in ribosomes extracted from T7 infected male cells (Condit and Steitz, *op. cit.*; Ponta *et al.*, *Eur. J. Biochem.*, **59,** 261; 1975; Young and Menard, *op. cit*), others have observed that these ribosomes are reduced in activity in an *in vitro* system by a factor of 3–5, relative to ribosomes from uninfected cells or cells undergoing a productive T7 infection (Yamada and Nakada, *J. Virol.*, **16,** 1483; 1975; Blumberg *et al.*, *J Virol.*, **17,** 94; 1976). The defect is generalised, that is, the ribosomes from infected male cells are defective regardless of the mRNA used in the test, the defect seems to be reversible by addition of a trypsin-sensitive, non-dialysable fraction from cells containing healthy ribosomes (Blumberg *et al.*, *J. Virol.*, **17,** 94, 1976), and the defect becomes apparent during infection of wild-type male cells at approximately the same time that everything else goes wrong (Yamada and Nakada, *J. Virol.*, *op. cit.*)

In summary, what remains of the translational control hypothesis is that the ribosomes in male cells seem to sustain a certain amount of damage as the T7 infection aborts.

In the search for an explanation for the cataclysmic death of the infected cell, it has been discovered (Britton and Haselkorn, *Proc. natn. Acad. Sci. U.S A*, **72,** 2222; 1975; Condit, *J. molec. Biol.*, **98,** 45; 1975) that at precisely the same time that macromolecular synthesis comes to a halt the T7 infected male cell becomes "leaky". There is a rapid loss of intracellular nucleoside triphosphates into the surrounding medium, the cells lose the ability to accumulate glutamine, and they become abnormally permeable to orthonitrophenylgalactoside Furthermore, the appearance of these permeability defects depends upon both the presence of the F-factor gene(s) controlling the abortive infection, and on phage protein synthesis.

It is tempting to tack ribosome damage onto the list of things that might go wrong if membrane function is tampered with, and to formulate a "permeability hypothesis" to explain the abortive infection Perhaps, because of the action of the F genes, a T7 protein misbehaves in the male cell and membrane function is rendered aberrant as a result. Macromolecular synthesis might be expected to cease because of a change in the intracellular ionic conditions and a decrease in the availability of small molecules A recent study by Blumberg, Mabie and Malamy (*J. Virol*, **17,** 94; 1976) however, questions the notion that membrane damage, ribosome damage, and the overall paralysis of macromolecular synthesis are causally related.

Blumberg *et al* have compared leakage of ATP with activity of ribosomes using four types of T7-infected cells: F$^-$ (productive infection, lysis at 30 min), PifA$^+$B$^+$ (wild-type male, infection aborts at approximately 8 min), PifA$^-$B$^+$ (mutant male, infection aborts at approximately 13 min) and PifA$^-$B$^-$ (mutant male, productive infection). They find that PifA$^-$B$^-$ cells behave exactly like F$^-$ cells, that is they contain healthy ribosomes wrapped in healthy membranes. Whereas PifA$^+$B$^+$ and PifA$^-$B$^+$ cells show virtually identical leakage of ATP, however, ribosomes extracted at 8 min after infection are defective in PifA$^+$B$^+$ cells and normal in PifA$^-$B$^+$ cells. These observations indicate that the sudden paralysis of protein synthesis and the damage to ribosomes observed during infection of a wild-type male cell cannot be accounted for solely in terms of leakage of ATP. The PifA$^-$B$^+$ cell begins

Table 1

	Infected cell type			
	F$^-$ (female)	PifA$^+$B$^+$ (male)	PifA$^-$B$^+$	PifA$^-$B$^-$
Infection phenotype	Permissive	Abortive	Abortive	Permissive
Phage protein synthesis *in vivo*	Ceases with cell lysis (30 min)	Ceases ~ 8 min	Ceases ~ 13 min	Ceases with cell lysis (30 min)
Ribosomes extracted at 8 min damaged?	No	Yes	No	No
Leakage of ATP at 8 min?	No	Yes	Yes	No

to leak ATP at 8 min after infection at the same rate as the infected PifA^+B^+ cell, and yet ribosomes are not immediately damaged, and protein synthesis continues for an additional 5 min.

Several matters need to be cleared up, therefore, before we will know whether or not the permeability hypothesis holds water. The results of Blumberg *et al.* may indicate that membrane damage is only a partial explanation for the abortive infection, or they may mean that leakage of ATP is an inadequate assay for the total amount of membrane damage sustained during infection of a wild-type male. Part of the difficulty in distinguishing between these two alternatives is that we do not know whether the Pif mutants really define two genes, or whether the PifA^-B^+ mutant simply contains a crippled Pif gene. In addition, it will help in evaluating the relative importance of ribosome damage and membrane damage when we know whether RNA synthesis is affected in the PifA^-B^+ male relative to the wild-type male, and whether or not ribosomes in the PifA^-B^+ male remain healthy even after the infection aborts.

A successful virus infection represents a very carefully balanced relationship between the virus and its host, which, in this case, has run amuck. There seems to be a T7 gene(s) which when expressed in male *E. coli* leads to permeability changes, and may ultimately be involved directly or indirectly in the observed paralysis of macromolecular synthesis and damage to ribosomes Especially because of the implied interaction with the cell envelope, it will be interesting to discover the normal role of this phage gene during T7 infection of female cells.

Hormone and antihormone action at the target cell

from Tom Blundell

A Dahlem Workshop on Antihormones and the Target Cell was held in Berlin on February 16–20, 1976. The proceedings will be published by Dahlem Konferenzen

SPECTACULAR advances in our knowledge have recently resulted from studies of hormone receptors. This is not only true for the membrane receptors of polypeptide hormones and catecholamines, but also for the intracellular receptors of steroid hormones, vitamin D metabolites and thyroid hormone. Can these new insights into the field of receptors now be useful in the design of biological tools and therapeutic agents?

This question was central to the Fourth Dahlem Workshop on "Hormone and Antihormone Action at the Target Cell" held in Berlin recently at which endocrinologists with a wide range of interests in hormone receptor interactions gathered together with biophysicists, molecular biologists and protein biochemists.

Unfamiliarity with the new no-lecture format of the Dahlem meetings resulted in a hesitant beginning but the discussions soon warmed up with the help of the generous hospitality and efficient organisation of Silke Bernhard and her colleagues. In the following days the debate ranged over a number of difficult and neglected areas in the study of hormone receptor interactions, and demonstrated the need for discussions between the various scientific disciplines represented.

The term "antihormone" refers to all those substances that act to attenuate hormone-induced responses regardless of their mechanism. Thus mechanisms changing the affinity of the receptor for the hormone by direct competitive binding of antagonists or indeed by allosteric effectors are included, as well as factors which affect hormone availability at the target cell, loss of receptors, and regulation of receptor synthesis.

For steroid receptors a combined steric and allosteric model presented by M Sherman (University of California Medical Center) seemed to be very useful In this model, a dimeric receptor can exist in two conformational states, one of which is inactive because the receptor molecule cannot enter the nuclei or cannot bind to the proper genomic sites or is not released normally from the nuclei. A steroid that binds the inactive state is an antagonist, and one that binds the active state is an agonist. Any steroid that exhibits some affinity for both states is a partial agonist because under some conditions it will be a suboptimal inducer of the function studied, but in the presence of a pure agonist it may act as a partial antagonist. Thus the antagonism by progesterone of glucocorticoid-induced tyrosine aminotransferase in hepatoma cells results from the formation of a glucocorticoid receptor–progesterone complex which does not undergo translocation to the nucleus. On the other hand the ability of steroids to act as partial agonists is exemplified by the partial action of 11-deoxycortisol on sodium transport. In this system aldosterone binds exclusively to the active state while the 11-deoxycortisol binds about half as well to the active and inactive states.

In the field of membrane receptors models seemed to be less in fashion and there was general emphasis on the need to define the macromolecular components more precisely. No hormone receptor or eukaryotic adenylate cyclase has as yet been purified although a characterisation using appropriate detergents as solubilising agents has been achieved for a number of membrane bound proteins such as Ca^{2+}–ATPase, glycophorin and the acetylcholine receptor. C. Tanford (Duke University Medical Center) emphasised the need for using detergents such as Tween 80 with long hydrophobic tails which simulate the membrane bilayer but pointed out that a rather different detergent, for example deoxycholate, may be preferable for initial disruption and fragmentation of the membrane. The presence of detergent bound to a protein receptor does not interfere with the determination of molecular weight using sedimentation equilibrium. With pure preparations, the conformational state of occupied and unoccupied receptors can be defined and the design of antihormones carried out on a more rational basis.

Many hormones have not evolved to fit best the receptor of the same species. Although there is good species specificity with vasopressin analogues, salmon calcitonin has high activity in man when compared with human calcitonin. In a similar way insulin receptors from different species bind insulins from various animals with similar relative affinities. J. Roth (National Institutes of Health, Bethesda) suggested that the receptor proteins may be under strong evolutionary constraints because they have other functions essential to the membrane. Thus similar molecules may exist in the membranes of cells to which the hormone has no biological response and even in prokaryotic cells. This would provide an explanation for the reported activity of insulin and glucagon on bacteria and algae. It also suggests that it may be worthwhile to explore the possibility of synthesising molecules which are better agonists than the natural hormone.

Another observation that gave rise to much discussion was the recent report on the enkephalin peptides which appear to be the natural opiates. These will clearly stimulate the search for other natural peptides which bind drug receptors. Conversely it implies that a non-peptide molecule such as morphine can bind a peptide receptor, and that in the design of therapeutic agents which are peptide-hormone agonists or antagonists it should be possible to use analogues of a very different chemistry. ☐

The hominid-bearing Plio–Pleistocene sequence of the west central Afar sedimentary basin in Hadar contains 120–140 m of fossiliferous lacustrine and lake margin sediments. The Hadar sequence is described and divided into four members. The mammalian fauna indicates an age of ~ 3.0 Myr which is confirmed under the Hadar formation by K–Ar determinations on a basalt.

THE Afar is a depression at the northern end of the East African rift at the triple intersection of the trends of the East African rift, the Red Sea and the Gulf of Aden (Fig. 1). After three field seasons by the International Afar Research Expedition (IARE), the site of Hadar in the Afar promises to become one of the richest fossiliferous Plio–Pleistocene localities associated with the East African rift system. Here we present the generalised geology and palaeontology of Hadar.

Earth Resources Technology Satellite (ERTS) photographs of the Afar reveal a region of predominantly dark tone, marked with lineaments and volcanoes. The rocks are mostly fissure erupted flood basalt, divided into a few long north trending grabens and horsts, with rhyolitic volcanic centres. Aside from the Tendaho graben containing Lake Abbe, the only sediment-filled area is the west central Afar sedimentary basin composed of Plio–Pleistocene deposits adjacent to the Western Ethiopian plateau[1] (Fig. 1). East of the sedimentary basin the flood basalt constitutes three fault blocks. Running from north to south these are: the Mille block, comprising the Guralle acidic centre overlain by the Amado sequence of the west central Afar sedimentary basin; the Magenta block; and the tilted Galalu block interbedded at its top with the sediments seen south of Hadar, and referred to as the Rougous sedimentary sequence. K–Ar ages have been determined regionally for these basalts[2,3], with most of them between 2–4 Myr.

The Plio–Pleistocene sedimentary basin is ~ 60 km wide and 150 km long. Much of this area is capped unconformably by an uppermost unit of Pleistocene gravels and some bedded sands containing Acheulean artefacts[4]. The underlying Plio–Pleistocene strata have already been referred to as the Central Afar Group[5]. The IARE has studied sequences of this group regionally at Amado, Gewane, Gueraru, Hadar, Haouna, Leadu, Ledi, and Meschelle (Fig. 1). Fauna from these sites were tentatively referred to a time range of 2–4 Myr in comparison with other eastern African sites[5]. Thus, the sedimentary basin was contemporaneous with the volcanism just to the east.

The Hadar Formation

WE refer to the area of Plio–Pleistocene sediments exposed in the drainage of the Awash basin in the tributaries of Gona, Sidi Hakoma, Kada Hadar, Ounda Hadar and south of the Awash River (Fig. 2) as the Hadar site of the west central Afar sedimentary basin. Operationally we refer to the exposed sequence in this area as the Hadar Formation, even though the upper and lower contacts of the formation have not yet been fully explored. The sediments represent lacustrine, lake margin and associated fluvial deposits, related to a Plio–Pleistocene lake which may have occupied nearly the entire sedimentary basin, at least periodically. The offshore deposits are predominately clay sediments with the remains of fish and ostracods. Nearer shore deposits are primarily silts or calcareous mudstones; shore deposits are sands with shallow cross-bedding. Fluvial deposits are represented by pebbly gravels and sands with steep cross-bedded channel fills cut in underlying strata. For the Hadar site generally, the sequence consists of a higher percentage of fluvial facies to the west near the Gona tributary, and offshore facies to the east near the Ounda Hadar, compared with Kada Hadar where the largest percentage of nearshore facies occurs. From Sidi Hakoma to Kada Hadar (Fig. 2), where the members of the formation have been defined, the sequence has ~ 45% clays, 25% silts, 25% sands and sandstone and 5% volcanic, carbonate and biogenic deposits. Most of the vertebrate fauna is found in the sands and sandstones. The frequent occurrence of complete fossil specimens as well as partially associated skeletons, and the general lack of taphic abrasion indicates a low energy depositional environment and a possible high rate of sedimentation.

The formation has an exposed thickness of 120–140 m in the Kada Hadar tributary. The sequence dips northwards by 2–4° with just a few steep normal faults trending 5°N–20°E with displacements of 5–40 m (Fig. 2). Several minor erosional unconformities can be seen in the Hadar Formation, but no major time gaps are suggested. The Hadar Formation has been conveniently subdivided into four members, separated by major tuff horizons as shown in the geological column (Fig. 3). A geological map (Fig. 2) and a generalised cross section (Fig. 4) are presented here. Each member in this tributary has three or

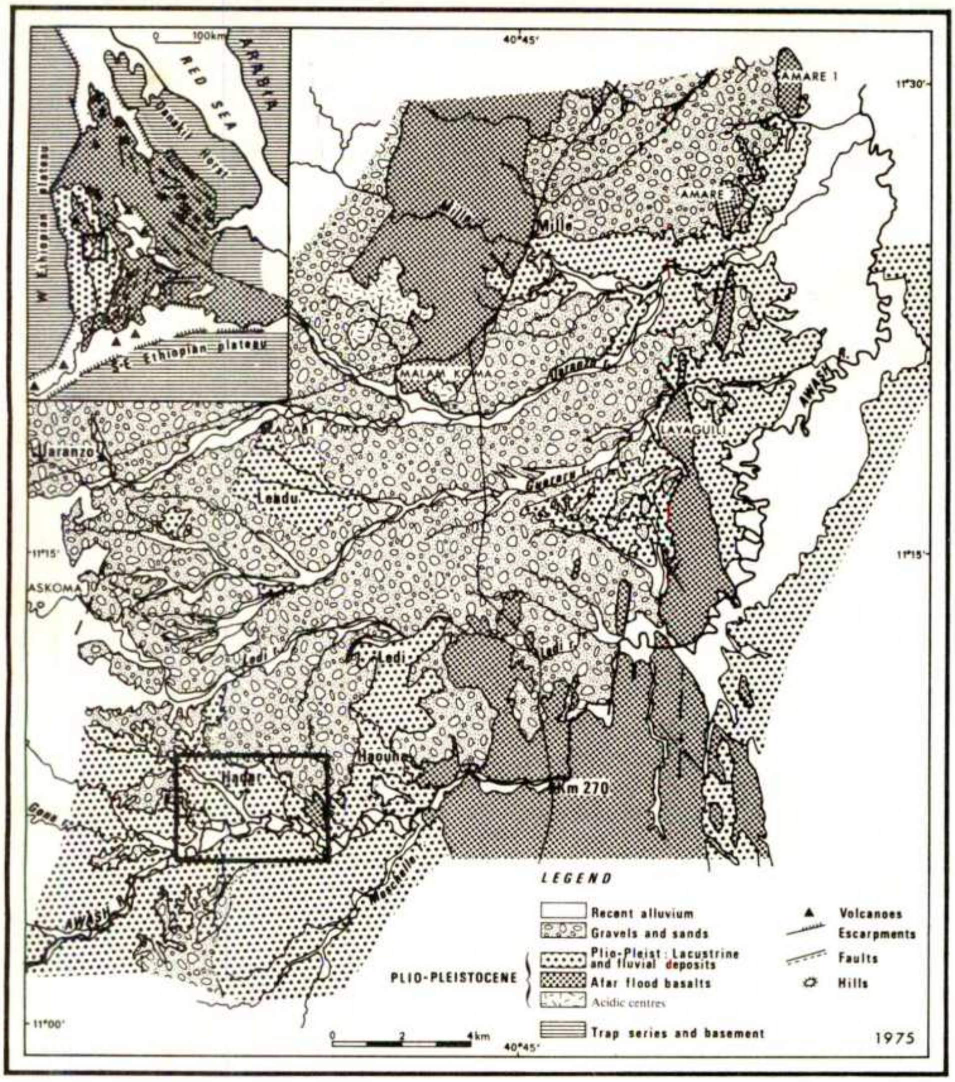

Fig. 1 General geological map of the north-western part of the west central Afar sedimentary basin (mapping with the collaboration of N. Page).

more submembers of alternating sands and clay–silt sediments. From the base to the top the members are: (1) the basal member (BM), 12 m exposed; (2) the Sidi Hakoma member (SH), with a series of white tuffs (SHT) at its base, 55 m thick; (3) the Denen Dora member (DD) with a series of thin tuffs (TT) in an extensive clayey marker horizon at its base, 25 m thick; and (4) the Kada Hadar member (KH), with a single tuff (KHT) at its base, 48 m thick.

Volcanics

In general the tuff horizons are laterally extensive and are nearly everywhere altered to a chalky white fine material. SHT and KHT have, however, been traced to palaeochannel fills in the underlying strata, where they are grey with a somewhat vitreous lustre, and consist of 95–98% glass shards derived from explosive pumice eruptions. Only the SHT channel fill shows closely spaced, steeply dipping cross bed sets in cut-and-fill troughs indicating a fast flowing current in the channel. The occurrence of fresh unaltered glass in the palaeochannels may arise from sorting of the coarsest glass, which resisted alteration.

At the eastern end of the Hadar site the Kadada Moumou subplateau is upheld by a single 1–4 m thick basalt flow, 60 m above the lowest exposures. The flow thins to the north-west where it ends. It lies over a section of largely clayey and silty sediments with two gastropod-rich layers (Fig. 4). Unconformably above the basalt is the post-Hadar Pleistocene gravel unit. In one locality, sediments of the Hadar Formation have been observed overlying the basalt. The Kadada Moumou subplateau geomorphic feature originated before the deposition of the overlying gravels when erosion was greatly slowed by exposure of the very resistant basalt. Extending from the north-western edge of the basalt into the dipping Hadar sedimentary sequence is a local unconformity with a relief of 4–6 m. Above the unconformity are local steep bedded sands with numerous boulders of the basalt. These sands contain abundant Hadar Formation fauna and are overlain by a distinctive sand unit which is laterally extensive within the Sidi Hakoma member. There is no fault between the Kadada Moumou flow and the sedimentary sequence. Twenty metres stratigraphically above the basalt level in the sediments is the persistent horizon (TT) which marks the base of the DD member. The basalt is thus in the upper portion of the Sidi Hakoma member.

The basalt is vesicular at the top, and denser, with few vesicles in the centre portion, and has calcite-filled vertical tubes near the base. The underlying clayey sediment exhibits a prismatic structure at the contact from baking. We cannot yet evaluate whether or not the flow is subaquatic.

Palaeontology

Over 6,000 specimens representing some 40 species of mammals including hominids[6,7] have been collected from > 250 localities in the Hadar area. They display remarkable preservation due to the unique taphonomic setting noted above. The collection can be closely compared to the Omo 1 Zone[8,9] (Usno Formation and the Basal Member and Members A and B of the Shungura Formation). Currently this time span in the Omo sequence is dated at ~ 2.6–3.1 Myr (ref. 10). The most significant elements of the assemblage for biostratigraphical correlation include: *Primelephas* (a progressive species with affinities to

units: lower, middle and upper. The lower unit corresponds to SH-1 and SH-2 submembers, the middle to SH-3 through DD-2, and the upper to DD-3 and above. The vast majority of the middle unit fauna is derived from DD-1 and DD-2. Most taxa are represented in all three units, although proportions do show some interesting variations. The lower unit is characterised by the association of Elephantidae, *Notochoerus euilus*, *Nyanzachoerus pattersoni*, *Tragelaphus* cf. *nakuae*, *Aepyceros* sp., and cercopithecines. The most common elements of the middle unit are *N. euilus*, *T.* cf. *nakuae*, *Aepyceros* sp., and abundant *Kobus*. Elephantidae are less well represented. The upper unit contains *N. euilus*, *T.* cf. *nakuae*, *Kobus* sp., Alcelaphini, *H.* cf. *primigenium* and Elephantidae.

After more detailed study the subdivision will provide valuable palaeoecological and chronological data. The surprisingly great number of *Kobus* specimens in the middle unit, for instance, or the absence of *Nyanzachoerus* in the upper unit is interesting. Clearly, however, several environmental zones are being sampled in each of these units, and further subdivision is required before detailed interpretations may be proffered.

Geochronological and palaeomagnetic evidence

One of us (J.L.A.) is performing a detailed geochronological study of the Hadar site. Thus far only five K–Ar measurements are available, two for the Kadada Moumou basalt and three for glass shard samples from the SHT channel fill (Fig. 2). The analyses were performed in an extraction system with an ^{38}Ar spike pipette and an MS-10 mass spectrometer with little memory and no mass 36 background. Table 2 presents the analytical data for these samples. Because of the high percentage of atmospheric argon, these determinations are, as yet, relatively imprecise. Two basalt determinations from separate localities in the flow are analytically consistent at 2.95±0.2 Myr and 3.0±0.2 Myr. Both samples consist of fine 0.015 mm plagioclase and augite and minor olivine in a magnetite-rich cryptocrystalline matrix, which comprises 35% of the rock. The content includes 6% of calcite fillings about 0.2 mm in size, surrounded by a fine yellowish, interstitial material (a possible alteration of glass) equalling 1% of the rock's content. The results of the glass shard separates represent three different experimental treatments and are inconsistent, ranging from 3.1–5.3 Myr, each with an analytical uncertainty of 0.3 Myr.

Table 2 Analytical results of K–Ar dating

Sample	^{40}Ar* g^{-1}	^{40}Ar*/^{40}Ar × 100	%K$_2$O†	K–Ar age (Myr‡)
A Basalt				
KM-1-73	0.0291	20.6	0.654±0.004(2)	3.0±0.2
KM-2-74	0.0327	15.2	0.748±0.004(4)	2.9_5±0.2
B SHT shard§				
$4l_1$	0.092	9.0	1.995±0.015(2)	3.1±0.3
$4l_2$	0.121	12.3	1.97	4.1±0.3
$4l_3$	0.157	16.6	1.98	5.3±0.3
LP6 40/60 Biotite standard (ref. 1)	18.14±0.30(5)		10.10±0.16(10)	

*Radiogenic argon, 10^{-10} mol.

†Average and average deviation, number of measurements in parentheses.

‡^{40}K/total K = 1.19×10^{-4}; λ_b = 4.72×10^{-10} yr^{-1}; λ_e = 5.85×10^{-11} yr^{-1}; age uncertainty calculated using 0.3% uncertainty in isotopic composition of sample and atmospheric argon, a 1% uncertainty in argon spike, 1% uncertainty in K$_2$O, and 1% uncertainty in sample homogeneity.

§Index of refraction = 1.500. All samples 150/200 mesh slide concentrates of flakey bubble sides, $4l_2$ and $4l_3$ further refined by floating in ρ = 2.52 g cm^{-3} liquid; $4l_1$ prebaked overnight in vacuum at 250 °C, $4l_2$ and $4l_3$ at 175 °C; $4l_3$ treated 13 min with cold 3% HF.

Until further experiments, these inconsistent results are not understood. They may result from the presence of excess radiogenic argon in the glass. The thicker glass shards, which represent interstices between three or more bubbles, display a microbubble structure which could house such magmatic ^{40}Ar.

Figure 2 shows the location of two sections sampled for preliminary palaeomagnetic examination, in addition to 3 samples of the Kadada Moumou basalt (measurements made by T. J. Schmitt). The lower palaeomagnetic sequence, consisting of 15 samples, spanning 25 m, derives from the basal member up to the SH-2 unit. The upper section comprises 10 samples spanning 20 m of the lower KH member (KH-1, 2 and the lower part of 3). Both sedimentary sequences are magnetised normally, whereas those of the basalt are reversed. All determinations retain their orientations under a.c. demagnetisation. These palaeomagnetic data are consistent with the basalt date, if the reversal is interpreted as representing the Mammoth or Kaena events within the Gauss normal epoch, itself represented by the two normally polarised sedimentary sequences above and below the basalt. This interpretation is to be tested by future palaeomagnetic sample collections from the intervening sedimentary sequence which, to be consistent, should contain the reversal recorded by the basalt.

The Hadar sequence will be a reference from which stratigraphic and palaeontological studies may be extended into adjacent parts of the west central Afar sedimentary basin. The palaeontology, geochronology, and palaeomagnetism tentatively suggest a short duration of sedimentation for the formation, probably less than a million years with no major time gaps. Thus the Hadar Formation together with its rich fauna and varied geological environments, will permit precise palaeoecological and palaeogeographical reconstruction for an important and previously poorly known segment of later Cainozoic hominid evolution.

Support from the following is acknowledged: the CNRS, the NSF, the Cleveland Museum of Natural History, the Wenner-Gren Foundation for Anthropological Research and Ethiopian Airlines. Special gratitude is expressed to the Ethiopian Government and the Ministry of Culture and Youth. Of great logistical support to the expedition have been the efforts of Richard Wilding, Dr Robert Caldwell and Willard Brown.

Plio–Pleistocene hominid discoveries in Hadar, Ethiopia

The International Afar Research Expedition has now recovered remains of twelve hominid individuals from geological deposits estimated to be ~ 3.0 Myr in Hadar, Ethiopia. A partial skeleton represents the most complete hominid known from this period. The collection suggests that Homo *and* Australopithecus *coexisted as early as 3.0 Myr ago.*

FOLLOWING a short reconnaissance expedition in 1972 (ref. 1) to the central Afar, one of us (M.T.) organised the International Afar Research Expedition. We have now codirected two field campaigns (September–December, 1973 and 1974 (refs 2 and 3)) in the area known as Hadar (see Fig. 1).

Although a number of other excellent fossil sites are known from the central Afar[4], Hadar was selected for intensive exploration for a number of reasons: first, the fossil vertebrate assemblage suggested a considerable antiquity (~ 3–4 Myr); second, the area is extremely rich in splendidly preserved fossils, deposited in low energy environments; third, the deposits are heavily dissected and characterised by clear marker-horizons which are laterally continuous; and fourth, the thick series of lake sediments contains a number of volcanic horizons available for absolute radiometric age determinations.

The Hadar site is located in the Afar depression in the west central Afar sedimentary basin[5] at 11°N and 40°30′E. It now encompasses ~ 42 km^2, but extension of study into adjacent, previously unexplored regions will substantially increase the area.

Preliminary palaeontological investigations, particularly of the suids and the elephants, have suggested a biostratigraphic correlation of the Hadar Formation with the Usno and the lower portion of the Shungura Formations[5,6]. Two radiometric K–Ar age determinations for a basalt support this with an age estimate of 3.0 ± 0.2 Myr (ref. 5).

All hominid fossils (Table 1), and most of the vertebrate material, were surface finds, although some small scale excavation and sieving operations were undertaken. A painted marker was placed at each palaeontological locality, each located on a map and the geological section carefully examined to determine the horizon yielding fossil material (see Fig. 2). At each hominid locality, a topographical map and detailed stratigraphical sections were drawn. Samples of matrix adhering to fossil hominid specimens are undergoing mineralogical and sedimentological analyses for comparison with sediment samples taken at their collection points. Their completeness and lack of anataxic abrasion[7] virtually precludes the possibility that the specimens were moved over great distances.

1973 hominid discoveries

The first discovery of fossil hominid remains in the Hadar region occurred on October 30, 1973, when four associated leg bone fragments (AL 128, 129) were collected from a mudstone horizon. These consist of fragmentary right and left proximal femora associated with a right proximal tibia

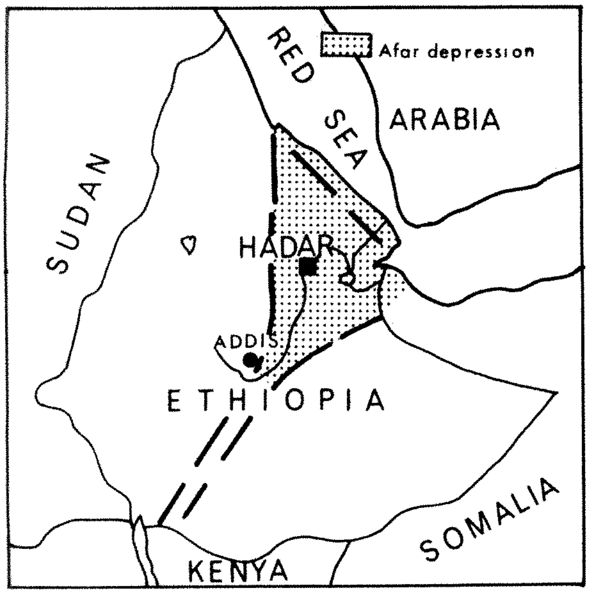

Fig. 1 Location of Hadar.

and distal femur. Their proximity to one another, as well as the morphological and size similarities of the proximal femora, strongly suggest that they represent a single individual. This provides a complete knee which will greatly enhance our understanding of the biomechanics of this important joint in early hominids (see Fig. 3).

Both proximal femora lack heads and necks. The left is best preserved with the shaft broken ~ 38.0 mm below the lesser trochanter. From the remaining portions of the femora it is clear that the neck is flattened anteroposteriorly and that its cross section is oval. There is an indication of trochanteric flare, the trochanteric fossa is well marked, a quadrate tubercle is clearly discernible, muscle markings are prominent on the greater trochanter, the spiral line is pronounced and the lesser trochanter is visible from the anterior aspect. Both fragments, particularly the right, exhibit some degree of predepositional crushing, which is suggestive of carnivore activity.

Table 1 Fossil hominid specimens from Hadar

Afar locality (AL)	Date of discovery	Description
	1973	
128–1	30 October	Left proximal femur fragment
129–1a	30 October	Right distal femur
129–1b	30 October	Right proximal tibia
129–1c	30 October	Right proximal femur fragment
166–9	11 December	Left temporal fragment
	1974	
188–1	16 October	Right mandibular corpus; M_2–M_3
198–1	18 October	Left mandibular corpus; C–P_4, dm, M_1–M_2
198–17a,b	5 December	Left I^1 and I^2
198–18	5 December	Right I_2
199–1	17 October	Right maxilla; C–M^3
